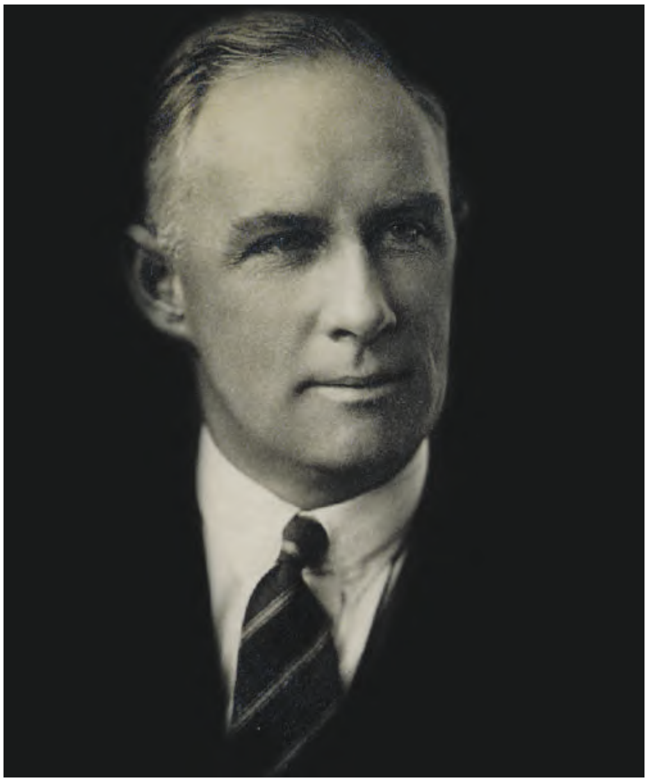
Davidson's
Principles and Practice of
Medicine



Sir Stanley Davidson (1894–1981)

This famous textbook was the brainchild of one of the great Professors of Medicine of the 20th century. Stanley Davidson was born in Sri Lanka and began his medical undergraduate training at Trinity College, Cambridge; this was interrupted by World War I and later resumed in Edinburgh. He was seriously wounded in battle, and the carnage and shocking waste of young life that he encountered at that time had a profound effect on his subsequent attitudes and values.

In 1930 Stanley Davidson was appointed Professor of Medicine at the University of Aberdeen, one of the first full-time Chairs of Medicine anywhere and the first in Scotland. In 1938 he took up the Chair of Medicine at Edinburgh and was to remain in this post until retirement in 1959. He was a renowned educator and a particularly gifted teacher at the bedside, where he taught that everything had to be questioned and explained. He personally gave most of the systematic lectures in Medicine, which were made available as typewritten notes that emphasised the essentials and far surpassed any textbook available at the time.

Principles and Practice of Medicine was conceived in the late 1940s with its origins in those lecture notes. The first edition, published in 1952, was a masterpiece of clarity and uniformity of style. It was of modest size and price, but sufficiently comprehensive and up to date to provide students with the main elements of sound medical practice. Although the format and presentation have seen many changes in 24 subsequent editions, Sir Stanley's original vision and objectives remain. Seventy-five years after its first publication, his book continues to inform and educate students, doctors and health professionals all over the world.

- **The complete, downloadable eBook** – for quick reference, anytime access
- **BONUS NEW self-assessment material** – 185 interactive questions and answers supplement each chapter, to help test your understanding of key points and aid exam preparation

Preface

Well over 2.5 million copies of *Davidson's Principles and Practice of Medicine* have been sold since it was first published in 1952. Now in its 25th Edition, *Davidson's* is regarded as a 'must-have' textbook for thousands of medical students, doctors and health professionals across the world, describing the pathophysiology, clinical features, investigation and management of the most important conditions encountered in the major specialties of adult medicine. The book is the winner of numerous awards and has been translated into many languages. Taking its origins from Sir Stanley Davidson's much-admired lecture notes, the book has endured because it continues to keep pace with how modern medicine is taught and to provide a wealth of information in an easy-to-read, concise and beautifully illustrated format.

Davidson's strives to ensure that readers can not only recognise the clinical features of a disease, but also understand the underlying causes. To achieve this, each chapter begins with a summary of the relevant pre-clinical science, linking pathophysiology with clinical presentation and treatment so that students can use the book from the start of their medical studies right through to their final examinations and beyond.

The regular introduction of new authors and editors is important for maintaining freshness. For the 25th Edition, we are delighted to welcome Professor Neeraj ('Bean') Dhaun and Dr Rebecca Sutherland as new Editors. Bean and Becky bring a wealth of clinical and academic experience to the team. We also warmly welcome Professor Dilip Patel to the new role of Imaging Editor. Fifteen new authors (Thomas Chambers, Thushan de Silva, Baljean Dhillon, Tony Duffy, Charlotte Fleury, Mohammed Khan, Anna Kyle, Barry Laird, Nazir Lone, Francesca Moroni, Thomas Russ, Anoop Shah, Paul Steptoe, Colin Stirrat and Shereen Tadros) have joined our existing contributors to make up an outstanding team of authorities in their respective fields. As well as recruiting authors from around the globe, particularly for topics such as infectious diseases, HIV and envenomation, we are delighted to have representatives from 14 countries on our International Advisory Board. These leading experts provide detailed comments that are crucial to our revision of each new edition. We welcome new members of our International Advisory Board (ABM Abdullah, Viswanathan Neelakantan and Jacek Rozanski), who have given us valuable advice as we prepared this new edition.

A particularly important aspect in planning the revision is for the editors to meet students, resident doctors and faculty in medical schools in those countries where the book is most widely read, so that we can respond to the feedback of our global readership and their tutors. We use this feedback, along with the information we gather via detailed student reviews and surveys, to craft each edition. The authors, editors and publishing team aim to ensure that readers all over the world are best served by a book that integrates medical science with clinical medicine to convey key knowledge and practical advice in an accessible and readable format. The amount of detail is tailored to the needs of medical students working towards their final examinations and medical licensing assessments, as well as resident doctors preparing for Membership of the Royal Colleges of Physicians of the United Kingdom (MRCP UK) or its equivalents.

For this edition, we have introduced many other changes in both structure and content. The opening nine chapters provide an account of the principles of genetics, immunology, nutrition, population health, infectious diseases, oncology and pain management, along with a discussion of the core principles behind clinical decision-making and good prescribing. Subsequent chapters discuss medical emergencies in poisoning, envenomation and medicine in austere environments, while common presentations in acute medicine, including recognition and management of the critically ill patient, are also addressed. The disease-specific chapters that follow cover the major medical specialties, each one thoroughly revised and updated to ensure that readers have access to the 'cutting edge' of medical knowledge and practice. We have incorporated stroke medicine into the neurology chapter and HIV/AIDS into the infectious diseases chapter to allow these major areas of medicine to be integrated fully with their main specialities. Radiology images have been extensively updated and improved, under the auspices of our new Imaging Editor.

The highly popular 'Clinical Examination' overviews have been extended and updated. The 'Presenting Problems' sections continue to provide an invaluable overview of the most common presentations in each disease area. The 'Emergency' and 'Practice Point' boxes have been retained along with the 'In Old Age', 'In Pregnancy' and 'In Adolescence' boxes, which emphasise key practical points in the presentation and management of the older adult, women with medical disorders who are pregnant or planning pregnancy, and adolescents transitioning between paediatric and adult services.

Education is achieved by assimilating information from many sources, and readers of this book can enhance their learning experience by using several complementary resources. We developed a self-testing companion book entitled *Davidson's Assessment in Medicine*, containing over 1250 multiple choice questions specifically tailored to the contents of *Davidson's* for the 23rd edition and have added more new online MCQs to accompany this 25th edition. The long-standing association of *Davidson's* with its sister books, *Macleod's Clinical Examination* and *Principles and Practice of Surgery*, still holds good. Our 'family' has also expanded with the publication of *Davidson's Essentials of Medicine*, a pocket-sized version of the main text, now in its 3rd edition; and *Macleod's Clinical Diagnosis*, which describes a systematic approach to the differential diagnosis of symptoms and signs. We congratulate the editors and authors of these books for continuing the tradition of easily digested and expertly illustrated texts.

We all take immense pride in continuing the great tradition first established by Sir Stanley Davidson and in producing an outstanding book for the next generation of doctors.

Additional Dean (Academic) and Professor and Head, Department of Medicine and Rheumatology Services, Seth G S Medical College and KEM Hospital, Mumbai, Maharashtra, India

Viswanathan Neelakantan MBBS, DNB, FRCPG, FRCP, FACP, AB
Senior Professor of Medicine and Consultant in Tropical Medicine, Department of Internal Medicine, Sri Manakula Vinayagar Medical College Hospital, Puducherry, India

Matthew Ng FRCP, FRCPE
Honorary Clinical Professor, Department of Medicine, University of Hong Kong, Pok Fu Lam, Hong Kong

Sarkar Nirmalendu MD
Honorary Professor, Department of General Medicine, Ramakrishna Mission Sevapratishthan and Vivekananda Institute of Medical Sciences, Kolkata, West Bengal, India

Ami Prakashvir Parikh MD
Professor and Head, Department of Medicine, Smt. NHL Municipal Medical College and SVP Hospital, Ahmedabad, Gujarat, India

Medha Y Rao MBBS, MD, PGDHHM
Senior Professor of Internal Medicine and Principal and Dean, Department of General Medicine, M.S. Ramaiah Medical College, Bangalore, Karnataka, India

NR Rau MD, FICP
Consultant Physician, Anugraha Medical Center, Udupi, Karnataka, India; Consultant Physician and Head, Department of Internal Medicine, Adarsh Hospital, Udupi, Karnataka, India; Former Professor and Head, Department of Medicine, Kasturba Medical College, Manipal, India

Jacek Rozanski MD, PhD
Professor of Medicine, Department of Nephrology, Transplantology, and Internal Medicine, Pomeranian Medical University, Szczecin, Poland

Surendra K Sharma MD (Internal Medicine), PhD
Adjunct Professor, Department of Molecular Medicine, Jamia Hamdard Institute of Molecular Medicine, Hamdard University, Hamdard Nagar, Delhi, India

Arvind K Vaish MD, FICP
Professor and Head, Department of Medicine, Hind Institute of Medical Sciences; Former Professor and Head of Medicine, King George's Medical University, Lucknow, India

Josanne Vassallo MD, PhD, FRCP, FACP, FACE
Professor and Consultant Endocrinologist, Department of Medicine, Division of Endocrinology, University of Malta Medical School, Msida, Malta

Acknowledgements

The editors would like to acknowledge and offer grateful thanks for the input of all previous editions' contributors, without whom this new edition would not have been possible. In particular, we owe an enormous debt of gratitude to retiring editors Dr Ian Penman and Dr Richard Hobson. Ian and Richard made an enormous contribution to the success of *Davidson's*, initially as chapter authors and then as editors. They were a pleasure to work with and brought considerable wisdom, clinical expertise and humour to the editorial table.

We are also indebted to those former authors who step down with the arrival of this new edition. They include Harry Campbell, Lesley A Colvin, Marie Fallon, David A McAllister, John DC Newell-Price, John A Olson, Jonathan AT Sandoe, Alan G Shand and Henry G Watson.

We are grateful to members of the International Advisory Board, all of whom provided detailed suggestions that have improved the book. Several members have now retired from the Board and we are grateful for their support during the preparation of previous editions. They include Ragavendra Bhat, Khalid I Bzeizi, Piotr Kuna, Pravin Manga, Moffat Nyirenda, Tommy Olsson, KR Sethuraman, Ibrahim Sherif, Ian J Simpson, SG Siva Chidambaram and Josanne Vassallo. Detailed chapter reviews were commissioned to help plan this new edition and we are grateful to all those who assisted, including Neil Basu, Charu Chopra, Emily Collis, Thushan de Silva, Alexandros Grammatikos, Sarah Keir, Emma Morrison, Monica Piris, Andrew Tomkins, Jonathan Virgo and Sarah Walsh.

The Editors and Publisher would like to thank all those who have provided valuable feedback on this textbook and whose comments have helped shape this new edition. We would particularly like to extend our thanks to the many readers who contact us with suggestions for improvements. This input has been invaluable and is much appreciated; we regret the names are too numerous to mention individually.

Two short sections in Chapter 3 on array comparative genomic hybridisation and single-molecule sequencing are adapted from Dr K Tatton-Brown's Massive Open Online Course for FutureLearn. We would like to thank the Open University and St George's, University of London, for permission to use this material.

There have also been changes to the publishing team. Robert Britton beautifully illustrated *Davidson's* over countless editions and is now enjoying a well-deserved retirement. Robert's shoes have been filled by Jason McAlexander and we also welcome Martin Mellor as Content Development Specialist. Additionally we thank Glenys Norquay, Copyeditor, and Kristine Feeherty, Book Production Specialist. Jeremy Bowes, our Publisher at Elsevier, has been an enormous support to the editorial team and it has been a total pleasure working with him and indeed all the members of the publishing team.

We are proud of this new edition and are confident it will remain an essential and invaluable resource for readers the world over.

Answers to problems 11

Introduction

A great deal of knowledge and skill is required to practise as a doctor. Physicians in the 21st century need to have a comprehensive knowledge of basic and clinical sciences, have good communication skills, be able to perform procedures, work effectively in a team and demonstrate professional and ethical behaviour. But how doctors think, reason and make decisions is arguably their most critical skill. Knowledge is necessary, but not sufficient on its own for good performance and safe care. This chapter describes the principles of clinical decision-making, also known as 'clinical reasoning'.

The problem of diagnostic error

It is estimated that diagnosis is wrong 10%–15% of the time in specialties such as emergency medicine, internal medicine and general practice. Diagnostic error is the most common, costly and dangerous of medical mistakes and much of it is preventable. For every diagnostic error there are usually several root causes. Studies identify three main categories, shown in Box 1.1. However, 'cognitive errors' (errors in thinking) appear to play a significant role in the majority of diagnostic errors.

Cognitive errors occur when the clinician has all the information necessary to make the diagnosis, but then makes the wrong diagnosis. Why does this happen? Three main reasons have been identified:

- knowledge gaps
- misinterpretation of diagnostic tests
- cognitive biases.

Examples of errors in these three categories are shown in Box 1.2.

Clearly, clinical knowledge is required for sound clinical reasoning, and an incomplete knowledge base or inadequate experience can lead to diagnostic error. However, this chapter will focus on some aspects of knowledge that are important for effective clinical reasoning, including use and interpretation of diagnostic tests, cognitive biases and human factors.

i 1.1 Root causes of diagnostic error in studies

Error category	Examples
No fault	Unusual presentation of a disease Missing information
System error	Inadequate diagnostic support Results not available Error-prone processes Poor supervision of inexperienced staff Poor team communication
Human cognitive error	Inadequate data-gathering Errors in reasoning

Adapted from Graber M, Gordon R, Franklin N. Reducing diagnostic errors in medicine: what is the goal? Acad Med 2002;77:981–992.

i 1.2 Reasons for errors in clinical reasoning

Source of error	Examples
Knowledge gaps	Telling a patient she cannot have biliary colic because she has had her gallbladder removed – gallstones can form in the bile ducts in patients who have had a cholecystectomy
Misinterpretation of diagnostic tests	Deciding a patient has not had a stroke because his brain scan is normal – computed tomography and even magnetic resonance imaging, especially when performed early, may not identify an infarct
Cognitive biases	Accepting a diagnosis handed over to you without question (the 'framing effect') instead of asking yourself 'What is the evidence that supports this diagnosis?'

Clinical reasoning: definitions

'Clinical reasoning' describes the thinking and decision-making processes associated with clinical practice. Our understanding of clinical reasoning derives from the fields of education, cognitive psychology, studies of expertise, and the diagnostic error and health systems literature.

For novices, clinical reasoning can be conceptualised as a process with different components, each requiring specific knowledge, skills and behaviours. The UK Clinical Reasoning in Medical Education Group (see 'Further information') lists five key areas of clinical reasoning education:

- evidence-based history and physical examination
- use and interpretation of diagnostic tests
- problem identification and management
- clinical reasoning concepts
- shared decision-making.

Underpinning all of this is formal and experiential knowledge of basic sciences and clinical medicine. The knowledge required for effective clinical reasoning includes factual knowledge, but also conceptual knowledge (understanding how things fit together), procedural knowledge (how to approach solving a particular problem) and metacognitive knowledge (an awareness of context and an ability to think about one's own thinking).

Evidence-based history and physical examination

Even with major advances in medical technology, the history remains the most important part of the clinical decision-making process. Studies show that physicians make a diagnosis in 70%–90% of cases from the history alone. It is important to remember that the history is explored not only with the patient, but, if necessary, from all available sources (with consent if required): for example, paramedic and emergency department notes, eye-witnesses, relatives and/or carers.

Clinicians also need to be aware of the diagnostic usefulness of clinical features in the history and physical examination. For example, students are often taught that meningitis classically presents with the following features:

- headache
- fever
- meningism (photophobia, neck stiffness and other signs of meningeal irritation, such as Kernig and Brudzinski signs).

However, knowing the frequency with which patients present with certain features and the diagnostic weight of each feature are important in clinical decision-making. Many patients with meningitis do not have 'classical' signs of meningism and the clinical presentation varies among different patient populations and in different parts of the world. In one prospective study conducted in the United States, nearly all adult patients with meningitis had headache and a fever, but less than half had neck stiffness on examination and only 5% of patients had Kernig and Brudzinski signs. All three signs had a likelihood ratio of around 1, meaning their presence or absence was of little use in deciding whether a patient had meningitis or not (Fig. 1.1).

Likelihood ratios (LRs) are clinical diagnostic weights. An LR of greater than 1 increases the probability of disease (the higher the value, the greater the probability). Similarly, an LR of less than 1 decreases the probability of disease. LRs are developed against a diagnostic standard

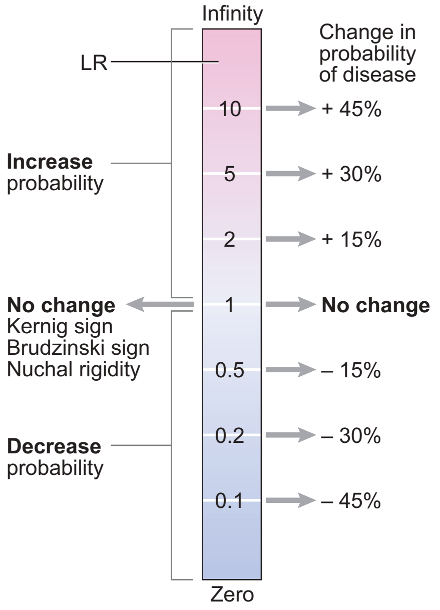

Fig. 1.1 Likelihood ratio (LR) of Kernig sign, Brudzinski sign and nuchal rigidity in the clinical diagnosis of meningitis. LRs are also used for diagnostic tests; here a physical examination finding can be considered a diagnostic test.

$$\text{LR} = \frac{\text{probability of finding in patients with disease}}{\text{probability of finding in patients without disease}}$$

Data from Thomas KE, Hasbun R, Jekel J, et al. The diagnostic accuracy of Kernig's sign, Brudzinski's sign, and nuchal rigidity in adults with suspected meningitis. Clin Infect Dis 2002;35:46–52.

(in the case of meningitis, lumbar puncture results), so do not exist for all clinical findings. LRs illustrate how an individual clinical finding changes the probability of a disease. LRs do not determine the prior probability of disease; they reflect only how a single clinical finding changes it. Clinicians have to take all the available information from the history and physical examination into account. If the overall clinical probability is high to begin with, a clinical finding with an LR of around 1 does not change this.

'Evidence-based history and examination' is a term used to describe how clinicians incorporate knowledge about prevalence of disease in the group to which the patient belongs, the history, physical examination and the diagnostic weight of clinical findings into their decision-making. In studies, students who are taught the probabilities of features being present in specific diseases rather than lists of features have better diagnostic accuracy. This is improved further by understanding the basic science explanation for symptoms and signs: bedside signs of meningism are found in patients with severe meningeal inflammation but not those with early or mild inflammation.

Evidence-based history and examination is important because estimating the clinical (pre-test) probability is vital not only for diagnostic accuracy, but also in the use and interpretation of diagnostic tests.

Use and interpretation of diagnostic tests

There is no such thing as a perfect diagnostic test. Test results give us test probabilities, not real probabilities. Test results have to be interpreted because they are affected by the following:

- how 'normal' is defined
- factors other than disease
- operating characteristics
- sensitivity and specificity
- prevalence of disease in the population.

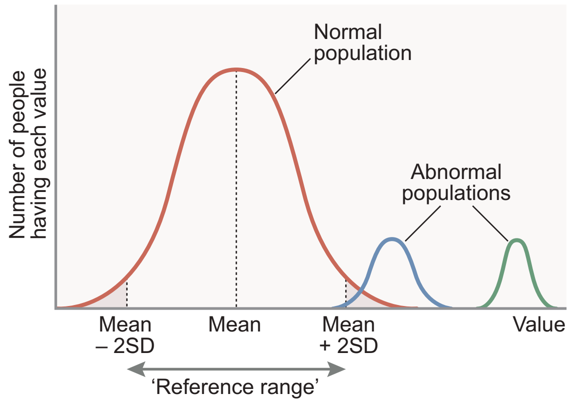

Fig. 1.2 Normal distribution and reference range. For many tests, the frequency distribution of results in the normal healthy population (red line) is a symmetrical bell-shaped curve. The mean ±2 standard deviations (SD) encompasses 95% of the normal population and usually defines the 'reference range'; 2.5% of the normal population have values above, and 2.5% below, this range (shaded areas). For some diseases (blue line), test results overlap with the normal population or even with the reference range. For other diseases (green line), tests may be more reliable because there is no overlap between the normal and abnormal population.

Normal values

Most tests provide quantitative results (i.e. a value on a continuous numerical scale). In order to classify quantitative results as normal or abnormal, it is necessary to define a cut-off point. Many quantitative measurements in populations have a Gaussian or 'normal' distribution. By convention, the normal range is defined as those values that encompass 95% of the population, or 2 standard deviations above and below the mean. This means that 2.5% of the normal population will have values above, and 2.5% will have values below the normal range. For this reason, it is more appropriate to talk about the 'reference range' rather than the 'normal range' (Fig. 1.2).

Test results in abnormal populations also have a Gaussian distribution, with a different mean and standard deviation. In some diseases there is no overlap between results from the abnormal and normal population. However, in many diseases there is overlap; in these circumstances, the greater the difference between the test result and the limits of the reference range, the higher the chance that the person has the disease.

However, there are also situations in medicine when 'normal' is abnormal and 'abnormal' is normal. For example, in the context of a life-threatening asthma attack, a 'normal' *P*aCO$_2$ is abnormal. Conversely, a low ferritin outside the reference range but in a young menstruating woman is not considered to be abnormal at all.

Laboratory results (e.g. cholesterol, thyroid-stimulating hormone) also vary from day to day in the same person in the absence of a real change because of biological variation and laboratory variation. The extent to which a blood test is allowed to vary before it has truly changed is called the 'critical difference'. The critical difference is different for each test, and can be high – 17% in the case of cholesterol and higher for some other blood tests.

Factors other than disease that influence test results

A number of factors other than disease influence test results:

- age
- ethnicity
- pregnancy
- sex
- spurious (in vitro) results.

Box 1.3 gives some examples.

i 1.3 Examples of factors other than disease that influence test results

Factor	Examples
Age	Creatinine is lower in old age (due to relatively lower muscle mass) – an older person can have a significantly reduced eGFR with a 'normal' creatinine
Ethnicity	Healthy people of African ancestry have lower white cell counts
Pregnancy	Several tests are affected by late pregnancy, due to the effects of a growing fetus, including: Reduced urea and creatinine (haemodilution) Iron deficiency anaemia (increased demand) Increased alkaline phosphatase (produced by the placenta) Raised D-dimer (physiological changes in the coagulation system) Mild respiratory alkalosis (physiological maternal hyperventilation) ECG changes (tachycardia, left axis deviation)
Sex	Males and females have different reference ranges for many tests, e.g. haemoglobin
Spurious (in vitro) results	A spurious high potassium is seen in haemolysis and in thrombocytosis ('pseudohyperkalaemia')

(ECG = electrocardiogram; eGFR = estimated glomerular filtration rate, a better estimate of renal function than creatinine)

Operating characteristics

Tests are also subject to operating characteristics. This refers to the way the test is performed. Patients need to be able to comply fully with some tests, such as spirometry (p. 538), and if they cannot, the test result will be affected. Some tests are very dependent on the skill of the operator and are also affected by the patient's body habitus and clinical state; ultrasound of the heart and abdomen are examples. A common mistake is when doctors refer to a test result as 'no abnormality detected' when, in fact, the report describes a technically difficult and incomplete scan that should more accurately be described as 'non-diagnostic'.

Some conditions are paroxysmal. For example, around half of patients with epilepsy have a normal standard electroencephalogram (EEG). A normal EEG therefore does not exclude epilepsy. On the other hand, around 10% of patients who do *not* have epilepsy have epileptiform discharges on their EEG. This is referred to as an 'incidental finding'. Incidental findings are common in medicine, and are increasing in incidence with greater availability of more sensitive tests. Test results should always be interpreted in the light of the patient's history and physical examination.

Sensitivity and specificity

Diagnostic tests have characteristics termed 'sensitivity' and 'specificity'. Sensitivity is the ability to detect true positives; specificity is the ability to detect true negatives. Even a very good test, with 95% sensitivity, will miss 1 in 20 people with the disease. Every test generates 'false positives' and 'false negatives' (Box 1.4).

A very sensitive test will detect most disease but may generate abnormal findings in healthy people. A negative result will therefore reliably exclude disease but a positive result does not mean the disease is present – it means further evaluation is required. On the other hand, a very specific test may miss significant pathology but is likely to establish the diagnosis beyond doubt when the result is positive. All tests differ in their sensitivity and specificity, and clinicians require a working knowledge of the tests they use in order to accurately interpret them.

i 1.4 Sensitivity and specificity

	Disease	No disease
Positive test	A (True positive)	B (False positive)
Negative test	C (False negative)	D (True negative)

Sensitivity = A/(A+C) × 100
Specificity = D/(D+B) × 100

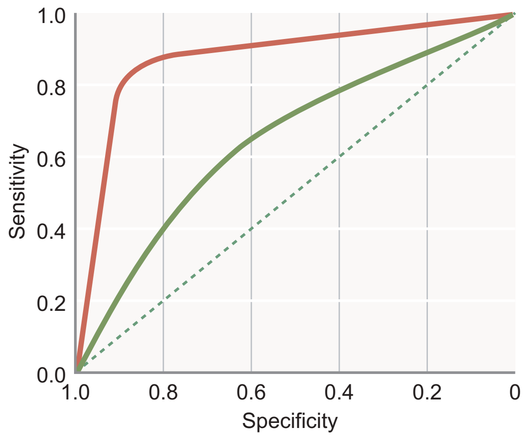

Fig. 1.3 Receiver operating characteristic graph illustrating the trade-off between sensitivity and specificity for a given test. The curve is generated by 'adjusting' the cut-off values defining normal and abnormal results, calculating the effect on sensitivity and specificity and then plotting these against each other. The closer the curve lies to the top left-hand corner, the more useful the test. The red line illustrates a test with useful discriminant value and the green line illustrates a less useful, poorly discriminant test.

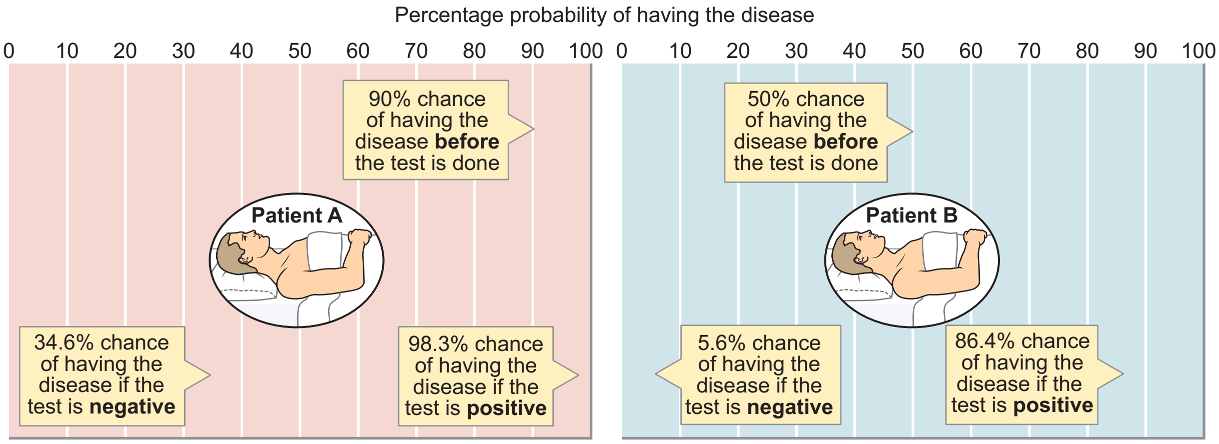
In choosing how a test is used to guide decision-making, there is a trade-off between sensitivity versus specificity. For example, defining an exercise electrocardiogram (p. 429) as abnormal if there is at least 0.5 mm of ST depression would ensure that very few cases of coronary artery disease are missed but would generate many false-positive results (high sensitivity, low specificity). On the other hand, a cut-off point of 2.0 mm of ST depression would detect most cases of important coronary artery disease with far fewer false positives. This trade-off is calculated using the receiver operating characteristic curve of the test (Fig. 1.3).

An important concept in clinical decision-making is this: the probability that a person has a disease depends on the pre-test (clinical) probability and the sensitivity and specificity of the test. For example, imagine an older woman has fallen and hurt her left hip. On examination, the hip is extremely painful to move and she cannot stand. However, her hip X-rays are normal. Does she have a fracture?

The sensitivity of plain X-rays of the hip performed in the emergency department for suspected hip fracture is around 95%. A small percentage of fractures are therefore missed. If our patient has (or is at risk of) osteoporosis, has severe pain on hip movement and cannot bear weight on the affected side, then the *clinical* probability of hip fracture is not low – there could still be a fracture.

Doctors are continually making judgements about whether something is true, given that something else is true. This is known as 'conditional probability'. Bayes' theorem (named after English clergyman Thomas Bayes, 1702–1761) is a mathematical way to describe the post-test probability of a disease by combining pre-test probability, sensitivity and specificity. In clinical practice, doctors are not able to make complex mathematical calculations for every decision they make. In practical terms, the answer to the question of whether there is a fracture is that in a high-probability patient a normal test result does not exclude it, but in a low-probability patient it (virtually) does. This principle is illustrated in Figure 1.4.

Sox and colleagues (see 'Further information') state a fundamental assertion, which they describe as a profound and subtle principle



Percentage probability of having the disease
0 10 20 30 40 50 60 70 80 90 100
0 10 20 30 40 50 60 70 80 90 100
90% chance of having the disease **before** the test is done
Patient A
34.6% chance of having the disease if the test is **negative**
98.3% chance of having the disease if the test is **positive**
50% chance of having the disease **before** the test is done
Patient B
5.6% chance of having the disease if the test is **negative**
86.4% chance of having the disease if the test is **positive**

Fig. 1.4 The interpretation of a test result depends on the probability of the disease before the test is carried out. In the example shown, the test being carried out has a sensitivity of 95% and a specificity of 85%. Patient A has very characteristic clinical findings, which make the pre-test probability of the condition for which the test is being used very high – estimated as 90%. Patient B has more equivocal findings, such that the pre-test probability is estimated as only 50%. If the result in Patient A is negative, there is still a significant chance that he has the condition for which he is being tested; in Patient B, however, a negative result makes the diagnosis very unlikely.

of clinical medicine: the interpretation of new information depends on what you believed beforehand. In other words, the interpretation of a test result depends on the probability of disease before the test.

Prevalence of disease

Consider this problem that was posed to a group of Harvard doctors. The problem originates from a 1978 article in the *New England Journal of Medicine* (Casscells et al, see 'Further information'): if a test to detect a disease whose prevalence is 1:1000 has a false-positive rate of 5%, what is the chance that a person found to have a positive result actually has the disease, assuming you know nothing about the person's symptoms and signs? Assume the test generates no false negatives and take a moment to work this out. In this problem, we have removed clinical probability and are only considering prevalence. The answer is at the end of the chapter (p. 11).

Sensitivity and specificity are characteristics of the test; the population does not change this. However, as doctors, we are interested in the question, 'What is the probability that a person with a positive test actually has the disease?' – or the test's positive predictive value. Predictive values combine sensitivity, specificity and prevalence of disease in the population. This is illustrated in Box 1.5.

Post-test probability and predictive values are different. Post-test probability is the probability of a disease after taking into account new information from a test result. Bayes' theorem can be used to calculate post-test probability for a patient in any population. The pre-test probability of disease is decided by the doctor; it is a judgement based on information gathered prior to ordering the test. Predictive value is the proportion of patients with a test result who have the disease (or no disease) and is calculated from a table of results in a specific population (see Box 1.5). It is not possible to transfer this value to a different population. This is important to realise because published information about the performance of diagnostic tests may not apply to different populations.

In deciding the pre-test probability of disease, clinicians often neglect to take prevalence into account and this distorts their estimate of probability. To estimate the probability of disease in a patient more accurately, clinicians should start with the prevalence of disease in the group to which the patient belongs (e.g. 'a 65-year-old male smoker with type 2 diabetes') and then consider individual factors, such as features in the history and examination, in this context.

Dealing with uncertainty

Clinical findings are imperfect and diagnostic tests are imperfect. It is important to recognise that clinicians frequently deal with uncertainty. By expressing uncertainty as probability, new information from diagnostic tests can be incorporated more accurately. However, subjective estimates of probability can sometimes be unreliable. As the section on clinical reasoning concepts will demonstrate (see below), intuition can be a source of error.

1.5 Predictive values: 'What is the probability that a person with a positive test actually has the disease?'

	Disease	No disease
Positive test	A (True positive)	B (False positive)
Negative test	C (False negative)	D (True negative)

Positive predictive value = A/(A+B) × 100
Negative predictive value = D/(D+C) × 100

Knowing the patient's true state is often unnecessary in clinical decision-making. Sox and colleagues (see 'Further information') argue that there is a difference between knowing that a disease is present and acting as if it were present. The requirement for diagnostic certainty depends on the penalty for being wrong. Different situations require different levels of certainty before starting treatment. How we communicate uncertainty to patients will be discussed later in this chapter (see Fig. 1.8).

The 'treatment threshold' combines factors such as the risks of the test, and the risks versus benefits of treatment. The point at which the factors are all evenly weighed is the threshold. If a test or treatment for a disease is effective and low risk (e.g. giving narrow spectrum or 'targeted' antibiotics for a suspected urinary tract infection), then there is a lower threshold for going ahead. On the other hand, if a test or treatment is less effective or high risk (e.g. starting chemotherapy for a malignant brain tumour), then greater confidence is required in the clinical diagnosis and potential benefits of treatment first. In principle, if a diagnostic test will not change the management of the patient, then careful consideration should be given to whether it is necessary to do the test at all.

In summary, test results shift our thinking, but do not necessarily give a 'yes' or a 'no' answer in terms of a diagnosis. Sometimes test results shift the probability of disease by less than we realise. Pre-test probability is key, and this is derived from the history and physical examination, combined with a sound knowledge of medicine and an understanding of the prevalence of disease in the particular care setting or the population to which the patient belongs.

Problem representation

Many students are taught to formulate a differential diagnosis after the history, physical examination and initial test results, but the ability to accurately articulate a ‘problem representation’ first and *then* construct a prioritised differential diagnosis based on this, including relevant ‘must-not-miss’ diagnoses, is a key step in the clinical reasoning process. Problem representation refers to how information about a problem is mentally organised. Studies show that expert clinicians spend far more time on defining and representing a problem before trying to solve it compared with novices, and novices are more likely to be unsuccessful in solving a problem because they have not accurately represented the problem in the first place. The ability to synthesise all the available information and encapsulate it into a problem representation using precise medical language is an important skill that needs to be learned. Problem representation works by translating the patient’s own words and data into a precise medical summary and matching this with relevant patterns (known as illness scripts) in the clinician’s long-term memory. It is associated with significantly higher diagnostic accuracy, particularly in complex cases (Bordage, 1994; see ‘Further information’).

Problem representation in medicine answers three questions: a) who is my patient? b) what is the key background information? and c) what are the key features of the case? However, formulating a problem representation (e.g. ‘A 30-year-old pregnant woman with acute left-sided pleuritic chest pain and breathlessness’) is not always possible. In these cases, a problem list can be used instead (e.g. found on floor, reduced conscious level, acute kidney injury, raised inflammatory markers). This helps to formulate an action plan while further information is being gathered when a diagnosis is not yet possible.

Clinical reasoning concepts

Advances in cognitive psychology in recent decades have demonstrated that human thinking and decision-making are prone to error. Cognitive biases are subconscious errors that lead to inaccurate judgement and illogical interpretation of information. They are prevalent in everyday life; as the famous saying goes, ‘to err is human’.

Take a few moments to look at this simple puzzle. Do not try to solve it mathematically but listen to your intuition:

> A bat and ball cost £1.10.
> The bat costs £1 more than the ball.
> How much does the ball cost?

The answer is at the end of the chapter. Most people get the answer to this puzzle wrong – even though they have all the knowledge and experience they need to solve this problem. This is because humans are always trying to conserve cognitive energy. British psychologist and patient safety pioneer James Reason said that, ‘Our propensity for certain types of error is the price we pay for the brain’s remarkable ability to think and act intuitively – to sift quickly through the sensory information that constantly bombards us without wasting time trying to work through every situation anew.’ This property of human thinking is highly relevant to clinical decision-making.

Type 1 and type 2 thinking

Decades of studies in cognitive psychology and, more recently, functional magnetic resonance imaging demonstrate two distinct types of processes when it comes to decision-making: humans have a fast, intuitive, pattern-recognising way of thinking which uses little cognitive effort (known as type 1 thinking) and a more deliberate, analytical one which engages our working memory (known as type 2 thinking). This is known as ‘dual process theory’ and Box 1.6 explains this in more detail.

Psychologists estimate that we spend 95% of our daily lives engaged in type 1 thinking – the intuitive, fast, subconscious mode of decision-making. Imagine driving a car, for example: it would be impossible to function efficiently if every decision and movement were as deliberate, conscious, slow and effortful as in our first driving lesson. With experience, complex procedures become automatic, fast and effortless. The same applies to medical practice. There is evidence that expert decision-making is well served by intuitive thinking. The problem is that although intuitive processing is highly efficient in many circumstances, in others it is prone to error.

i 1.6 Type 1 and type 2 thinking

Type 1	Type 2
Intuitive, heuristic (pattern recognition)	Analytical, systematic
Automatic, subconscious	Deliberate, conscious
Fast, effortless	Slow, effortful
Low/variable reliability	High/consistent reliability
Vulnerable to error	Less prone to error
Highly affected by context	Less affected by context
High emotional involvement	Low emotional involvement
Low scientific rigour	High scientific rigour

Clinicians use both type 1 and type 2 thinking, and both types are important in clinical decision-making. When encountering a problem that is familiar, clinicians employ pattern recognition and reach a working diagnosis or differential diagnosis quickly (type 1 thinking). When encountering a problem that is more complicated, they use a slower, systematic approach (type 2 thinking). Both types of thinking interplay – they are not mutually exclusive. Figure 1.5 illustrates the interplay between type 1 and type 2 thinking in clinical practice.

Errors can occur in both type 1 and type 2 thinking. For example, people can apply the wrong rules or make errors in their application while using type 2 thinking. However, it has been argued that the common cognitive biases encountered in medicine tend to occur when clinicians are engaged in type 1 thinking.

For example, imagine being asked to see a young woman who is drowsy. She is handed over to you as a ‘probable overdose’ because she has a history of depression and a packet of painkillers was found beside her at home. Her observations show she has a Glasgow Coma Scale score of 10/15, heart rate 100 beats/min, blood pressure 100/60 mmHg, respiratory rate 14 breaths/min, oxygen saturations 98% on air and temperature 37.5°C. Already your mind has reached a working diagnosis. It fits a pattern (type 1 thinking). You think she has taken an overdose. At this point you can stop to *think about your thinking* (rational override in Fig. 1.5): ‘What is the evidence for this diagnosis? What else could it be?’

On the other hand, imagine being asked to assess a patient who has been admitted with syncope. There are several different causes of syncope and a systematic approach is required to reach a diagnosis (type 2 thinking). However, you recently heard about an unusual case of syncope due to a painless leaking abdominal aortic aneurysm. At the end of your assessment, following evidence-based guidelines, it is clear the patient can be discharged. Despite this, you decide to observe the patient overnight *just in case* (irrational override in Fig. 1.5). In this example, your intuition is actually ‘availability bias’ (when things are at the forefront of your mind), which has significantly distorted your estimate of probability.

Common cognitive biases in medicine

Figure 1.6 illustrates the common cognitive biases prevalent in medical practice. Biases often work together; for example, in overconfidence bias (the tendency to believe we know more than we actually do), too much faith is placed in opinion instead of gathered evidence. This bias can be augmented by availability bias and finally by commission bias (the tendency towards action rather than inaction) – sometimes with disastrous results.

The mark of a well-calibrated thinker is the ability to recognise what mode of thinking is being employed and to anticipate and recognise situations in which cognitive biases and errors are more likely to occur.

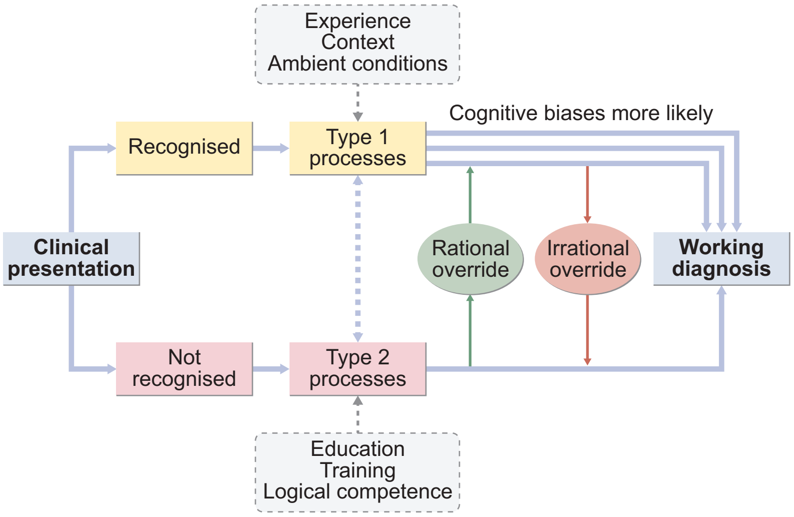


Fig. 1.5 **The interplay between type 1 and type 2 thinking in the diagnostic process.** *Adapted from Croskerry P. A universal model of diagnostic reasoning. Acad Med 2009;84:1022–1028.*

Thinking about thinking

Research has highlighted the importance of being aware of and being able to think about one's own thinking (also known as metacognition). Several studies have demonstrated that engaging in reflection during diagnostic decision-making improves performance (Prakash et al, see 'Further information'). This can be as simple as asking, 'What is the evidence for this diagnosis? What else could it be?' Reflection is most effective when the case is more complex (relative to the clinician).

Some people have a natural tendency to look for evidence, weigh things up, be aware of context, not take things at face value, and think about their own thinking. Others can learn to develop this skill. This is referred to as a person's 'cognitive style', as opposed to their cognitive ability, which relates to their intelligence and knowledge. In fact, the tendency to engage in reflection during decision-making has been found to be independent of cognitive ability, and accounts for the greatest variation in individual performance on reasoning tasks in psychology.

With increasing knowledge and experience, intuitive type 1 thinking is used more; it is fast and highly accurate and commonly used by experts. Reflection interrupts type 1 processing, even briefly, to simulate alternatives. So, good decision-making relies on knowledge and experience, but also the ability to 'stop and think' when needed. However, this requires cognitive effort, which is impaired by things like fatigue, sleep deprivation, interruptions, stress and cognitive overload.

Human factors

'Human factors' is the science of the limitations of human performance, and how technology, the work environment and team communication can adapt for this to reduce diagnostic and other types of error. Analysis of serious adverse events in clinical practice shows that human factors and poor team communication play a significant role when things go wrong.

Research shows that many errors are beyond an individual's conscious control and are precipitated by many factors. The discipline of human factors seeks to understand interactions between:

- people and tasks or technology
- people and their work environment
- people in a team.

An understanding of these interactions makes it easier for health-care professionals, who are committed to 'first, do no harm', to work in the safest way possible. For example, performance is adversely affected by factors such as poorly designed processes and equipment, fatigue and poor communication. So simple, clear processes, good design of equipment and shift patterns, and clear team communication all help to minimise errors.

The areas of the brain required for type 2 thinking are most affected by things like fatigue and cognitive overload, and the brain reverts to type 1 thinking to conserve cognitive energy. Figure 1.7 illustrates some of the internal and external factors that affect human judgement and decision-making. An awareness of the factors that impact on decision-making can allow clinicians (and the health-care systems in which they work) to take steps to mitigate these.

Several studies demonstrate that we focus our attention to filter out distractions. This is advantageous in many situations (for example, when performing a procedure), but in focusing on what we are trying to see we may not notice the unexpected. In a team context, what is obvious to one person may not be to someone else. Safe and effective team communication therefore requires us never to assume, and to verbalise things, even though they may seem 'obvious'.

Shared decision-making

Good decision-making is often shared with patients, relatives and carers, within teams, and by using guidelines, clinical prediction rules and other decision aids, including artificial intelligence. Good decision-making also includes optimal decision-making behaviours such as involving the patient and/or carers in the diagnostic and management process, listening to them, following evidence-based guidelines, asking for help when needed including from colleagues, and clearly communicating, especially when handing over care.

Patient-centred evidence-based medicine

'Patient-centred evidence-based medicine' refers to the application of best available research evidence while taking individual patient factors into account; these include both clinical and non-clinical factors (e.g. the patient's social circumstances, values and wishes). For example, a 95-year-old man with dementia and a recent gastrointestinal bleed is admitted with an inferior myocardial infarction. He is clinically well. Should he be treated with dual antiplatelet therapy and low-molecular-weight heparin as recommended in clinical guidelines for myocardial infarction?

As this chapter has described, clinicians frequently deal with uncertainty/probability. Clinicians need to be able to explain risks and benefits

Anchoring describes the common tendency to rely too heavily on the first piece of information offered (the 'anchor') when making decisions.

Ascertainment Bias is when we see what we expect to see. For example, a frequent self-harmer attends the emergency department with drowsiness – everyone assumes he has taken another overdose and misses a brain injury.

Availability Bias is when things are at the forefront of your mind because you have seen several cases recently or have been studying that condition in particular.

Base Rate Neglect is the tendency to ignore the prevalence of a disease. In some cases, clinicians do this deliberately in order to rule out an unlikely but worst-case scenario.

Commission Bias is the tendency towards action rather than inaction or watching and waiting, in the assumption that only good can come from doing something (rather than 'watching and waiting').

Confirmation Bias is the tendency to look for confirming evidence to support a theory rather than looking for contradictory evidence to refute it. Confirmation bias is common when a patient has been seen first by another doctor.

Diagnostic Momentum Once a diagnostic label has been attached to a patient, it can gather momentum with each review, leading others to exclude other possibilities in their thinking.

Framing Effect is when how a case is presented can generate bias in the listener. This can be mitigated by always having 'healthy scepticism' about other people's diagnoses.

Hindsight Bias is when knowing the outcome profoundly influences the perception of past events and decision-making, preventing a realistic appraisal of what actually occurred.

Overconfidence Bias is the tendency to believe we know more than we actually do, placing too much faith in opinion instead of gathered evidence.

Omission Bias is the tendency towards inaction, rooted in the principle of 'first do no harm.' Events that occur through natural progression of disease are more acceptable than those that may be attributed directly to the action of the health-care team.

Posterior Probability occurs when our estimate of the likelihood of disease is unduly influenced by what has gone on before – for example, a patient who has been extensively investigated for headaches presents with a severe headache and serious causes are discounted.

Premature Closure is the tendency to prematurely close the decision-making process and accept a diagnosis before it, and other possibilities, have been fully explored.

Psych-Out Error Psychiatric patients who present with medical problems are under-assessed because problems are presumed to be due to, or exacerbated by, their psychiatric condition.

Search Satisficing is when we stop searching because we have found something that fits or is convenient, instead of systematically looking for the best alternative.

Triage-Cueing Triage ensures patients get sent to the right department. This leads to 'geography is destiny' – for example, a diabetic ketoacidosis patient with abdominal pain and vomiting gets sent to surgery. The wrong location (surgical ward) stops people thinking about medical causes of abdominal pain and vomiting.

Unpacking Principle is when failure to 'unpack' all the available information means things get missed. For example, if a thorough history is not obtained from either the patient or carers, diagnostic possibilities may be discounted.

Visceral Bias refers to the influence of either negative or positive feelings towards patients, which can affect our decision-making.

Fig. 1.6 Common cognitive biases in medicine. *Adapted from Croskerry P. Achieving quality in clinical decision-making: cognitive strategies and detection of bias. Acad Emerg Med 2002;9:1184–1204.*

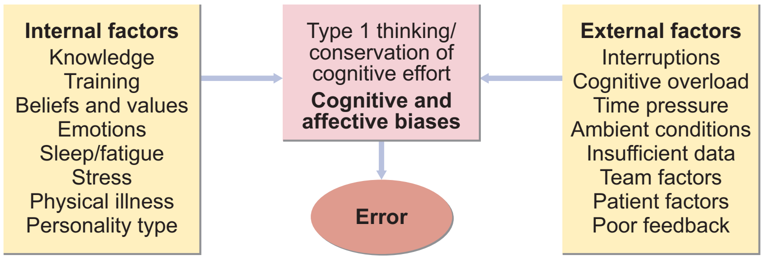

Fig. 1.7 Factors that affect our judgement and decision-making. (Type 1 thinking = fast, intuitive, subconscious, low effort)

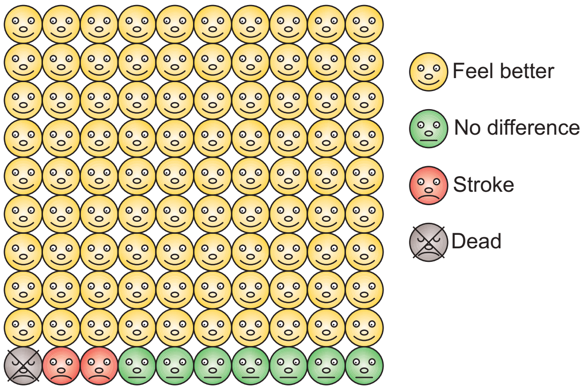

Fig. 1.8 Visual portrayal of benefits and risks. The image refers to an operation that is expected to relieve symptoms in 90% of patients, but cause stroke in 2% and death in 1%. *From Edwards A, Elwyn G, Mulley A. Explaining risks: turning numerical data into meaningful pictures. BMJ 2002;324:827–830, reproduced with permission from the BMJ Publishing Group.*

of treatment in an accurate and understandable way. Providing the relevant statistics is seldom sufficient to guide decision-making because a patient's perception of risk may be influenced by irrational factors as well as individual values.

Research evidence provides statistics but these can be confusing. Terms such as 'common' and 'rare' are unclear. Whenever possible, clinicians should quote numerical information using consistent denominators (e.g. '90 out of 100 patients who have this operation feel much better, 1 will die during the operation and 2 will suffer a disabling stroke'). Visual aids can be used to present complex statistical information (Fig. 1.8).

How uncertainty is conveyed to patients is important. Many studies demonstrate a correlation between effective clinician–patient communication and improved health outcomes. If patients feel they have been listened to and understand the problem and proposed treatment plan, they are more likely to follow the plan and less likely to re-attend.

Realistic medicine

Realistic medicine is a movement that started in Scotland (see 'Further information') with the aim of empowering patients and their families to discuss their tests and treatment, including any side effects and potentially negative outcomes, and whether they need a test or treatment at all. Examples of questions that may help in these discussions include:

- Is this test, treatment or procedure really needed?
- What are the potential benefits and risks?
- What are the possible side effects?
- What are the alternative treatment options?
- What would happen if I didn't have the test or treatment?

The ethos of realistic medicine is to base care on what matters most to people and create a shared understanding of what medicine can realistically contribute to this.

Effective team communication

In increasingly complex health-care systems, patients are looked after by a wide variety of professionals, each of whom has access to important information required to make clinical decisions. Strict hierarchies are hazardous to patient safety if certain members of the team do not feel able to speak up.

The SBAR system of communication has been recommended by the UK's Patient Safety First campaign. It is a structured way to communicate about a patient with another health-care professional (e.g. during handover or when making a referral) and increases the amount of relevant information being communicated in a shorter time. It is illustrated in Box 1.7.

i 1.7 The SBAR system of communicating

SBAR	Example (a telephone call to the Intensive Care team)
Situation	I am [name] calling from [place] about a patient with a NEWS* of 10.
Background	[Patient's name], 30-year-old woman, no past medical history, was admitted last night with community-acquired pneumonia. Since then her oxygen requirements have been steadily increasing.
Assessment	Her vital signs are: blood pressure 115/60 mmHg, heart rate 120 beats/min, temperature 38°C, respiratory rate 32 breaths/min, oxygen saturations 89% on 15 L via reservoir bag mask. An arterial blood gas shows H^+ 50 nmol/L (pH 7.3), $PaCO_2$ 4.0 kPa (30 mmHg), PaO_2 7 kPa (52.5 mmHg), standard bicarbonate 14 mmol/L. Chest X-ray shows extensive right lower zone consolidation.
Recommendation	Please can you come and see her as soon as possible? I think she needs admission to Intensive Care.

*NEWS = National Early Warning Score; a patient with normal vital signs scores 0. See Royal College of Physicians. National Early Warning Score (NEWS) 2: Standardising the assessment of acute-illness severity in the NHS. Updated report of a working party. London: RCP; December 2017.

Using clinical prediction rules and other decision aids

A clinical prediction rule is a statistical model of the diagnostic process. When clinical prediction rules are matched against the opinion of experts, the model usually outperforms the experts, because it is applied consistently in each case. However, it is important that clinical prediction rules are used correctly – that is, applied to the patient population that was used to create the rule. Clinical prediction rules force a scientific assessment of the patient's symptoms, signs and other data to develop a numerical probability of a disease or an outcome. They help clinicians to estimate probability more accurately.

A good example of a clinical prediction rule to estimate pre-test probability is the Wells score in suspected deep vein thrombosis (see Box 10.18). Other commonly used clinical prediction rules predict outcomes and therefore guide the management plan. These include the GRACE score in acute coronary syndromes (see Fig. 16.61) and the CURB-65 score in community-acquired pneumonia (see Fig. 17.32).

Artificial intelligence (AI) is increasingly being used in diagnosis – in analysing medical images, cancer diagnosis and genetics, recognising patterns in large databases, and providing decision support. AI has the potential to save time and reduce errors. However, human expertise and involvement are still essential in the clinical decision-making process. Human clinicians gather and interpret data through exploring (not simply listening to) a patient's story. This requires knowledge and skill – not only in medicine, but in consultation and communication skills as well. Clinical reasoning involves the senses: touch and smell, as well as vision and hearing. It sometimes involves our 'sixth sense' – our human intuition. Interaction with a human clinician can be therapeutic in its own right, simply because of *how* the clinician listens and communicates, as well as *what* they communicate.

Reducing errors in clinical decision-making

In addition to knowledge and experience and effortful practice in the areas covered so far in this chapter, there are some simple and established techniques that can be used to avoid errors and cognitive biases during clinical decision-making. These are collectively termed 'cognitive debiasing strategies'.

History and physical examination

Taking a history and performing a physical examination may seem obvious, but these are sometimes carried out inadequately. This is the 'unpacking principle': failure to unpack all the available information means things can be missed and this can lead to error.

Problem representation/list and differential diagnosis

Once all the available data from history, physical examination and (sometimes) initial test results are available, these need to be synthesised into a problem representation or problem list. The process of generating a problem list ensures nothing is missed. The process of generating a differential diagnosis works against anchoring on a particular diagnosis too early, thereby avoiding premature closure (see Fig. 1.6) and 'satisficing' (searching through options and stopping when finding one that seems to fit).

Mnemonics and checklists

These are used frequently in medicine in order to reduce reliance on fallible human memory. ABCDE (airway, breathing, circulation, disability, exposure/examination) is probably the most successful checklist in medicine, used during the assessment and treatment of critically ill patients (ABCDE is sometimes prefixed with 'C' for 'control of any obvious problem'; see p. 228). Checklists ensure that important issues have been considered and completed, especially under conditions of complexity, stress or fatigue.

Red flags and ROWS ('rule out worst-case scenario')

These are strategies that force doctors to consider serious diseases that can present with common symptoms. Red flags in back pain are listed in Box 25.19. Considering and investigating for possible pulmonary embolism in patients who present with pleuritic chest pain and breathlessness is a common example of ruling out a worst-case scenario, as pulmonary embolism can be fatal if missed. Red flags and ROWS help to avoid cognitive biases such as the 'framing effect' and 'premature closure'.

Newer strategies to avoid cognitive biases and errors in decision-making are emerging. These involve explicit training in clinical reasoning and human factors. In theory, if doctors are aware of the science of human thinking and decision-making, then they are more able to think about their thinking, understand situations in which their decision-making may be affected, and take steps to mitigate this.

Clinical decision-making: putting it all together

The following is a practical example that brings together many of the concepts outlined in this chapter:

A 25-year-old woman presents with right-sided pleuritic chest pain and breathlessness. She reports that she had an upper respiratory tract infection a week ago and was almost back to normal when the symptoms started. The patient has no past medical history and no family history, and her only medication is the combined oral contraceptive pill. On examination, her vital signs are normal (respiratory rate 19 breaths/min, oxygen saturations 98% on air, blood pressure 115/60 mmHg, heart rate 90 beats/min, temperature 37.5°C) and the physical examination is also normal. You have been asked to assess her for the possibility of a pulmonary embolism.

(More information on pulmonary embolism can be found in Chapter 17.)

Evidence-based history and examination

Information from the history and physical examination is vital in deciding whether this could be a pulmonary embolism. Pleurisy and breathlessness are common presenting features of this disease but are also common presenting features in other diseases. There is nothing in the history to suggest an alternative diagnosis (e.g. high fever, productive cough, recent chest trauma). The patient's vital signs are normal, as is the physical examination. However, very few individual findings help to distinguish patients with pulmonary embolism from those without it. The presence of wheeze and a high fever modestly decrease the probability of pulmonary embolism. The presence or absence of hypoxaemia is unhelpful (likelihood ratio not significant).

Deciding pre-test probability

The prevalence of pulmonary embolism (PE) in 25-year-old women is low. We anchor on this prevalence and then adjust for individual patient factors. This patient has no major risk factors for pulmonary embolism. To assist our estimate of pre-test probability, we could use a clinical prediction rule: in this case, the modified Wells score for pulmonary embolism (see Box 10.18), which would give a score of 3 (low probability – answering yes only to the criterion 'PE is the number one diagnosis, an alternative is less likely' if there is no alternative explanation for her symptoms).

Interpreting test results

Imagine the patient goes on to have a normal chest X-ray and blood results, apart from a raised D-dimer of 900 (normal <500 ng/mL). A normal chest X-ray is a common finding in pulmonary embolism. Several studies have shown that the D-dimer assay has at least 95% sensitivity in acute pulmonary embolism but it has a low specificity. A very sensitive test will detect most disease but generate abnormal findings in healthy people. On the other hand, a negative result virtually, but not completely, excludes the disease. It is important at this point to recognise that a raised D-dimer does not mean this patient has a pulmonary embolism; it just means that we have not been able to exclude it. Since pulmonary embolism is a potentially fatal condition we need to rule out the worst-case scenario (ROWS) and the next step is therefore to arrange further imaging. What kind of imaging depends on individual patient characteristics and what is available.

Treatment threshold

The treatment threshold combines factors such as the risks of the test, and the risks versus benefits of treatment. A CT pulmonary angiogram (CTPA) could be requested for this patient, although a ventilation–perfusion single-photon emission computed tomography ($\dot{V}/\dot{Q}$ SPECT, p. 586) may be a more suitable alternative. However, what if the scan cannot be performed until the next day? Because pulmonary embolism is potentially fatal and the risks of treatment in this case are low, the patient should be started on treatment while waiting for the scan.

Post-test probability

The patient's scan result is subsequently reported as 'no pulmonary embolism'. Combined with the low pre-test (clinical) probability, this scan result reliably excludes pulmonary embolism.

Cognitive biases

Imagine during this case that the patient had been handed over to you as 'nothing wrong – probably a pulled muscle'. Cognitive biases (our subconscious tendencies to respond in a certain way) would come into play, such as the 'framing effect', 'confirmation bias' and 'search satisficing'. The normal clinical examination might confirm the diagnosis of musculoskeletal pain in your mind, despite the examination being entirely consistent with pulmonary embolism and despite the lack of history and examination findings (e.g. chest wall tenderness) to support the diagnosis of musculoskeletal chest pain.

Human factors

Imagine that, after you have seen the patient, a colleague hands you some blood forms and asks you what tests you would like to request on 'this lady'. You request blood tests including a D-dimer on the wrong patient. Luckily, this error is intercepted.

Shared decision-making

The diagnosis of pulmonary embolism can be difficult. Clinical prediction rules (e.g. modified Wells score), guidelines (e.g. from the UK's National Institute for Health and Care Excellence, or NICE) and decision aids (e.g. pulmonary embolism rule-out criteria or 'PERC rule') are frequently used in combination with the doctor's opinion, derived from information gathered in the history and physical examination.

The patient is treated according to evidence-based guidelines that apply to her particular situation. Tests alone do not make a diagnosis and at the end of this process the patient is told that the combination of history, examination and test results mean she is extremely unlikely to have a pulmonary embolism. Viral pleurisy is offered as an alternative diagnosis and she is reassured that her symptoms are expected to settle over the coming days with analgesia. She is advised to re-present to hospital if her symptoms get worse.

Answers to problems

Harvard problem (p. 5)

Almost half of doctors surveyed said 95%, but they neglected to take prevalence into account. If 1000 people are tested, there will be 51 positive results: 50 false positives and 1 true positive. The chance that a person found to have a positive result actually has the disease is therefore only 1/51 or ~2%.

Bat and ball problem (p. 6)

This puzzle is from the book *Thinking, Fast and Slow*, by Nobel laureate Daniel Kahneman (see 'Further information'). He writes, 'A number came to your mind. The number, of course, is 10p. The distinctive mark of this easy puzzle is that it evokes an answer that is intuitive, appealing – and wrong. Do the math, and you will see.' The correct answer is 5p.

Multiple Choice Questions

1.1. Which of the following best describes what is meant by the term ‘shared decision-making’?

A. Allowing the patient to make decisions about their care
B. Asking for help when needed
C. Making decisions with the wider clinical team
D. Patient-centred evidence-based medicine
E. Sharing decision-making with the patient, relatives, clinical team, guidelines and decision support tools

Answer: E.

Shared decision-making refers to the fact that clinical reasoning does not necessarily take place solely within a clinician’s head. Good decision-making is often shared with patients, relatives and carers, within teams, and by using guidelines, clinical prediction rules and other decision aids. Integral to all of this is the ability to engage in optimal decision-making behaviours: involving the patient and/or carers in the diagnostic and management process, listening to others, following evidence-based guidelines, asking for help when needed, and using clear communication, especially when handing over care.

1.2. Which of the following best describes what is meant by the term ‘metacognitive knowledge’?

A. An awareness of and an ability to think about one’s own thinking
B. An understanding of how things fit together
C. An understanding of how to do something, what techniques to use
D. The tendency to engage in effortful practice
E. The tendency to look for evidence, weigh things up and be aware of context

Answer: A.

Metacognition literally means ‘thinking about thinking’, ‘knowing about knowing’, and being ‘aware of one’s awareness’. Metacognitive knowledge is about being aware of one’s own cognitive processes and is a key ingredient for successful learning and the development of expertise.

1.3. When using a clinical prediction rule for a specific condition, which of the following is true?

A. The tool can be applied to any patient with the condition
B. The tool can determine the clinical probability that a patient has a disease
C. The tool is not necessarily based on evidence
D. The tool uses the receiver operating characteristic curve to statistically model the diagnostic process
E. Use of the tool removes the need for clinical decision-making on the part of the clinician

Answer: B.

A clinical prediction rule is a statistical model of the diagnostic process. When clinical prediction rules are matched against the opinion of experts, the model usually outperforms the experts, because it is applied consistently in each case. However, it is important that clinical prediction rules are used correctly – that is, applied to the patient population that was used to create the rule. Clinical prediction rules force a scientific assessment of the patient’s symptoms, signs and other data to develop a numerical probability of a disease or an outcome. They help clinicians to estimate probability more accurately. A good example of a clinical prediction rule to estimate pre-test probability is the Wells score in suspected deep vein thrombosis.

1.4. Regarding normal values, which of the following statements is true?

A. A normal result means that disease is not present
B. A normal result specific to a particular disease is not found in a person with the disease
C. Normal values do not vary significantly within the same person
D. Normal values follow a Poisson distribution
E. One in 20 healthy people will have values that lie outside the reference range

Answer: E.

Most tests provide quantitative results on a continuous numerical scale. In order to classify quantitative results as normal or abnormal, it is necessary to define a cut-off point. Many quantitative measurements in populations have a Gaussian or ‘normal’ distribution. By convention, the normal (reference) range is defined as those values that encompass 95% of the population, or 2 standard deviations above and below the mean. This means that 2.5% of the normal population will have values above, and 2.5% will have values below the normal range. In some diseases there is no overlap between results from the abnormal and normal population. However, in many diseases there is overlap. So a healthy person can have an ‘abnormal’ result, and a person with disease can have a ‘normal’ result. Normal values also vary from day to day in the same person in the absence of a real change because of biological variation and laboratory variation. The extent to which a blood test is allowed to vary before it has truly changed is called the ‘critical difference’.

1.5. An 80-year-old man presented with a fall on a background of a 2-week history of his legs ‘giving way’ and a history of increasing low back pain. In this scenario, which of the following strategies to reduce errors in clinical reasoning would be most appropriate?

A. An assessment of his mobility
B. An X-ray of the lumbar spine
C. Generating a problem representation
D. Use of a clinical prediction rule
E. Using red flags and ‘ROWS’ (rule out worst-case scenario)

Answer: E.

Various strategies can be used to reduce errors in clinical reasoning including: taking a proper history and performing a thorough physical examination, generating a problem representation, and using mnemonics and checklists. Using red flags and ROWS (rule out worst-case scenario) forces clinicians to think about serious diseases that can present with common symptoms. In this example, it forces clinicians to consider the possibility of cord compression. Red flags and ROWS helps to avoid cognitive biases such as the ‘framing effect’ and ‘premature closure’.

Managing the use of medicines 28
Prescribing in practice 29
Decision-making in prescribing 29
Monitoring drug therapy 32
Prescribing in special circumstances 33

Prescribing medicines is the major tool used by doctors to restore or preserve the health of patients. Medicines contain drugs (the specific chemical substances with pharmacological effects), either alone or in combination with additional drugs, in a formulation mixed with other ingredients. The beneficial effects of medicines must be weighed against their cost and potential adverse drug reactions and interactions. The latter two factors are sometimes caused by injudicious prescribing decisions and by prescribing errors. The modern prescriber must meet the challenges posed by the increasing number of drugs and formulations available, of the indications for prescribing them and the greater complexity of treatment regimens leading to the use of multiple medications (polypharmacy), particularly in older people. The purpose of this chapter is to elaborate on the principles and practice that underpin good prescribing (Box 2.1).

2.1 Steps in good prescribing

- Make a diagnosis
- Consider factors that might influence the patient's response to therapy (age, concomitant drug therapy, renal and liver function)
- Establish the therapeutic goal*
- Choose the therapeutic approach*
- Choose the drug and its formulation (the 'medicine')
- Choose the dose, route and frequency
- Choose the duration of therapy
- Write an unambiguous prescription (or 'medication order')
- Inform the patient about the treatment and its likely effects
- Monitor treatment effects, both beneficial and harmful
- Review/alter the prescription

*These steps in particular take the patient's views into consideration to establish a therapeutic partnership that aims to achieve 'concordance' based on shared decision-making.

Principles of clinical pharmacology

Prescribers need to understand what the drug does to the body (pharmacodynamics) and what the body does to the drug (pharmacokinetics) (Fig. 2.1). Although this chapter is focused on the most common drugs, which are synthetic small molecules, the same principles apply to the use of peptides, proteins, enzymes and monoclonal antibodies, which are collectively known as biologics.

Pharmacodynamics

Drug targets and mechanisms of action

Modern drugs are usually discovered by screening compounds for activity either to stimulate or to block the function of a specific molecular target, which is predicted to have a beneficial effect in a particular disease (Box 2.2). Other drugs do not have a specific target. Examples are desferrioxamine, a chelator used in the treatment of iron overload; mannitol, an osmotic agent used for cerebral oedema; and general anaesthetics, which work by altering the biophysical properties of lipid membranes. The following characteristics of the interaction of drugs with receptors illustrate some of the important determinants of the effects of drugs:

- *Affinity* describes the propensity for a drug to bind to a receptor and is related to the 'molecular fit' and the strength of the chemical bond. Some drug–receptor interactions are *irreversible*, either because the affinity is so strong or because the drug modifies the structure of its molecular target.
- *Selectivity* describes the propensity for a drug to bind to one target rather than another. Selectivity is a relative term, not to be confused with absolute specificity. It is common for drugs targeted at a particular subtype of receptor to exhibit some effect at other subtypes. For example, β-adrenoceptors can be subtyped on the basis of their responsiveness to the endogenous agonist noradrenaline (norepinephrine): the concentration of noradrenaline required to cause bronchodilatation (via β_2-adrenoceptors) is 10 times higher than that required to cause tachycardia (via β_1-adrenoceptors). Cardioselective β-adrenoceptor antagonists (β-blockers) have anti-anginal effects on the heart (β_1), but may still cause bronchospasm in the lung (β_2) and are contraindicated for asthmatic patients.
- *Agonists* bind to a receptor to produce a conformational change that is coupled to a biological response. As agonist concentration increases, so does the proportion of receptors occupied and hence the biological effect. *Partial agonists* activate the receptor, but cannot produce a maximal signalling effect equivalent to that of a full agonist even when all available receptors are occupied.
- *Antagonists* bind to a receptor, but do not produce the conformational change that initiates an intracellular signal. A *competitive antagonist* competes with endogenous agonist ligands to occupy receptor-binding sites, with the resulting antagonism depending on the relative affinities and concentrations of the antagonist drug and endogenous agonist. *Non-competitive antagonists* inhibit the effect of an agonist by mechanisms other than direct competition for receptor binding with the agonist, such as by affecting downstream signalling pathways.

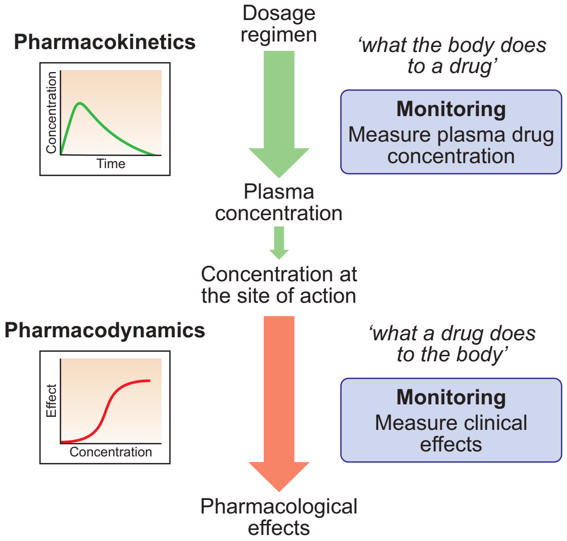

Fig. 2.1 Pharmacokinetics and pharmacodynamics.

Dose–response relationships

Plotting the logarithm of drug dose against drug response typically produces a sigmoidal dose–response curve (Fig. 2.2). Progressive increases in drug dose (which, for most drugs, is proportional to the plasma drug concentration) produce increasing response, but only within a relatively narrow range of dose; further increases in dose beyond this range produce little extra effect. The following characteristics of the drug response are useful in comparing different drugs:

- *Efficacy* describes the extent to which a drug can produce a target-specific response when all available receptors or binding sites are occupied (E_{max} on the dose–response curve). A full agonist can produce the maximum response of which the receptor is capable, while a partial agonist at the same receptor will have lower efficacy. *Therapeutic efficacy* describes the effect of the drug on a desired biological endpoint and can be used to compare drugs that act via different pharmacological mechanisms. For example, loop diuretics have greater therapeutic efficacy than thiazide diuretics.

2.2 Examples of target molecules for drugs

Drug target	Description	Examples
Receptors		
Channel-linked receptors	Ligand binding controls a linked ion channel that is described as ligand-gated	Nicotinic acetylcholine receptor GABA receptor Sulfonylurea receptor
G-protein-coupled receptors (GPCRs)	Ligand binding affects one of a family of 'G-proteins' that mediate signal transduction either by activating intracellular enzymes (such as adenylate or guanylate cyclase, producing cyclic AMP or GMP, respectively) or by controlling ion channels	Muscarinic acetylcholine receptor β-adrenoceptors Dopamine receptors 5-Hydroxytryptamine (5-HT, serotonin) receptors Opioid receptors
Kinase-linked receptors	Ligand binding activates an intracellular protein kinase that triggers a cascade of phosphorylation reactions	Insulin receptor Cytokine receptors Growth factor receptors
Transcription factor receptors	Also known as nuclear receptors, these are intracellular. Ligand binding promotes or inhibits gene transcription and synthesis of new proteins	Steroid receptors Thyroid hormone receptors Vitamin D receptors Retinoid receptors PPARγ and α receptors
Other targets		
Voltage-gated ion channels	Mediate electrical signalling in excitable tissues such as muscle and nerve	Na^+ channels Ca^{2+} channels
Enzymes	Catalyse biochemical reactions. Drugs interfere with binding of substrate to the active site or of co-factors to the enzyme	Cyclo-oxygenase ACE Xanthine oxidase
Transporter proteins	Carry ions or molecules across cell membranes	5-HT re-uptake transporter Sodium-glucose co-transporter 2 (SGLT2) Na^+/K^+ ATPase
Cytokines and other signalling molecules	Small proteins that are important in cell signalling (autocrine, paracrine and endocrine), especially affecting the immune response	Tumour necrosis factors Interleukins
Cell surface antigens	Block the recognition of cell surface molecules that modulate cellular responses	Cluster of differentiation molecules (e.g. CD20, CD80)

(ACE = angiotensin-converting enzyme; AMP = adenosine monophosphate; ATPase = adenosine triphosphatase; GABA = γ-aminobutyric acid; GMP = guanosine monophosphate; PPAR = peroxisome proliferator-activated receptor; 5-HT = 5-hydroxytryptamine)

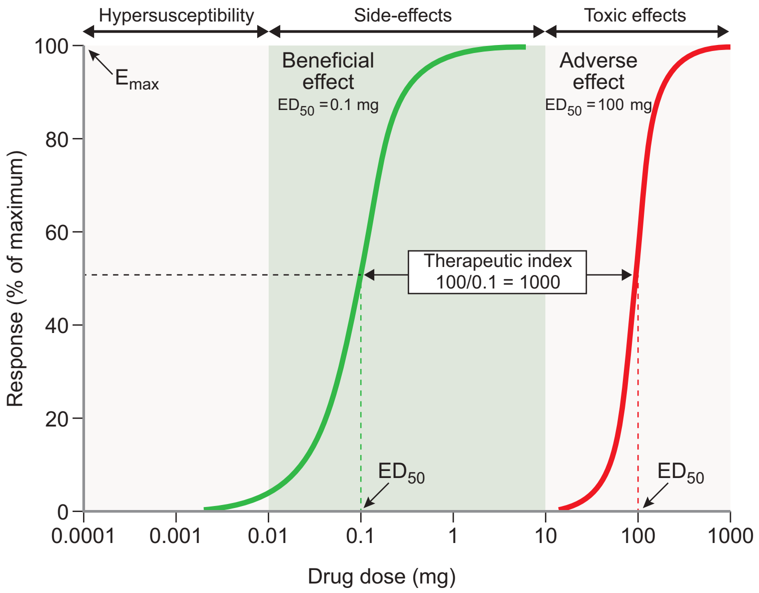

Fig. 2.2 Dose–response curve. The green curve represents the beneficial effect of the drug. The maximum response on the curve is the E_{max} and the dose (or concentration) producing half this value ($E_{max}/2$) is the ED_{50} (or EC_{50}). The red curve illustrates the dose–response relationship for the most important adverse effect of this drug. This occurs at much higher doses; the ratio between the ED_{50} for the adverse effect and that for the beneficial effect is the 'therapeutic index', which indicates how much margin there is for prescribers when choosing a dose that will provide beneficial effects without also causing this adverse effect. Adverse effects that occur at doses above the therapeutic range are normally called 'toxic effects', while those occurring within the therapeutic range are 'side-effects' and those below it are 'hyper-susceptibility effects'.

- *Potency* describes the amount of drug required for a given response. More potent drugs produce biological effects at lower doses, so they have a lower ED_{50}. A less potent drug can still have an equivalent or greater efficacy than drugs in the same class if it is given in higher doses.

The dose–response relationship for a specific drug varies between patients because of variations in the many determinants of pharmacokinetics and pharmacodynamics. In clinical practice, the prescriber is unable to construct a dose–response curve for each individual patient. Therefore, most drugs are licensed for use within a recommended range of doses that is expected to reach close to the top of the dose–response curve for most patients. However, it is sometimes possible to achieve the desired therapeutic efficacy at doses towards the lower end of, or even below, the recommended range. This curve explains why increasing the dosage of a drug may not result in a greater pharmacological response.

Therapeutic index

The adverse effects of drugs are often dose-related in a similar way to the beneficial effects, although the dose–response curve for these adverse effects is normally shifted to the right (see Fig. 2.2). The ratio of the ED_{50} for therapeutic efficacy and for a major adverse effect is known as the 'therapeutic index'. In reality, drugs have multiple potential adverse effects, but the concept of therapeutic index is usually based on adverse effects that might require dose reduction or discontinuation. For most drugs, the therapeutic index is greater than 100, but there are some notable exceptions, such as digoxin, warfarin, insulin, phenytoin and opioids, with therapeutic indices of less than 10. The doses of such drugs have to be titrated carefully for individual patients to maximise benefits, but avoid adverse effects.

Desensitisation and withdrawal effects

Desensitisation refers to the common situation in which the biological response to a drug diminishes when it is given continuously or repeatedly. It may be possible to restore the response by increasing the dose of the drug but, in some cases, the tissues may become completely refractory to its effect.

- *Tachyphylaxis* describes desensitisation that occurs very rapidly, sometimes with the initial dose. This rapid loss of response implies depletion of chemicals that may be necessary for the pharmacological actions of the drug, such as release of stored neurotransmitter released from nerve terminals or receptor phosphorylation.
- *Tolerance* describes a more gradual loss of response to a drug that occurs over days or weeks. This slower change implies changes in receptor numbers or the development of counter-regulatory physiological changes that offset the actions of the drug. An example is accumulation of salt and water in response to vasodilator therapy.
- *Drug resistance* is a term normally reserved for describing the loss of effectiveness of an antimicrobial agent or chemotherapeutic agent used in cancer.

In addition to these pharmacodynamic causes of desensitisation, reduced response may be the consequence of lower plasma and tissue drug concentrations as a result of altered *pharmacokinetics* (see below).

When drugs induce chemical, hormonal and physiological changes that offset their actions, discontinuation may allow these changes to cause rebound withdrawal effects (Box 2.3).

Pharmacokinetics

Understanding what the body does to the drug (Fig. 2.3) is extremely important for prescribers because this forms the basis on which the optimal route of administration and dose regimen are chosen and explains the majority of inter-individual variation in the response to drug therapy.

Drug absorption and routes of administration

Absorption is the process by which drug molecules gain access to the blood stream. The rate and extent of drug absorption depend on the route of administration (see Fig. 2.3).

Enteral administration

These routes involve administration via the gastrointestinal tract:

- *Oral*. This is the most common route of administration because it is simple, convenient and readily used by patients to self-administer their medicines. Absorption after an oral dose is a complex process that depends on the drug being swallowed, surviving exposure to gastric acid, binding to food, being absorbed by the small bowel into the portal venous system, and surviving metabolism by gut wall or liver enzymes (first-pass metabolism). As a consequence of all of these factors, absorption is often incomplete following oral administration. The term bioavailability is used to describe the proportion of the dose that reaches the systemic circulation intact.
- *Buccal and sublingual (SL)*. These routes have the advantage of enabling rapid absorption into the systemic circulation without the uncertainties associated with oral administration.

2.3 Examples of drugs associated with withdrawal effects

Drug	Symptoms	Signs	Treatment
Alcohol	Anxiety, panic, paranoid delusions, visual and auditory hallucinations	Agitation, restlessness, delirium, tremor, tachycardia, ataxia, disorientation, seizures	Treat immediate withdrawal syndrome with benzodiazepines
Barbiturates, benzodiazepines	Similar to alcohol	Similar to alcohol	Transfer to long-acting benzodiazepine then gradually reduce dosage
Glucocorticoids	Weakness, fatigue, decreased appetite, weight loss, nausea, vomiting, diarrhoea, abdominal pain	Hypotension, hypoglycaemia	Prolonged therapy suppresses the hypothalamic–pituitary–adrenal axis and causes adrenal insufficiency requiring glucocorticoid replacement. Withdrawal should be gradual after prolonged therapy (p. 725)
Opioids	Rhinorrhoea, sneezing, yawning, lacrimation, abdominal and leg cramping, nausea, vomiting, diarrhoea	Dilated pupils	Transfer addicts to long-acting agonist methadone
Selective serotonin re-uptake inhibitors (SSRIs)	Dizziness, sweating, nausea, insomnia, tremor, delirium, nightmares	Tremor	Reduce SSRIs slowly to avoid withdrawal effects

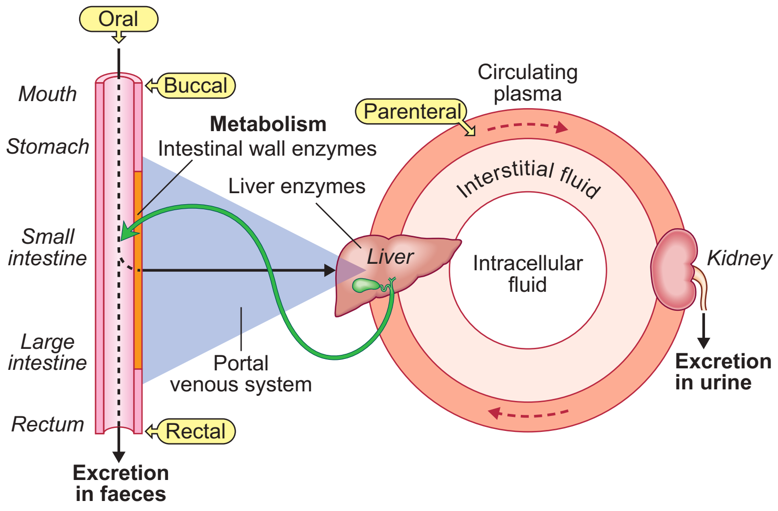

Fig. 2.3 Pharmacokinetics summary. Most drugs are taken orally, are absorbed from the intestinal lumen and enter the portal venous system to be conveyed to the liver, where they may be subject to first-pass metabolism and/or excretion in bile. Active drugs then enter the systemic circulation, from which they may diffuse (or sometimes be actively transported) in and out of the interstitial and intracellular fluid compartments. Drug that remains in circulating plasma is subject to liver metabolism and renal excretion. Drug excreted in bile may be reabsorbed, creating an enterohepatic circulation. First-pass metabolism in the liver is avoided if drugs are administered via the buccal or rectal mucosa, or parenterally by subcutaneous, intramuscular or intravenous injection.

- *Rectal (PR)*. The rectal mucosa is occasionally used as a site of drug administration when the oral route is compromised because of nausea and vomiting or unconsciousness.

Parenteral administration

These routes avoid absorption via the gastrointestinal tract and first-pass metabolism in the liver:

- *Intravenous (IV)*. The IV route enables all of a dose to enter the systemic circulation reliably, without any concerns about absorption or first-pass metabolism, and rapidly achieve a high plasma concentration. It is ideal for very ill patients when a rapid, certain effect is critical to outcome.
- *Intramuscular (IM)*. IM administration is easier to achieve than the IV route, but absorption is less predictable and depends on muscle blood flow.
- *Subcutaneous (SC)*. The SC route is ideal for drugs that have to be administered parenterally because of low oral bioavailability, are absorbed well from subcutaneous fat and can ideally be injected by patients themselves.
- *Transdermal*. A transdermal patch can enable a drug to be absorbed through the skin and into the circulation.
- *Nasal*. The nasal mucosa provides another potential route for absorption of some drugs with systemic action.

Other routes of administration

- *Topical* application of a drug involves direct administration to the site of action, such as the skin, eye or ear. This has the advantage of achieving sufficient concentration at this site while minimising systemic exposure and adverse effects.
- *Inhaled (INH)* administration allows drugs to be delivered directly to a target in the respiratory tree, usually the small airways. However, a significant proportion of the inhaled dose may be absorbed from the lung or is swallowed and can reach the systemic circulation. The most common mode of delivery is the metered-dose inhaler, but its success depends on some degree of manual dexterity and timing (see Fig. 17.23). Patients who find these difficult may use a spacer device to improve drug delivery. A special mode of inhaled delivery is through use of a nebulised solution created by using pressurised oxygen or air to break up solutions and suspensions into small aerosol droplets that can be directly inhaled from the mouthpiece of the device.

Drug distribution

Distribution is the process by which drug molecules transfer between the circulating blood, interstitial space and intracellular fluid. This is influenced by the drug's molecular size and lipid solubility, the extent to which it binds to proteins in plasma, its susceptibility to drug transporters expressed on cell surfaces and its binding to its molecular target and to other cellular proteins (which can be irreversible). Most drugs diffuse passively across capillary walls down a concentration gradient into the interstitial fluid until the concentration of free drug molecules in the interstitial fluid is equal to that in the plasma. As drug in the blood is removed by metabolism or excretion, the plasma concentration falls, leading to diffusion of drug from the tissue compartment into the blood until eventually all of the drug is eliminated. Note that this reverse movement of drug from the tissues to the blood will be prevented if further drug doses are administered and absorbed into the plasma.

Volume of distribution

The apparent volume of distribution (V_d) is the volume into which a drug appears to have distributed following intravenous injection. It is calculated from the equation

$$LR = \frac{\text{probability of finding in patients with disease}}{}$$

where D is the amount of drug given and C_0 is the initial plasma concentration (Fig. 2.4A). Drugs that are highly bound to plasma proteins, such as warfarin, have a V_d below 10 L while those that diffuse into the interstitial fluid but do not enter cells because they have low lipid solubility, such as gentamycin, have a V_d between 10 and 30 L. Drugs that are lipid-soluble and highly tissue-bound, such as digoxin, may have a V_d of greater than 100 L. Drugs with a large V_d have longer half-lives (see below), take longer to reach steady state on repeated administration and are eliminated more slowly from the body following discontinuation.

Drug elimination

Drug metabolism

Metabolism is the process by which drugs are chemically altered from a lipid-soluble form suitable for absorption and distribution to a more water-soluble form that is necessary for excretion. Some drugs, like enalapril and clopidogrel, are inactive when they are administered (prodrugs), but are converted to an active metabolite in vivo.

Phase I metabolism involves oxidation, reduction or hydrolysis to make drug molecules suitable for phase II reactions or for excretion. Oxidation is by far the most common form of phase I reaction and chiefly involves members of the cytochrome P450 family of membrane-bound enzymes in the endoplasmic reticulum of hepatocytes.

Phase II metabolism involves combining phase I metabolites with an endogenous substrate to form an inactive conjugate that is much more water-soluble. Reactions include glucuronidation, sulfation, acetylation, methylation and conjugation with glutathione. This is necessary to enable

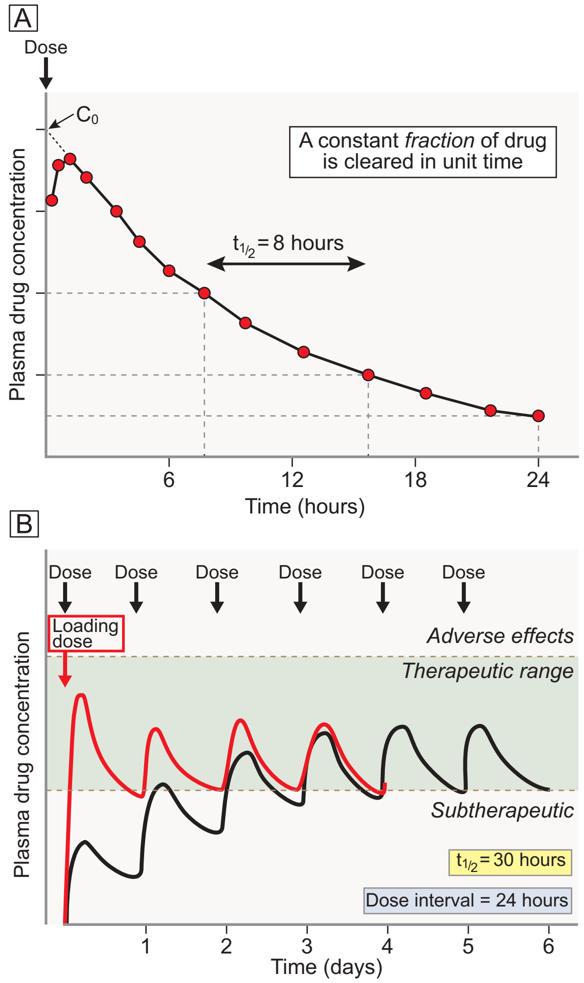

Fig. 2.4 Drug concentrations in plasma following single and multiple drug dosing. **A** In this example of first-order kinetics following a single intravenous dose, the time period required for the plasma drug concentration to reduce by 50% (half-life, $t_{1/2}$) remains constant throughout the elimination process. **B** After multiple dosing, the plasma drug concentration rises if each dose is administered before the previous dose has been entirely cleared. In this example, the drug's half-life is 30 hours, so that with daily dosing, the peak, average and trough concentrations steadily increase as drug accumulates in the body (black line). Steady state is reached after approximately 5 half-lives, when the rate of elimination (the product of concentration and clearance) is equal to the rate of drug absorption (the product of rate of administration and bioavailability). The long half-life in this example means that it takes 6 days for steady state to be achieved and, for most of the first 3 days of treatment, plasma drug concentrations are below the therapeutic range. This problem can be overcome if a larger loading dose (red line) is used to achieve steady-state drug concentrations more rapidly.

renal excretion, because lipid-soluble metabolites will simply diffuse back into the body after glomerular filtration.

Drug excretion

Excretion is the process by which drugs and their metabolites are removed from the body.

Renal excretion is the usual route of elimination for drugs or their metabolites that are of low molecular weight and sufficiently water-soluble to avoid reabsorption from the renal tubule. Drugs bound to plasma proteins are not filtered by the glomeruli. The pH of the urine is more acidic than that of plasma, so that weakly acidic drugs like salicylates are un-ionised in the urine and tend to be reabsorbed. Alkalinisation of the urine can hasten excretion of drugs like aspirin and may be used clinically after an overdose. For some drugs, active secretion into the proximal tubule lumen, rather than glomerular filtration, is the predominant mechanism of excretion.

Faecal excretion is the predominant route of elimination for drugs with high molecular weight, including those that are excreted in the bile after conjugation with glucuronide in the liver and any drugs that are not absorbed after enteral administration. Drugs and their metabolites that are excreted in the bile enter the small intestine where they may be reabsorbed through the gut wall and return to the liver via the portal vein if they are sufficiently lipid-soluble (see Fig. 2.3). This recycling between the liver, bile, gut and portal vein is known as the enterohepatic circulation and can significantly prolong the residence of drugs like digoxin and morphine in the body.

Elimination kinetics

The net removal of drug from the circulation results from a combination of drug metabolism and excretion and is usually described as clearance, which is defined as the volume of plasma that is completely cleared of drug per unit time.

For most drugs, elimination is a high-capacity process that does not become saturated, even at high dosage. The rate of elimination is directly proportional to the drug concentration because of the law of mass action, whereby higher drug concentrations will drive faster metabolic reactions and support higher renal filtration rates. This is called first-order kinetics, when a constant fraction of the drug remaining in the circulation is eliminated in a given time and the decline in concentration over time is exponential (see Fig. 2.4A). This elimination can be described by the drug's half-life ($t_{1/2}$), which is the time taken for the plasma drug concentration to reduce by 50%. This remains constant throughout the period of drug elimination. The significance of this phenomenon for prescribers is that the effect of increasing doses on plasma concentration is predictable – a doubled dose leads to a doubled concentration at all time points.

For a few drugs in common use, like phenytoin, elimination capacity is exceeded (saturated) within the usual dose range. This is called zero-order kinetics. The significance for prescribers is that, if the rate of administration exceeds the maximum rate of elimination, the drug will accumulate progressively, leading to serious toxicity.

Repeated dose regimens

The goal of therapy is usually to maintain drug concentrations within the therapeutic range (see Fig. 2.2) over several days, months or years. This goal is rarely achieved with single doses, so prescribers have to plan a regimen of repeated doses. This involves choosing the size of each individual dose and the frequency of dose administration.

As illustrated in Figure 2.4B, the time taken to reach drug concentrations within the therapeutic range depends on the half-life of the drug. Typically, with doses administered regularly, it takes approximately 5 half-lives to reach a steady state in which the rate of drug elimination is equal to the rate of drug administration. This applies when starting new drugs and when adjusting doses of current drugs. With appropriate dose selection, steady-state drug concentrations will be maintained within the therapeutic range. This is important for prescribers because it means that the effects of a new prescription, or dose titration, for a drug with a long half-life may not be known for a few days. In contrast, drugs with a very short half-life have to be given continuously by infusion, but reach a new steady state within minutes.

For drugs with a long half-life, it is generally unacceptable to wait for several days until concentrations within the therapeutic range are achieved. In these circumstances, an initial loading dose can be given that is much larger than the maintenance dose and equivalent to the amount of drug required in the body at steady state. This achieves a peak plasma concentration close to the plateau concentration, which can then be maintained by successive maintenance doses.

In practice, fluctuations in drug concentrations are seen at steady state with peaks just after administration of the dose followed by troughs just prior to the next administration. What is important is that the recommended dosing regimens result in oscillations that are within the therapeutic range in most patients with peaks that are not high enough to cause adverse effects. The optimal dose interval is a compromise between convenience for the patient and a constant level of drug exposure. More frequent administration achieves a smoother plasma concentration profile than daily administration but is much more difficult for patients to sustain. A solution that enables less frequent administration for drugs with short half-lives is the use of modified-release (m/r) formulations, which allows drugs to be absorbed more slowly from the gastrointestinal tract and reduces the oscillation in plasma drug concentration profile. This is especially valuable for drugs with a narrow therapeutic index.

Inter-individual variation in drug responses

Prescribers have numerous sources of guidance about how to use drugs for many conditions. However, this advice is based on average dose–response data derived from observations in many individuals. When applying this information to an individual patient, prescribers must take account of inter-individual variability in response. Some of this variability is predictable and good prescribers are able to anticipate it and adjust their prescriptions accordingly to maximise the chances of benefit and minimise harm. Inter-individual variation in responses also mandates that effects of some treatment should be monitored (p. 32).

Some inter-individual variation in drug response is accounted for by differences in pharmacodynamics. For example, the beneficial natriuresis produced by the loop diuretic furosemide is often significantly reduced in patients with renal impairment, while delirium caused by opioid analgesics is more likely in the elderly. However, it is differences in pharmacokinetics that more commonly account for different drug responses. Examples of factors influencing the absorption, metabolism and excretion of drugs are shown in Box 2.4.

A significant proportion of the inter-individual variation in drug responses can be explained by studying genetic differences between individuals. The term pharmacogenetics is used to describe the effect of single gene variants on drug responses, whereas the term pharmacogenomics is used to describe the effects of multiple gene variants on drug responses. The aim is to identify patients most likely to benefit from specific treatments and those most susceptible to adverse effects and to promote personalised medicine. Important examples of pharmacogenetic variations that influence drug responses are shown in Box 2.5.

Adverse outcomes of drug therapy

The decision to prescribe a drug always involves a judgement of the balance between therapeutic benefits and risk of an adverse outcome. Both prescribers and patients tend to be more focused on the former, but a truly informed decision requires consideration of both.

Adverse drug reactions

Some important definitions for the adverse effects of drugs are:

- *Adverse event*. A harmful event that occurs while a patient is taking a drug, irrespective of whether the drug is suspected of being the cause.
- *Adverse drug reaction (ADR)*. An unwanted or harmful reaction that is experienced following the administration of a drug or combination of drugs under normal conditions of use and is suspected to be related to the drug. An ADR will usually require the drug to be discontinued or the dose reduced.
- *Side-effect*. This term refers to any effect caused by a drug other than the intended therapeutic effect, whether beneficial, neutral or harmful. The term 'side-effect' is often used in preference to ADR to describe the situation where the unwanted effect occurs as the result of the drug's mechanism of action and when the concentrations of the drug are in the normal therapeutic range. A common example is vasodilator-induced ankle oedema.
- *Hypersensitivity reaction*. This ADR occurs as a result of an immunological reaction, often after exposure to subtherapeutic drug concentrations. These include: (1) acute anaphylaxis (Ch. 4) – which is the result of an interaction between drug antigens and immunoglobulin E (IgE) on mast cells and basophils, resulting in a release of vasoactive biomolecules; this is also known as a type I hypersensitivity reaction. (2) 'Anaphylactoid' reactions – these present in a similar manner to acute anaphylaxis, but are a consequence of non-IgE-mediated degranulation of mast cells and basophils or direct complement activation. Commonly implicated drugs

2.4 Patient-specific factors that influence pharmacokinetics

Age

- Drug metabolism is low in the fetus and newborn, may be enhanced in young children and becomes less effective with age
- Drug excretion falls with the age-related decline in renal function

Sex

- Women have a greater proportion of body fat than men, increasing the volume of distribution and half-life of lipid-soluble drugs

Body weight

- Obesity increases volume of distribution and half-life of lipid-soluble drugs
- Patients with higher lean body mass have larger body compartments into which drugs are distributed and may require higher doses

Liver function

- Metabolism of most drugs depends on several cytochrome P450 enzymes that are impaired in patients with advanced liver disease
- Hypoalbuminaemia influences the distribution of drugs that are highly protein-bound

Kidney function

- Renal disease and the decline in renal function with ageing may lead to drug accumulation

Gastrointestinal function

- Small intestinal absorption of oral drugs may be delayed by reduced gastric motility
- Absorptive capacity of the intestinal mucosa may be reduced in diseases like Crohn or coeliac disease or after surgical resection

Food

- Food in the stomach delays gastric emptying and reduces the rate (but not usually the extent) of drug absorption
- Some food constituents bind to certain drugs and prevent their absorption

Smoking

- Tar in tobacco smoke stimulates the oxidation of certain drugs

Alcohol

- Regular alcohol consumption stimulates liver enzyme synthesis, while binge drinking may temporarily inhibit drug metabolism

Drugs

- Drug–drug interactions cause marked variation in pharmacokinetics (see Box 2.12)

2.5 Examples of pharmacogenetic variations that influence drug response

Genetic variant	Drug affected	Clinical outcome
Pharmacokinetic		
Aldehyde dehydrogenase-2 deficiency	Ethanol	Elevated blood acetaldehyde causes facial flushing and increased heart rate in ~50% of Japanese, Chinese and other Asian populations
Acetylation	Isoniazid, hydralazine, procainamide	Increased responses in slow acetylators, up to 50% of some populations
Oxidation (CYP2D6)	Nortriptyline Codeine	Increased risk of toxicity in poor metabolisers Reduced responses with slower conversion of codeine to more active morphine in poor metabolisers, in 10% of European populations Increased risk of toxicity in ultra-fast metabolisers, in 3% of Europeans but 25% of North Africans
Oxidation (CYP2C9)	Warfarin	The genetic variants *CYP2C9*2* and **3* are associated with lower dose requirements
Oxidation (CYP2C19)	Clopidogrel Proguanil	Reduced enzymatic activation results in reduced antiplatelet effect Reduced efficacy with slower conversion to active cycloguanil in poor metabolisers
Sulphoxidation	Penicillamine	Increased risk of toxicity in poor metabolisers
Pseudocholinesterase deficiency	Suxamethonium (succinylcholine)	Decreased drug inactivation leads to prolonged paralysis and sometimes persistent apnoea requiring mechanical ventilation until the drug can be eliminated by alternate pathways; occurs in 1 in 1500 people
Pharmacodynamic		
Glucose-6-phosphate dehydrogenase (G6PD) deficiency	Oxidant drugs, including the antimalarials chloroquine and primaquine	Risk of haemolysis in G6PD deficiency
Acute intermittent porphyria	Enzyme-inducing drugs	Increased risk of an acute attack
SLC01B1 polymorphism	Statins	Increased risk of rhabdomyolysis
HLA-B*5701 polymorphism	Abacavir	Increased risk of skin hypersensitivity reaction
HLA-B*5801 polymorphism	Allopurinol	Increased risk of rashes in Han Chinese
HLA-B*1502 polymorphism	Carbamazepine	Increased risk of serious dermatological reactions like Stevens–Johnson syndrome
Hepatic nuclear factor 1 alpha (HNF1A) polymorphism	Sulphonylureas	Increased sensitivity to the blood glucose-lowering effects
Human epidermal growth factor receptor 2 (HER2)-positive breast cancer cells	Trastuzumab	Increased sensitivity to the inhibitory effects on growth and division of the target cancer cells
Ryanodine (RYR1) receptor gene mutations	Halothane, enflurane, suxamethonium (succinylcholine)	Provokes fast and uncontrolled calcium increase from skeletal muscle cells causing malignant hyperthermia

are aspirin, non-steroidal anti-inflammatory drugs, and opioids). (3) Types II–IV hypersensitivity reactions – these occur via other mechanisms, such as antibody-dependent (IgM or IgG), immune complex-mediated or cell-mediated pathways. Examples of such reactions are listed in Box 2.6.

- *Drug toxicity*. Adverse effects of a drug that occur because the dose or plasma concentration has risen above the therapeutic range, either unintentionally or intentionally (drug overdose; see Fig. 2.2).
- *Drug misuse*. The misuse of recreational or therapeutic drugs that may lead to addiction or dependence, serious physiological injury (such as liver damage), psychological harm (abnormal behaviour patterns, hallucinations, memory loss) or death (Ch. 29).

Prevalence of Adverse Drug Reactions

Adverse drug reactions are a common cause of illness, accounting in the UK for approximately 3% of consultations in primary care, 7% of emergency admissions to hospital and affecting around 15% of hospital inpatients. Many 'disease' presentations are eventually attributed to ADRs, emphasising the importance of always taking a careful drug history (Box 2.7). Factors accounting for the rising prevalence of ADRs are the increasing age of patients, polypharmacy (higher risk of drug interactions), increasing availability of over-the-counter medicines, increasing use of herbal or traditional medicines and the increase in medicines available via the Internet that can be purchased without a prescription from a health-care professional. Risk factors for ADRs are shown in Box 2.8. These reactions are important because they reduce quality of life for patients, reduce adherence to, and efficacy of, beneficial treatments, cause diagnostic confusion, undermine the confidence of patients in their health-care professional(s) and consume health-care resources.

Retrospective analysis of ADRs has shown that more than half could have been avoided if the prescriber had taken more care in anticipating the potential hazards of drug therapy. For example, non-steroidal anti-inflammatory drug (NSAID) use accounts for many thousands of emergency admissions, gastrointestinal bleeding episodes and a significant number of deaths. In many cases, the patients are at increased risk due to their age, interacting drugs or a past history of peptic ulcer disease. Drugs that commonly cause ADRs are listed in Box 2.9.

Prescribers and their patients ideally want to know the frequency with which ADRs occur for a specific drug. Although this may be well characterised for more common ADRs observed in clinical trials, it is less clear for rarely reported ADRs when the total numbers of reactions and patients exposed are not known. The words used to describe frequency can be misinterpreted by patients, but widely accepted meanings include: very common (10% or more), common (1%–10%), uncommon (0.1%–1%), rare (0.01%–0.1%) and very rare (0.01% or less).

2.6 Examples of drug-mediated types I–IV hypersensitivity reactions[1]

Type I (mediated by IgE antibodies and mast cell degranulation)

Acute anaphylaxis

- Penicillins
- Chemotherapy
- Monoclonal antibodies
- Neuromuscular blocking drugs

Type II (mediated by IgM and IgG antibodies)

Haemolytic anaemia (latency less than 7 days)

- Methyldopa
- Penicillins
- Cephalosporins
- NSAIDs
- Quinidine/quinine
- Neutropenia/agranulocytosis (latency days to weeks)
- Anti-arrhythmics
- Antibiotics
- NSAIDs
- Antimalarials
- Antithyroid drugs
- Clozapine
- Ticlopidine
- Thrombocytopenia (latency 1–2 weeks)
- Carbamazepine
- Heparin
- Penicillins
- Cephalosporins
- NSAIDs
- Quinidine/quinine
- Thiazide diuretics

Type III (mediated by immune complex deposition)

Glomerulonephritis, serum sickness and vasculitis

- Penicillins
- Cephalosporins
- Sulphonamides

Type IV (mediated by T cells)

Skin eruptions, including maculopapular rash, lichenoid or pemphigoid-like reaction, drug rash with eosinophilia and systemic symptoms (DRESS), Stevens–Johnson syndrome (SJS), toxic epidermal necrolysis (TEN)[2]

- Carbamazepine
- Abacavir
- Trimethoprim
- Dapsone
- Drug-induced lupus
- Allopurinol
- Thiazide diuretics
- Hydralazine

[1] Type I is often known as 'immediate' hypersensitivity while types II–IV are known as 'delayed' hypersensitivity.
[2] See also Boxes 26.33 and 26.34.

2.7 How to take a drug history

Information from the patient (or carer)

Use language that patients will understand. Use 'medicines' rather than 'drugs', which may be mistaken for drugs of abuse, while gathering the following information:

- Ask about currently prescribed drugs, including formulations, doses, routes of administration, frequency and timing, duration of treatment.
- Ask about contraceptives, over-the-counter drugs, herbal remedies, and vitamins.
- Ask about drugs that have been taken in the recent past and reasons for stopping them.
- Ask about previous drug hypersensitivity reactions, their nature and time course.
- Ask about previous ADRs, their nature and time course.
- Assess adherence to therapy by asking if the patient is taking their medicine regularly.

Information from GP medical records and/or pharmacist

- Up-to-date list of medications
- Previous ADRs
- Last order dates for each medication

Inspection of medicines

- Drugs and their containers (e.g. blister packs, bottles, vials) should be inspected for name, dosage and the number of dosage forms taken since dispensed.

(ADR = adverse drug reaction)

2.8 Risk factors for adverse drug reactions

Patient factors

- Advanced age
- Sex
- Polypharmacy
- Genetic predisposition (see Box 2.5)
- Hypersensitivity/allergy
- Diseases altering pharmacokinetics (hepatic or renal impairment) or pharmacodynamic responses (bladder instability)
- Adherence problems associated with cognitive impairment

Drug factors

- Steep dose–response curve
- Low therapeutic index

Prescriber factors

- Inadequate understanding of the principles of clinical pharmacology
- Inadequate knowledge of the patient
- Inadequate knowledge of the prescribed drug
- Inadequate instructions and warnings provided to patients
- Inadequate monitoring arrangements planned

Classification of ADRs

ADRs have traditionally been classified into two major groups:

- *Type A (augmented) ADRs*. These are predictable from the known pharmacodynamic effects of the drug and are dose-dependent, common (detected early in drug development) and usually mild. Examples include constipation caused by opioids, hypotension caused by antihypertensives and dehydration caused by diuretics.
- *Type B (bizarre) ADRs*. These are not predictable, are not obviously dose-dependent in the therapeutic range, are rare (remaining undiscovered until the drug is marketed) and often severe. Patients who experience type B reactions are generally hyper-susceptible because of unpredictable immunological or genetic factors. Examples include anaphylaxis caused by penicillin, and peripheral neuropathy caused by isoniazid in poor acetylators.

This simple classification has shortcomings, and a more detailed classification based on Dose (see Fig. 2.2), Timing and Susceptibility (DoTS) is now used by those analysing ADRs in greater depth (Box 2.10). The AB classification can be extended as a reminder of some other types of ADR:

- *Type C (chronic/continuous) ADRs*. These occur only after prolonged continuous exposure to a drug. Examples include osteoporosis caused by glucocorticoids, retinopathy caused by hydroxychloroquine and tardive dyskinesia caused by phenothiazines.
- *Type D (delayed) ADRs*. These are delayed until long after drug exposure, making diagnosis difficult. Examples include malignancies that may emerge after immunosuppressive treatment

2.9 Drugs that are common causes of adverse drug reactions

Drug or drug class	Common adverse drug reactions
ACE inhibitors	Renal impairment Hyperkalaemia
Antibiotics	Nausea Diarrhoea
Anticoagulants	Bleeding
Antipsychotics	Falls Sedation Delirium
Aspirin	Gastrotoxicity (dyspepsia, gastrointestinal bleeding)
Benzodiazepines	Drowsiness Falls
β-blockers	Cold peripheries Bradycardia
Calcium channel blockers	Ankle oedema
Digoxin	Nausea and anorexia Bradycardia
Diuretics	Dehydration Electrolyte disturbance (hypokalaemia, hyponatraemia) Hypotension Renal impairment
Insulin	Hypoglycaemia
NSAID	Gastrotoxicity (dyspepsia, gastrointestinal bleeding) Renal impairment
Opioid analgesics	Nausea and vomiting Delirium Constipation

(ACE = angiotensin-converting enzyme; NSAID = non-steroidal anti-inflammatory drug)

2.10 DoTS classification of adverse drug reactions

Category	Example
Dose	
Below therapeutic dose In the therapeutic dose range At high doses	Anaphylaxis with penicillin Nausea with morphine Hepatotoxicity with paracetamol
Timing	
With the first dose Early stages of treatment On stopping treatment Significantly delayed	Anaphylaxis with penicillin Hyponatraemia with diuretics Benzodiazepine withdrawal syndrome Clear-cell cancer with diethylstilbestrol
Susceptibility	See patient factors in Box 2.8

2.11 TREND analysis of suspected adverse drug reactions

Factor	Key question	Comment
*T*emporal relationship	What is the time interval between the start of drug therapy and the reaction?	Most ADRs occur soon after starting treatment and within hours in the case of anaphylactic reactions
*R*e-challenge	What happens when the patient is re-challenged with the drug?	Re-challenge is rarely possible because of the need to avoid exposing patients to unnecessary risk
*E*xclusion	Have concomitant drugs and other non-drug causes been excluded?	ADR is a diagnosis of exclusion following clinical assessment and relevant investigations for non-drug causes
*N*ovelty	Has the reaction been reported before?	The suspected ADR may already be recognised and mentioned in the SPC approved by the regulatory authorities
*D*e-challenge	Does the reaction improve when the drug is withdrawn or the dose is reduced?	Most, but not all, ADRs improve on drug withdrawal, although recovery may be slow

(ADR = adverse drug reaction; SPC = summary of product characteristics)

post-transplantation and vaginal cancer occurring many years after exposure to diethylstilbestrol.

- *Type E (end-of-treatment) ADRs*. These occur after abrupt drug withdrawal (see Box 2.3).

A special type of ADR is one which affects the development of the fetus. Drugs that cause these ADRs are referred to as teratogens and include valproate, isotretinoin and warfarin. The thalidomide disaster in the early 1960s highlighted the risk of teratogenicity and led to mandatory testing of all new drugs for teratogenicity. Congenital defects in a live infant or aborted fetus should provoke suspicion of an ADR and a careful exploration of maternal drug exposures (including self-medication and herbal remedies).

Detecting ADRs – pharmacovigilance

Type A ADRs become apparent early in the development of a new drug. By the time a new drug is licensed and launched on to a possible worldwide market, a relatively small number of patients (just several hundred) may have been exposed to it, meaning that rarer but potentially serious type B ADRs may remain undiscovered. Pharmacovigilance is the process of detecting less common ADRs so that prescribers and patients are better informed about the risks of drug therapy. Drug regulatory agencies may respond to this information by placing restrictions on the licensed indications, reducing the recommended dose range, adding special warnings and precautions for prescribers in the product literature, writing to all health-care professionals or withdrawing the product from the market.

Voluntary reporting systems allow health-care professionals and patients to report suspected ADRs to the regulatory authorities. A good example is the 'Yellow Card' scheme that was set up in the UK in response to the thalidomide tragedy. Reports are analysed to assess the likelihood that they represent a true ADR (Box 2.11). Although voluntary reporting is a continuously operating and effective early-warning system for previously unrecognised rare ADRs, its weaknesses include low reporting rates (only 3% of all ADRs and 10% of serious ADRs are ever reported), an inability to quantify risk (because the ratio of ADRs to prescriptions is unknown) and the influence of prescriber awareness on likelihood of reporting (reporting rates rise rapidly following publicity about potential ADRs).

More systematic approaches to collecting information on ADRs include prescription event monitoring, in which a sample of prescribers of a particular drug are issued with questionnaires concerning the clinical outcome for their patients, and the collection of population statistics. Many health-care systems routinely collect patient-identifiable data on prescriptions (a surrogate marker of exposure to a drug), health-care events (hospitalisation, operations, new clinical diagnoses) and other clinical data (haematology, biochemistry). If these records can be linked, with appropriate safeguards for confidentiality and data protection, they may provide a much more powerful mechanism than voluntary reporting for assessing both the harms and benefits of drugs.

All prescribers will inevitably see patients experiencing ADRs caused by prescriptions written by themselves or their colleagues. It is important that these are recognised early. In addition to the features in Box 2.11, features that should raise suspicion of an ADR and the need to respond (by drug withdrawal, dosage reduction or reporting to the regulatory authorities) include:

- concern expressed by a patient that a drug has harmed them
- abnormal clinical measurements (blood pressure, temperature, pulse, blood glucose and weight) or laboratory results (abnormal liver or renal function, low haemoglobin or white cell count) while on drug therapy
- new therapy started that could be in response to an ADR
- the presence of risk factors for ADRs (see Box 2.8).

Drug interactions

A drug interaction has occurred when the administration of one drug increases or decreases the beneficial or adverse responses to another drug. Although the number of potential interacting drug combinations is very large, only a small number are common in clinical practice. Important drug interactions are most likely to occur when the affected drug has a low therapeutic index, steep dose–response curve, high first-pass or saturable metabolism, or a single mechanism of elimination.

Mechanisms of drug interactions

Pharmacodynamic interactions occur when two drugs produce additive, synergistic or antagonistic effects at the same drug target or physiological system. These are the most common interactions in clinical practice and some important examples are given in Box 2.12.

Pharmacokinetic interactions occur when the administration of a second drug alters the concentration of the first at its site of action. There are numerous potential mechanisms:

- *Absorption interactions*. Drugs that either delay (anticholinergic drugs) or enhance (prokinetic drugs) gastric emptying influence the rate of rise in plasma concentration of other drugs, but not the total amount of drug absorbed. Drugs that bind to form insoluble complexes or chelates, such as aluminium-containing antacids binding with ciprofloxacin and calcium supplements binding with bisphosphonates, can reduce drug absorption.
- *Distribution interactions*. Co-administration of drugs that compete for protein binding in plasma can increase the unbound drug concentration, but the effect is usually short-lived due to increased elimination and hence restoration of the pre-interaction equilibrium.

2.12 Common drug interactions

Mechanism	Object drug	Precipitant drug	Result
Pharmaceutical*			
Chemical reaction	Sodium bicarbonate	Calcium gluconate	Precipitation of insoluble calcium carbonate
Pharmacokinetic			
Reduced absorption	Tetracyclines Bisphosphonates	Calcium, aluminium and magnesium salts	Reduced absorption
Reduced protein binding	Phenytoin	Aspirin	Increased unbound and reduced total phenytoin plasma concentration
Reduced metabolism:			
CYP3A4	Amiodarone	Grapefruit juice	Cardiac arrhythmias because of prolonged QT interval (p. 454)
	Warfarin	Clarithromycin	Enhanced anticoagulation
CYP2C19	Phenytoin	Miconazole	Phenytoin toxicity
CYP2D6	Tamoxifen	Fluoxetine	Reduced tamoxifen efficacy
Xanthine oxidase	Azathioprine	Allopurinol	Azathioprine toxicity
Monoamine oxidase	Catecholamines	Monoamine oxidase inhibitors	Hypertensive crisis due to monoamine toxicity
Increased metabolism (enzyme induction)	Ciclosporin	St John's wort	Loss of immunosuppression
Reduced renal elimination	Lithium	Diuretics	Lithium toxicity
	Methotrexate	NSAID	Methotrexate toxicity
Pharmacodynamic			
Direct antagonism at same receptor	Opioids	Naloxone	Reversal of opioid effects (used therapeutically)
	Salbutamol	Atenolol	Inhibits bronchodilator effect
Direct potentiation in same organ system	Benzodiazepines	Alcohol	Increased sedation
	ACE inhibitors	NSAIDs	Increased risk of renal impairment
Indirect potentiation by actions in different organ systems	Digoxin	Diuretics	Digoxin toxicity enhanced because of hypokalaemia
	Warfarin	Aspirin, NSAIDs	Increased risk of bleeding because of gastrotoxicity and antiplatelet effects
	Diuretics	ACE inhibitors	Blood pressure reduction (may be therapeutically advantageous) because of the increased activity of the renin–angiotensin system in response to diuresis

*Pharmaceutical interactions are related to the formulation of the drugs and occur before drug absorption.
(ACE = angiotensin-converting enzyme; CYP = cytochrome P450; NSAID = non-steroidal anti-inflammatory drug)

- *Metabolism interactions*. Many drugs rely on metabolism by different isoenzymes of cytochrome P450 (CYP) in the liver. CYP enzyme inducers like carbamazepine, ritonavir, and rifampicin generally reduce plasma concentrations of other drugs, although they may enhance activation of prodrugs. The opposite effects are seen with CYP enzyme inhibitors like clarithromycin and grapefruit juice. Enzyme induction effects usually take a few days to manifest because of the need to synthesise new CYP enzyme in contrast to the rapid effects of enzyme inhibition.
- *Excretion interactions*. These primarily affect renal excretion. For example, drug-induced reduction in glomerular filtration rate can reduce the clearance and increase the plasma concentration of many drugs, including some with a low therapeutic index. Less commonly, interactions may be due to competition for a common tubular organic anion transporter. An example of this is when methotrexate excretion is inhibited by competition with NSAIDs, which use the same transporter.

Avoiding drug interactions

Drug interactions are increasing as the result of polypharmacy. Prescribers can avoid the adverse consequences of drug–drug interactions by taking a careful drug history (see Box 2.7) before prescribing additional drugs, only prescribing for clear indications and taking special care when prescribing drugs with a narrow therapeutic index. When prescribing an interacting drug is unavoidable, good prescribers will seek further information and anticipate the potential risk. This will allow them to provide special warnings for the patient and arrange for monitoring, either of the clinical effects (for example coagulation tests for those on warfarin) or of plasma concentration of drugs like digoxin.

Medication errors

A medication error is any *preventable* event that may lead to inappropriate medication use or patient harm while the medication is in the control of the health-care professional or patient. Errors may occur in prescribing, dispensing, preparing solutions, administration or monitoring. Many ADRs are considered in retrospect to have been avoidable with more care or forethought; in other words, an adverse event considered by one prescriber to be an unfortunate ADR might be considered by another to be a prescribing error.

Medication errors are very common. Several thousand medication orders are dispensed and administered each day in a medium-sized hospital. Recent UK studies suggest that 7%–9% of hospital prescriptions contain an error, and most are written by junior doctors. Common prescribing errors in hospitals include omission of medicines (especially failure to prescribe regular medicines at the point of admission or discharge – so-called medicines reconciliation), dosing errors, unintentional prescribing and poor documentation (Box 2.13).

Most prescription errors result from a combination of failures by the individual prescriber and the health-service systems in which they work (Box 2.14). Health-care organisations increasingly encourage reporting of errors within a no-blame culture so that they can be subject to root cause analysis using human error theory (Fig. 2.5). Prevention is targeted at the factors in Box 2.14 and can be supported by prescribers communicating and cross-checking with colleagues. Examples are when calculating doses adjusted for body weight, or planning monitoring after drug administration. Prescription errors may also be reduced by clinical pharmacist support to check the patient's previous medications and current prescriptions and electronic prescribing. This can help avoid errors due to illegible writing and serious dosing mistakes. It can also be combined with a clinical decision support system to take account of patient characteristics and drug history, and provide warnings of potential contraindications and drug interactions.

2.13 Hospital prescribing errors

Error type	Approximate % of total
Omission on admission	30
Underdose	11
Overdose	8
Strength/dose missing	7
Omission on discharge	6
Administration times incorrect/missing	6
Duplication	6
Product or formulation not specified	4
Incorrect formulation	4
No maximum dose	4
Unintentional prescribing	3
No signature	2
Clinical contraindication	1
Incorrect route	1
No indication	1
Intravenous instructions incorrect/missing	1
Drug not prescribed but indicated	1
Drug continued for longer than needed	1
Route of administration missing	1
Start date incorrect/missing	1
Risk of drug interaction	< 0.5
Controlled drug requirements incorrect/missing	< 0.5
Daily dose divided incorrectly	< 0.5
Significant allergy	< 0.5
Drug continued in spite of adverse effects	< 0.5
Premature discontinuation	< 0.5
Failure to respond to out-of-range drug level	< 0.5

Avoiding prescribing errors

There are several circumstances which make prescribing errors more likely. These are summarised in Box 2.15. Prescribers should take extra care when prescribing medicines under these circumstances.

Responding when an error is discovered

All prescribers make errors. When they do, their first duty is to protect the patient's safety. This will involve a clinical review and the taking of any steps that will reduce harm (remedial treatment, monitoring, recording the event in the notes, informing colleagues). Patients should be informed if they have been exposed to potential harm. Even if errors do not impact on the patient, it is the prescriber's duty to report them, so that others can learn from the experience and take the opportunity to reflect on how a similar incident might be avoided in the future.

Drug regulation and management

Given the powerful beneficial and potentially adverse effects of drugs, the production and use of medicines are strictly regulated (by the Food and Drug Administration in the United States, the European Medicines Agency in Europe, the Medicines and Healthcare Products Regulatory Agency in the UK, and the Central Drugs Standard Control

2.14 Causes of prescribing errors

Systems factors

- Working hours of prescribers (and others)
- Patient throughput
- Professional support and supervision by colleagues
- Availability of information (medical records)
- Design of prescription forms
- Distractions
- Availability of decision support
- Checking routines by clinical pharmacists
- Reporting and reviewing of incidents

Prescriber factors

Knowledge

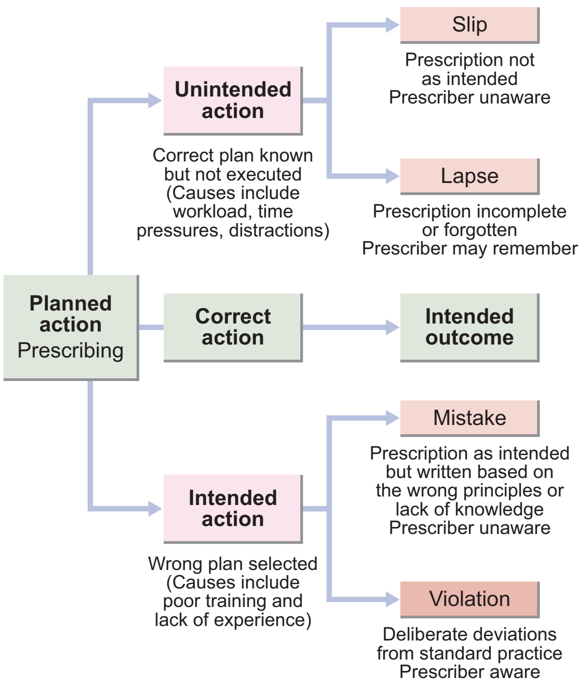
- Clinical pharmacology principles
- Drugs in common use
- Therapeutic problems commonly encountered
- Knowledge of workplace systems

Skills

- Taking a good drug history
- Obtaining information to support prescribing
- Communicating with patients
- Numeracy and calculations
- Prescription writing

Attitudes

- Coping with risk and uncertainty
- Monitoring of prescribing
- Checking routines



Slip
Prescription not as intended
Prescriber unaware
Unintended action
Correct plan known but not executed (Causes include workload, time pressures, distractions)
Lapse
Prescription incomplete or forgotten
Prescriber may remember
Planned action
Prescribing
Correct action
Intended outcome
Mistake
Prescription as intended but written based on the wrong principles or lack of knowledge
Prescriber unaware
Intended action
Wrong plan selected (Causes include poor training and lack of experience)
Violation
Deliberate deviations from standard practice
Prescriber aware

Fig. 2.5 Human error theory. Unintended errors may occur because the prescriber fails to complete the prescription correctly. They comprise what is called a 'slip' when the dose is written as mg when micrograms was intended or a 'lapse' when part of the action that is important for success is forgotten, such as to co-prescribe folic acid with methotrexate. Prevention requires the system to provide appropriate checking routines. Intended errors ('mistakes') occur when the prescriber acts incorrectly due to lack of knowledge. An example would be prescribing atenolol for a patient with known severe asthma because of ignorance about the contraindication. Prevention of these errors must focus on training the prescriber. A 'violation' is when the prescriber intentionally deviates from normal practice.

2.15 High-risk prescribing moments

- Trying to amend an active prescription – *always avoid and start again*
- Writing up drugs in the immediate presence of more than one prescription chart or set of notes – *avoid*
- Allowing one's attention to be diverted in the middle of completing a prescription – *avoid*
- Prescribing 'high-risk' drugs – *ask for help if necessary*
- Prescribing parenteral drugs – *take care*
- Rushing prescribing in the middle of a busy ward round – *avoid*
- Prescribing unfamiliar drugs – *consult the formulary and ask for help if necessary*
- Transcribing multiple prescriptions from an expired chart to a new one – *take care to review the rationale for each medicine*
- Writing prescriptions based on information from another source, such as a referral letter (the list may contain errors and some of the medicines may be the cause of the patient's illness) – *review the justification for each as if it is a new prescription*
- Writing up drugs for the patient to take home (because these will become the patient's regular medication for the immediate future) – *take care and seek advice if necessary*
- Calculating drug doses – *ask a colleague to perform an independent calculation or use approved electronic dose calculators*
- Prescribing sound-alike or look-alike drugs (for example chlorphenamine and chlorpromazine) – *take great care*

Organisation in India). Regulators are responsible for licensing medicines, monitoring their safety (pharmacovigilance), approving clinical trials, and inspecting and maintaining standards of drug development and manufacture.

Drug development and marketing

Naturally occurring products have been used to treat illnesses for thousands of years and some remain in common use today. Examples include morphine from the opium poppy (*Papaver somniferum*) and digitalis from the foxglove (*Digitalis purpurea*). Although plants and animals remain a source of discovery, the majority of new drugs come from drug discovery programmes that aim to identify small-molecule compounds with specific interactions with a molecular target that will induce a predicted biological effect.

The usual pathway for development of these small molecules includes: identifying a plausible molecular target by investigating pathways in disease; screening a large library of compounds for those that interact with the molecular target in vitro; conducting extensive medicinal chemistry to optimise the properties of lead compounds; testing efficacy and toxicity of these compounds in vitro and in animals; and undertaking a clinical development programme (Box 2.16). This process typically takes longer than 10 years and may cost up to US$2 billion. Manufacturers have a defined period of exclusive marketing of the drug while it remains protected by an original patent, typically 10–15 years, during which time they must recoup the costs of developing the drug. Once the drug's patent has expired, other manufacturers frequently step in to produce the same drug. These are referred to as generic formulations, or in the case of biologics, biosimilar medicine. Generic and biosimilar drugs are usually cheaper than the originator but, if they are produced by only one manufacturer, the price may actually rise, sometimes substantially.

New therapeutic agents

The traditional approach of targeting membrane-bound receptors and enzymes with small molecules (see Box 2.2) is now giving way to drug development that focuses on new targets, such as complex second-messenger systems, cytokines, cell surface receptors, nucleic acids and cellular networks (Box 2.17). These require the development of novel therapeutic agents, as illustrated in Figure 2.6. These new approaches have, in many cases, led to significant therapeutic advances in diseases that would not easily have been treatable with traditional small-molecule drugs.

Manufacturers

There are multiple challenges at every stage of the development and quality assurance of high-quality biological products. Challenges in manufacturing biologics include the initial molecular cloning process, development of clone expression by stable cell lines, purification and characterisation procedures, performing post-translation modifications, ensuring chemical stability, deploying novel sensitive bio-analytical methods and meeting stringent regulatory expectations. There are also new hurdles to overcome in the clinical development phase, including definition of the clinical indication with linked inclusion and exclusion criteria, study design and appropriate comparator product, selecting the appropriate therapeutic dose based on interpretation of pharmacokinetic/pharmacodynamic (PK/PD) data, and addressing specific safety concerns (notably immunogenicity) that arise after exposure to large biological molecules.

2.16 Clinical development of new drugs

Phase I

- Healthy volunteers (20–80)
- These involve initial single-dose, ‘first-into-man’ studies, followed by repeated-dose studies. They aim to establish the basic pharmacokinetic and pharmacodynamic properties, and short-term safety
- Duration: 6–12 months

Phase II

- Patients (100–200)
- These investigate clinical effectiveness (‘proof of concept’), safety and dose–response relationship, often with a surrogate clinical endpoint, in the target patient group to determine the optimal dosing regimen for larger confirmatory studies
- Duration: 1–2 years

Phase III

- Patients (100s–1000s)
- These are large, expensive clinical trials that confirm safety and efficacy in the target patient population, using relevant clinical endpoints. They may be placebo-controlled studies or comparisons with other active compounds
- Duration: 3–5 years

Phase IV

- Patients (1000s–10,000s)
- These are undertaken after the medicine has been marketed for its first indication to evaluate new indications, new doses or formulations, long-term safety or cost-effectiveness

Clinical trials

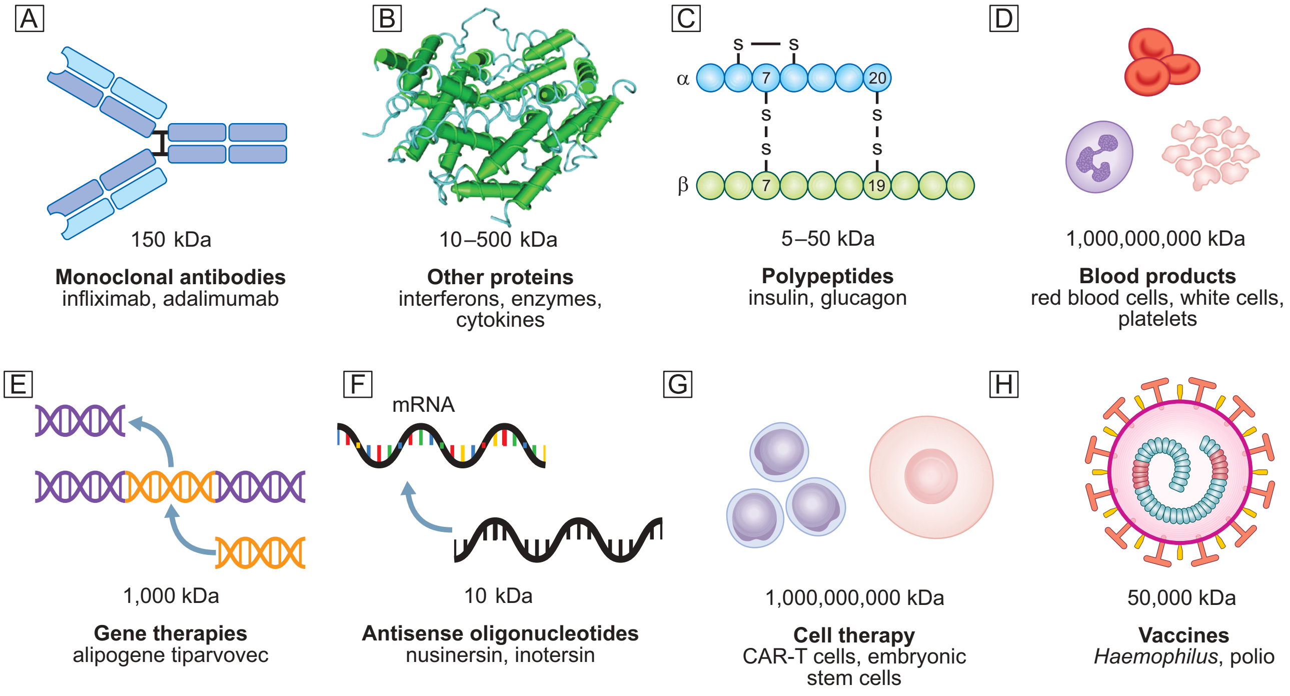
Clinical trial designs are also evolving in response to the need for new medicines. Due to the high specificity of many novel agents, early-phase trials often combine safety and preliminary efficacy assessments. Many are now based on smaller cohorts and enabled by adaptive trial designs, in which aspects of the trial design, such as dosing, are adapted in the light of emerging data with the aim of reducing the numbers of patients involved. Other novel trial designs use master protocols to conduct basket trials, umbrella trials and platform trials. Basket trials employ a targeted therapy on multiple diseases that have a common molecular basis. Umbrella trials evaluate multiple targeted therapies for a single disease that is stratified into subgroups by the underlying molecular mechanism of disease. Platform trials refer to the situation where different treatments are tried in succession using the same trial design. The UK-based Recovery Trial for Covid was an example of a platform trial design. Novel therapies, especially for rare or severe conditions, may receive conditional or accelerated approval based on early-phase data, with post-marketing studies required. This accelerated regulatory approval is predicated on the need for ongoing real-world data collection, long-term follow-up and the presence of a clear risk management plan to monitoring safety. This more dynamic and efficient style of drug development programme has the perceived disadvantages that it reduces the number of exposures prior to licensing, is often based on short-term efficacy based on surrogate biomarkers and is even more dependent on post-marketing surveillance.

Health services

Biological drugs are often much more expensive than conventional synthetic molecules because of the complex manufacturing process outlined above, but also because they often have much narrower indications for use based on specific molecular profiling of the recipients. This means that the development costs have to be recouped from a relatively smaller patient group. After the patent for the originator product expires, other manufacturers frequently develop similar products, termed biosimilars, that have the same pharmacological actions, but are not completely identical because of differences that may arise during the manufacturing process, such as in glycosylation of the molecule. Like the originator product, biosimilars must be prescribed by name but are usually considerably cheaper than the originator. Because of their increased cost relative to small molecules, biological agents are often subject to scrutiny on the basis of cost-effectiveness and funders may put additional requirements in place prior to access, such as failure of conventional treatments.

2.17 Novel therapeutic alternatives to conventional small-molecule drugs

Approaches	Therapeutic indications	Challenges
Monoclonal antibodies		
Targeting of receptors or other molecules with relatively specific antibodies	Cancer Chronic inflammatory diseases	Selectivity of action Complex manufacturing process
Small interfering RNA (siRNA)		
Inhibition of gene expression	Macular degeneration Hypercholesterolaemia	Delivery to target
Gene therapy		
Delivery of modified genes that supplement or alter host DNA	Neurological diseases Cancer Haematological diseases	Delivery to target Adverse effects of delivery vector
Stem cell therapy		
Stem cells differentiate and replace damaged host cells	Parkinson disease Spinal cord injury Ischaemic heart disease	Delivery to target Immunological compatibility Long-term effects unknown



150 kDa
Monoclonal antibodies
infliximab, adalimumab

10–500 kDa
Other proteins
interferons, enzymes, cytokines

5–50 kDa
Polypeptides
insulin, glucagon

1,000,000,000 kDa
Blood products
red blood cells, white cells, platelets

1,000 kDa
Gene therapies
alipogene tiparvovec

10 kDa
Antisense oligonucleotides
nusinersin, inotersin

1,000,000,000 kDa
Cell therapy
CAR-T cells, embryonic stem cells

50,000 kDa
Vaccines
Haemophilus, polio

Fig. 2.6 The mechanism of action and molecular weight of various types of biologic therapies. A Monoclonal antibodies are synthesised proteins that bind cytokines or cell surface molecules that are involved in the inflammatory response or in the pathogenesis of certain types of cancer. B Other proteins include analogues of cytokines involved in cell signalling and enzymes that increase the activity of metabolic pathways. C Polypeptides are typically analogues of endogenous peptide hormones. D Blood products are given as replacement for natural blood constituents. E Gene therapies are used to regulate, repair, replace, add to, or remove a nucleic acid sequence in native DNA. F Antisense oligonucleotides are short, synthetic, single-stranded oligodeoxynucleotides that can alter RNA and reduce, restore or modify protein expression. G Cell therapies include injection of cells that replace damaged cells. These might include embryonic stem cells or genetically manipulated T cells, which are designed to destroy a target cell (CAR-T cells). H Vaccines are used to stimulate the immune system to respond to and remember specific antigens associated with viral or bacterial infections. Some examples of each type of biologic or cell therapy are shown. (CAR-T cells = chimeric antigen recipient T cells; kDa = kilodaltons; mRNA = messenger ribonucleic acid; TNF = tumour necrosis factor)

Prescribers

For prescribers there are some important considerations when assessing the balance of beneficial and adverse effects of biologics, for example, the use of recombinant antibodies for autoimmune inflammatory conditions. Cytokine inhibitors like anti-TNF therapies carry a significantly increased risk of infection when compared to classical disease-modifying anti-rheumatic drugs and this risk is increased by age, comorbidities and concomitant use of other immunosuppressant drugs. Patients receiving those drugs should be protected with appropriate vaccinations, and treatment is contraindicated in the presence of active infection. The increased immunogenicity of biological molecules has two important consequences. First, there is an increased chance of immediate and delayed hypersensitivity reactions (see Box 2.6). Second, anti-drug antibodies can develop causing loss of effect. A recent Cochrane review of exposure to nine commonly used biologics for up to 5 years concluded that there was a 5% absolute increase in all adverse effects combined, a 1% absolute increase in risk of serious infection, but little or no increased risk of cancer or other serious outcomes.

Licensing new medicines

New drugs are given a market authorisation, based on the evidence of quality, safety and efficacy presented by the manufacturer. The regulator not only will approve the drug, but also will take great care to ensure that the accompanying information reflects the evidence that has been presented. The summary of product characteristics (SPC), or label, provides detailed information about indications, dosage, adverse effects, warnings and monitoring requirements. If approved, drugs can be made available with different levels of restriction:

- *Controlled drugs (CD)* such as opioids are subject to strict legal controls on supply and possession, due to their abuse potential.
- *Prescription-only medicines (PoM)* are available only from a pharmacist and can be supplied only if prescribed by an appropriate practitioner.
- *Pharmacy medicines (P)*. These are available only from a pharmacist, but can be supplied without a prescription.
- *General sales list (GSL)* medicines may be bought over the counter (OTC) from any shop and without a prescription.

Although the regulators take great care to agree the exact indications for prescribing a medicine, based on the evidence provided by the manufacturer, there are some circumstances in which prescribers may direct its use outside the terms stated in the SPC (off-label prescribing). Common situations where this occurs include prescribing outside the approved age group (such as for children) or using an alternative formulation (such as administering a medicine provided in a solid form as an oral solution). Other important examples might include prescribing for an indication for which there are no approved medicines or where all of the approved medicines have caused unacceptable adverse effects. Occasionally, medicines may be prescribed when there is no marketing authorisation in the country of use. Examples include when a medicine licensed in another country is imported for use for an individual patient (unlicensed import) or when a patient requires a specific preparation of a medicine to be manufactured (unlicensed special). There is an increased requirement for prescribers to be able to justify their actions and to inform and agree the decision with the patient when using medicines that are unlicensed.

Drug marketing

The marketing activities of the pharmaceutical industry are well resourced and are important in the process of recouping the massive costs of drug development. In some countries, such as the United States, it is possible to promote a new drug by direct-to-consumer advertising, although this is illegal in the UK and the European Union. Pharmaceutical companies promote their drugs to prescribers through educational events, sponsorship of meetings, advertisements in journals, direct contact by company representatives and involvement of opinion leaders in the field. Such largesse has the potential to cause significant conflicts of interest and might tempt prescribers to favour one drug over another, even in the absence of greater effectiveness or cost-effectiveness.

Managing the use of medicines

Many medicines meet the three key regulatory requirements of quality, safety and efficacy. Although prescribers are legally entitled to prescribe any of them, it is desirable to limit the choice so that treatments for specific diseases can be focused on the most effective and cost-effective options, prescribers (and patients) gain familiarity with a smaller number of medicines, and pharmacies can concentrate stocks on them.

The process of ensuring optimal use of available medicines is known as medicines management or quality use of medicines. It involves careful evaluation of the evidence for benefit and harm, an assessment of cost-effectiveness and support for processes to implement the resulting recommendations. These activities often involve national organisations like the National Institute for Health and Care Excellence (NICE) in the UK and local organisations such as drug and therapeutics committees.

Evaluating evidence

Drugs are often evaluated in high-quality randomised controlled trials, the results of which can be combined by systematic reviews (Fig. 2.7). Ideally, data are available not only for comparison with placebo, but also for head-to-head comparison with alternative therapies. It is important to remember that trials are conducted in selected patient populations where many comorbid conditions are excluded and may not be representative of routine clinical practice. Furthermore, racial and ethnic minority population groups, and women, continue to be underrepresented in clinical trials. Because of this, extrapolation to individual patients is not always straightforward. Other subtle bias may be introduced because of the sources of funding and the desire for investigators to be involved in research that yields positive results. These biases may be manifest in the way the trials are designed, conducted and how they are interpreted or reported. A common example of the latter is the difference between relative and absolute risk of clinical events reported in prevention trials. If a clinical event is encountered in the placebo arm at a rate of 1 in 50 patients (2%), but only 1 in 100 patients (1%) in the active treatment arm, then the impact of treatment can be described as either a 50% relative risk reduction or 1% absolute risk reduction. Although the former sounds more impressive, it is the latter that is of more importance to the individual patient. It means that the number of patients that needed to be treated (NNT) for 1 to benefit (compared to placebo) was 100. This illustrates how large clinical trials of new medicines can produce highly statistically significant and impressive relative risk reductions and still predict a very modest clinical impact. The NNT, as well as the numbers needed to treat for one person to suffer harm (NNH), are the figures that matter most to patients and prescribers when trying to have an open conversation about whether to embark on treatment. There is increased focus on them as part of the delivery of realistic medicine and when stopping long-term medicines (deprescribing) in elderly patients subjected to polypharmacy.

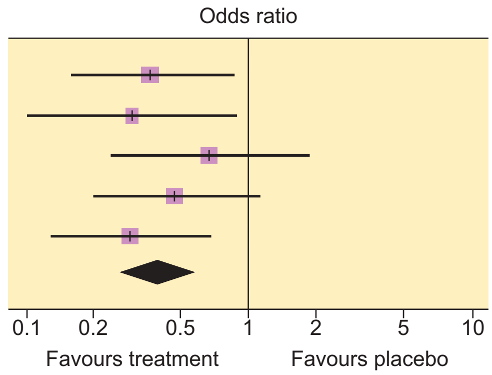


Fig. 2.7 Systematic review of the evidence from randomised controlled clinical trials. This forest plot shows the effect of warfarin compared with placebo on the likelihood of stroke in patients with atrial fibrillation in five randomised controlled trials that passed the quality criteria required for inclusion in a meta-analysis. For each trial, the size of purple box is proportionate to the number of participants. The tick marks show the mean odds ratio and the black lines indicate its 95% confidence intervals. Note that not all the trials showed statistically significant effects (the confidence intervals cross 1.0). However, the meta-analysis, represented by the black diamond, confirms a highly significant statistical benefit. The overall odds ratio is approximately 0.4, indicating a mean 60% risk reduction with warfarin treatment in patients with the characteristics of the participants in these trials.

Evaluating cost-effectiveness

New drugs often represent an incremental improvement over the current standard of care, but are usually more expensive. Health-care budgets are limited in every country and so it is impossible to fund all new medicines. This means that very difficult financial decisions have to be taken with due regard to the principles of ethical justice. The main approach taken is cost-effectiveness analysis (CEA), where a comparison is made between the relative costs and outcomes of different courses of action. CEA is usually expressed as a ratio where the denominator is a gain in health and the numerator is the cost associated with the health gain. A major challenge is to compare the value of interventions for different clinical outcomes. One method is to calculate the quality-adjusted life years (QALYs) gained if the new drug is used rather than standard treatment. This analysis involves estimating the 'utility' of various health states between 1 (perfect health) and 0 (dead). If the additional costs and any savings are known, then it is possible to derive the incremental cost-effectiveness ratio (ICER) in terms of cost/QALY. These principles are exemplified in Box 2.18. There are, however, inherent weaknesses in this kind of analysis: it usually depends on modelling future outcomes well beyond the duration of the clinical trial data; it assumes that QALYs gained at all ages are of equivalent value; and the appropriate standard care against which the new drug should be compared is often uncertain.

These pharmacoeconomic assessments are challenging and resource-intensive, and are undertaken at national level in most countries.

Implementing recommendations

Many recommendations about drug therapy are included in clinical guidelines written by an expert group after systematic review of the evidence. Guidelines provide recommendations rather than obligations for prescribers and are helpful in promoting more consistent and higher-quality prescribing. They are often written without concern for cost-effectiveness, however, and may be limited by the quality of available evidence. Guidelines cannot anticipate the extent of the variation between individual patients who may, for example, have unexpected contraindications to recommended drugs or choose different priorities for treatment. When deviating from respected national guidance, prescribers should be able to justify their practice. Additional recommendations for prescribing are often implemented locally or imposed by bodies responsible for paying for health care. Most health-care units have a drug and therapeutics committee (or equivalent) comprised of medical staff, pharmacists and nurses, as well as managers (because of the implications of the committee's work for governance and resources). This group typically develops local prescribing policy and guidelines, maintains a local drug formulary and evaluates requests to use new drugs. The local formulary contains a more limited list than any national formulary, such as the *British National Formulary* and the *Indian National Formulary*, because national formularies list all licensed medicines that can be prescribed legally, while local formularies list only

2.18 Cost-effectiveness analysis

A clinical trial lasting 2 years compares two interventions for the treatment of colon cancer:

- Treatment A: standard treatment, cost £1000/year, oral therapy
- Treatment B: new treatment, cost £6000/year, monthly intravenous infusions, often followed by a week of nausea.

The new treatment (B) significantly increases the average time to progression (18 months versus 12 months) and reduces overall mortality (40% versus 60%). The health economist models the survival curves from the trial in order to undertake a cost–utility analysis and concludes that:

- Intervention A: allows an average patient to live for 2 extra years at a utility 0.7 = 1.4 QALYs (cost £2000)
- Intervention B: allows an average patient to live for 3 extra years at a utility 0.6 = 1.8 QALYs (cost £18 000).

The health economists conclude that treatment B provides an extra 0.4 QALYs at an extra cost of £16 000, meaning that the ICER = £40 000/QALY. They recommend that the new treatment should not be funded on the basis that their threshold for cost acceptability is £30 000/QALY.

(ICER = incremental cost-effectiveness ratio; QALY = quality-adjusted life year)

2.19 Factors to consider when balancing benefits and harms of drug therapy

- Seriousness of the disease or symptom
- Efficacy of the drug
- Seriousness of potential adverse effects
- Likelihood of adverse effects
- Efficacy of alternative drugs or non-drug therapies
- Safety of alternative drugs or non-drug therapies

those that the health-care organisation has approved for local use. The local committee may also be involved, with local specialists, in providing explicit protocols for management of specific clinical scenarios.

Prescribing in practice

Decision-making in prescribing

Prescribing should be based on a rational approach to a series of challenges (see Box 2.1).

Making a diagnosis

Ideally, prescribing should be based on a confirmed diagnosis but, in reality, many prescriptions are based on the balance of probability, taking into account the most likely differential diagnosis.

Establishing the therapeutic goal

The goals of treatment are usually clear, particularly when relieving symptoms such as pain or nausea. Sometimes the goal of treatment is to prevent future events, such as the use of bisphosphonates to prevent fractures. In this circumstance, patients do not feel any symptomatic benefit of treatment. Prescribers should be clear about the therapeutic goal against which they will judge success or failure of treatment and establish that the goal of the prescriber is shared by the patient to maximise adherence to treatment.

Choosing the therapeutic approach

It is not always necessary to prescribe a drug for the patient's problem. Prescribers must consider whether drug therapy is in the patient's interest and is preferred to no treatment or alternatives like physiotherapy, psychotherapy or surgery, having taken the potential benefits and harms into account. Assessing the balance of benefit and harm is often complicated and depends on various features associated with the patient, disease and drug (Box 2.19).

Choosing a drug

More than one drug is available for most common clinical indications. Although prescribers often have guidance about which represents the rational choice for the average patient, they still need to consider whether this is the optimal choice for the individual patient. Certain factors may influence the choice of drug:

Absorption

Patients may find some formulations easier to swallow than others or may be vomiting and require a drug available for parenteral administration.

Distribution

Distribution of a drug to a particular tissue sometimes dictates choice. For example, tetracyclines and rifampicin are concentrated in the bile, and lincomycin and clindamycin in the bone.

Metabolism

Drugs like opioids that are extensively metabolised should be avoided in severe liver disease.

Excretion

Drugs that depend on renal excretion for elimination should be avoided in patients with impaired renal function if suitable alternatives exist.

Efficacy

Prescribers normally choose drugs with the greatest efficacy in achieving the goals of therapy, but it may be appropriate to compromise on efficacy if other drugs are more convenient, safer to use or less expensive.

Avoiding adverse effects

Prescribers should be wary of choosing drugs that are more likely to cause adverse effects or worsen coexisting conditions.

Features of the disease

This is most obvious when choosing antibiotic therapy, which should be based on the known or suspected sensitivity of the infective organism.

Severity of disease

The choice of drug should be appropriate to disease severity.

Coexisting disease

This may be either an indication or a contraindication to therapy. Hypertensive patients might be prescribed a β-blocker if they also have left ventricular impairment, but not if they have asthma.

Avoiding adverse drug interactions

Prescribers should avoid giving combinations of drugs that might interact, either directly or indirectly (see Box 2.12).

Patient adherence to therapy

Prescribers should choose drugs with a simple dosing schedule or easier administration.

Cost

Prescribers should choose the cheaper drug if two drugs are of equal efficacy and safety. Even if cost is not a concern for the individual patient, it is important to remember that unnecessary expenditure will ultimately limit choices for other prescribers and patients. Sometimes a more costly drug may be appropriate if adherence is likely to be better.

Genetic factors

There are already a small number of examples where genotype influences the choice of drug therapy (see Box 2.5).

Choosing a dosage regimen

Prescribers have to choose a dose, route and frequency of administration (dosage regimen) to achieve a steady-state drug concentration that provides sufficient exposure of the target tissue without producing toxic effects. Manufacturers draw up dosage recommendations based on average observations in many patients, but the optimal regimen that will maximise the benefit to harm ratio for an individual patient is never certain. Rational prescribing involves treating each prescription as an experiment and gathering sufficient information to amend it if necessary. There are some general principles that should be followed, as described below.

Dose titration

Prescribers should generally start with a low dose and titrate this slowly upwards as necessary. This cautious approach is particularly important if the patient is likely to be more sensitive to adverse pharmacodynamic effects, if there may be altered pharmacokinetic handling (renal or hepatic impairment) and when using drugs with a low therapeutic index (benzodiazepines, lithium, digoxin). However, there are some exceptions. Some drugs must achieve therapeutic concentration quickly because of the clinical circumstances. When early effect is important and there may be a delay in achieving steady state because of a drug's long half-life, an initial loading dose is appropriate (see Fig. 2.4).

If adverse effects occur, the dose should be reduced or an alternative drug prescribed; in some cases, a lower dose may suffice if it can be combined with another synergistic drug. It is important to remember that the shape of the dose–response curve (see Fig. 2.2) means that higher doses may produce little added therapeutic effect and might increase the chances of toxicity.

Route

There are many reasons for choosing a particular route of administration (Box 2.20).

Frequency

Frequency of doses is usually dictated by a manufacturer's recommendation. Less frequent doses are more convenient for patients, but result in greater fluctuation between peaks and troughs in drug concentration (see Fig. 2.4). This is relevant if the peaks are associated with adverse effects or the troughs are associated with loss of effect. These problems can be tackled either by splitting the dose or by employing a modified-release formulation, if available.

Timing

For many drugs the time of administration is unimportant. There are occasionally pharmacokinetic or therapeutic reasons, however, for giving drugs at particular times (Box 2.21).

Formulation

For some drugs there is a choice of formulation, some for use by different routes. For example, children usually find elixirs easier to take than tablets. The formulation is important when writing repeat prescriptions for drugs with a low therapeutic index that come in different formulations. Even if the prescribed dose remains constant, an alternative formulation

2.20 Factors influencing the route of drug administration

Reason	Example
Only one route possible	Dobutamine (IV) Gliclazide (oral)
Patient adherence	Phenothiazines and thioxanthenes (2 weekly IM depot injections rather than daily tablets, in schizophrenia)
Poor absorption	Furosemide (IV rather than oral, in severe heart failure)
Rapid action	Haloperidol (IM rather than oral, in acute behavioural disturbance)
Vomiting	Phenothiazines (PR or buccal rather than oral, in nausea)
Avoidance of first-pass metabolism	Glyceryl trinitrate (SL, in angina pectoris)
Certainty of effect	Amoxicillin (IV rather than oral, in acute chest infection)
Direct access to the site of action (avoiding unnecessary systemic exposure)	Bronchodilators (INH rather than oral, in asthma) Local application of drugs to skin, eyes and other mucous membranes
Ease of access	Diazepam (PR, if IV access is difficult in status epilepticus) Adrenaline (epinephrine) (IM, if IV access is difficult in acute anaphylaxis)
Comfort	Morphine (SC rather than IV in terminal care)

(IM = intramuscular; INH = by inhalation; IV = intravenous; PR = per rectum; SC = subcutaneous; SL = sublingual)

2.21 Factors influencing the timing of drug therapy

Drug	Recommended timing	Reasons
Diuretics	Once in the morning	Night-time diuresis undesirable
Statins	Once at night	HMG CoA reductase activity is greater at night
Antidepressants	Once at night	Allows adverse effect of drowsiness to occur during sleep
Salbutamol	Before exercise	Reduces symptoms in exercise-induced asthma
Glyceryl trinitrate **Paracetamol**	When required	Relief of acute symptoms only
Regular nitrate therapy	Eccentric dosing regimen (twice daily at 0800 hrs and 1400 hrs)	Reduces development of nitrate tolerance by allowing drug-free period each night
Aspirin	With food	Minimises gastrotoxic effects
Alendronate	Once in the morning before breakfast, sitting upright	Minimises risk of oesophageal irritation, maximises therapeutic effect
Tetracyclines	2 hours before or after food or antacids	Divalent and trivalent cations chelate tetracyclines, preventing absorption
Hypnotics	Once at night	Maximises therapeutic effect and minimises daytime sedation
Antihypertensive drugs	Once in the morning	Blood pressure is higher during the daytime

(HMG CoA = 3-hydroxy-3-methylglutaryl-coenzyme A) may differ in its absorption and bioavailability, and hence plasma drug concentration. These are examples of the small number of drugs that should be prescribed by specific brand name rather than generic international non-proprietary name (INN).

Duration

Some drugs require a single dose, while for others the duration of the course of treatment is decided at the outset of starting therapy. For most, the duration will be largely at the prescriber's discretion and will depend on response and disease progression. For others the treatment will be long-term.

Involving the patient

Patients should, whenever possible, be engaged in making choices about drug therapy. Their beliefs and expectations affect the goals of therapy and help in judging the acceptable benefit/harm balance when selecting treatments. Very often, patients may wish to defer to the professional expertise of the prescriber. Nevertheless, they play key roles in adherence to therapy and in monitoring treatment, not least by providing early warning of adverse events. It is important for them to be provided with the necessary information to understand the choice that has been made, what to expect from the treatment, and any measurements that must be undertaken (Box 2.22).

A major drive to include patients has been the recognition that up to half of the drug doses for chronic preventative therapy are not taken. This is termed non-adherence and may or may not be intentional. Non-adherence to the dose regimen reduces the likelihood of benefits to the patient and can be costly in terms of wasted medicines and unnecessary health-care episodes. An important reason is that the patient lacks understanding of the prescriber's goals of treatment. A more open and shared decision-making process can help to resolve misunderstandings at the outset and foster improved adherence, as well as improved satisfaction with health-care services and confidence in prescribers. Considerable efforts are now made to help patients to access the reliable information they require to engage more fully with clinicians. Patient-focused websites and leaflets provided by national services, local health-care providers and charities are increasingly supplementing the Patient Information Leaflet (PIL) approved by the regulatory authorities and supplied with all medicines. Fully engaging patients in shared decision-making is sometimes constrained by various factors, such as limited consultation time, language barriers and challenges in communicating complex numerical data.

Writing the prescription

The culmination of the planning described above is writing an accurate and legible prescription so that the drug will be dispensed and administered as planned. The prescription is a means by which a prescriber communicates the intended plan of treatment to the pharmacist who dispenses a medicine and to a nurse or patient who administers it. It should be precise, accurate, clear and legible. The two main kinds of prescription are those written, dispensed and administered in hospital (Fig. 2.8) and those written in primary care. Prescriptions written in hospital are dispensed and administered by nursing staff whereas those written in primary care are dispensed at a community pharmacy and self-administered by the patient. The information supplied in a prescription must include:

- the date
- the identification details of the patient
- the name of the drug
- the formulation
- the dose
- the frequency of administration
- the route and method of administration
- the amount to be supplied (primary care only)
- instructions for labelling (primary care only)
- the prescriber's signature.

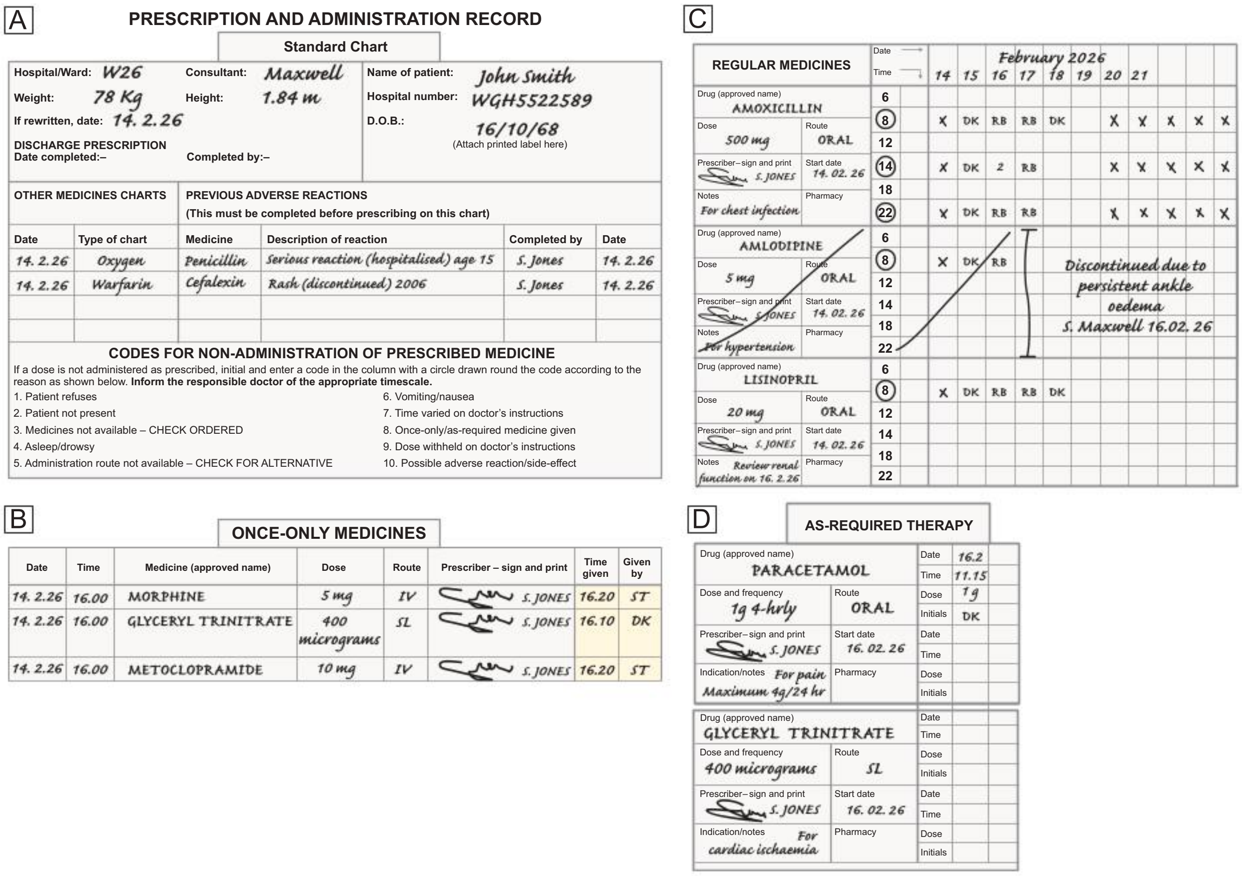
Electronic prescribing

Electronic prescribing (EP) systems are increasingly replacing handwritten prescriptions in primary and secondary health-care settings. These systems significantly reduce prescribing errors, especially those that are related to illegibility and missing information. If they are linked with the electronic health record, including routine investigations, it is possible to deploy sophisticated clinical decision support (CDS) tools that can provide additional benefits, such as promoting evidence-based prescribing choices, preventing prescribing of contraindicated medicines and highlighting potentially serious drug–drug interactions. Warning alerts for prescribers can either be interruptive, requiring immediate action by the prescriber before the prescription can be completed, or non-interruptive, where the workflow can continue without the need to act on or dismiss the alert. Further benefits of EP are better medicines reconciliation, improved antimicrobial stewardship, prompting intravenous-to-oral switching, avoiding the need to transcribe prescriptions from one chart to another, avoiding losing paper charts and continuous availability for review. Furthermore, EP enables better governance oversight, supported by the ability to rapidly audit a large number of prescribing episodes, and facilitates research projects focused on prescribing safety and efficacy. Notwithstanding these considerable advantages there are potential pitfalls. EP systems also introduce the possibility of making new errors, primarily by making incorrect selections from dropdown menus or accepting inappropriate default doses.

i 2.22 What patients need to know about their medicines*

Knowledge	Comment
The reason for taking the medicine	What are the goals of therapy? What are the alternatives? What might happen without the treatment?
How the medicine works	Better understanding can support concordance and adherence
How to take the medicine	May be important for the effectiveness (inhaled salbutamol in asthma) and safety of treatment (alendronate for osteoporosis)
What benefits to expect	May help to support adherence or prompt review because of treatment failure (reduced episodes of bronchospasm with inhaled corticosteroids)
What adverse effects might occur	Discuss common and mild effects that may be transient and might not require discontinuation (vasodilator-related headache) Mention rare but serious effects that might influence the patient's consent (effects on fertility or cancer risk)
Precautions that improve safety	Explain symptoms to report that might allow serious adverse effects to be averted, need for monitoring when required and potentially important drug–drug interactions
When to return for review	To enable monitoring in a timely manner

*All medicines are provided with a Patient Information Leaflet (PIL) approved by the regulatory agency, which the patient should be encouraged to read.



A

PRESCRIPTION AND ADMINISTRATION RECORD

Standard Chart

Hospital/Ward: W26　Consultant: Maxwell
Weight: 78 Kg　Height: 1.84 m
If rewritten, date: 14. 2. 26
DISCHARGE PRESCRIPTION
Date completed:–　Completed by:–

Name of patient: John Smith
Hospital number: WGH5522589
D.O.B.: 16/10/68
(Attach printed label here)

OTHER MEDICINES CHARTS		PREVIOUS ADVERSE REACTIONS (This must be completed before prescribing on this chart)			
Date	Type of chart	Medicine	Description of reaction	Completed by	Date
14. 2. 26	Oxygen	Penicillin	Serious reaction (hospitalised) age 15	S. Jones	14. 2. 26
14. 2. 26	Warfarin	Cefalexin	Rash (discontinued) 2006	S. Jones	14. 2. 26

CODES FOR NON-ADMINISTRATION OF PRESCRIBED MEDICINE

If a dose is not administered as prescribed, initial and enter a code in the column with a circle drawn round the code according to the reason as shown below. **Inform the responsible doctor of the appropriate timescale.**

1. Patient refuses
2. Patient not present
3. Medicines not available – CHECK ORDERED
4. Asleep/drowsy
5. Administration route not available – CHECK FOR ALTERNATIVE
6. Vomiting/nausea
7. Time varied on doctor's instructions
8. Once-only/as-required medicine given
9. Dose withheld on doctor's instructions
10. Possible adverse reaction/side-effect

Fig. 2.8 Example of a hospital prescription drug chart. **A** The front page of the chart includes patient details and is critical to reducing the risk of an administration error. This page also clearly identifies other prescriptions charts in use and previous adverse reactions to drugs to minimise the risk of repeated exposure. It also may include codes employed by the nursing staff to indicate reasons why drugs may not have been administered. The patient's name and date of birth should be written on each page of the chart. The patient's weight and height may be required to calculate safe doses for many drugs with narrow therapeutic indices. **B** This area is used for prescribing medicines that are unlikely to be repeated on a regular basis. Note that the prescriber has written the **names of all drugs** legibly in block capitals. **C** This area is used for prescribing medicines that are going to be given regularly. In addition to the name, dose and route, a **frequency of administration** is required for each medicine. The hospital chart usually requires specific times to be identified for regular medicines that coincide with nursing drug rounds and these can be circled. If treatment is for a known time period, cross off subsequent days when the medicine is not required. The **'notes' box** can be used to communicate additional important information, such as whether a medicine should be taken with food, type of inhaler device used, and anything else that the drug dispenser should know. The times for monitoring peak/trough blood levels for drugs requiring therapeutic monitoring should be noted in this box. Prescriptions should be **discontinued** by drawing a vertical line at the point of discontinuation, horizontal lines through the remaining days on the chart, and diagonal lines through the drug details and administration boxes. This action should be signed and dated, and a supplementary note written to explain why (for example describing any adverse effect). In this example, amlodipine has been discontinued because of ankle oedema. There is room for the ward pharmacist to sign to indicate that the prescription has been reviewed and that a supply of the medicine is available. The administration boxes allow the nurse to initial to confirm that the dose has been given. Note that these boxes also allow for recording of reasons for non-administration (in this example '2' indicates that the patient was not present on the ward at the time – see panel A) and the prevention of future administration by placing an 'X' in the box. **D** These prescriptions leave the administration of the drug to the discretion of the nursing staff. The prescription must describe clearly the indication, frequency, minimal time interval between doses, and maximum dose in any 24-hour period (in this case, the maximum daily dose of paracetamol is 4 g). When prescribing, the generic international non-proprietary name (INN) should be used in preference to the brand name. Use numbers/Fig. (1 or 'one') to denote use of a sachet/enema but avoid prescribing numbers of tablets without specifying their strength. Always include the dose of inhaled drugs in addition to stating numbers of 'puffs', as strengths can vary. Accepted abbreviations for **route of administration** are described in the text but the ones in this figure are SL (sublingual) and IV (intravenous). The prescriber should sign and print their name clearly so that they can be identified by colleagues. The prescription should be dated and have an administration time. The person who administered the prescription has added initials to confirm that the dose has been administered.

Monitoring drug therapy

The aim of monitoring drug therapy is to inform decisions about dose titration (up or down), discontinuation or substitution of treatment. Monitoring can be achieved subjectively by asking the patient about symptoms or by measuring a clinical effect, on clinical examination, such as extent of an eczematous rash or joint swelling, physiological measurements, like assessment of blood pressure, and pulse oximetry, imaging or by laboratory tests. If the pharmacodynamic effects of the drug are difficult to assess using the above approaches, the plasma drug concentration may be measured if this is closely related to the effect of the drug (see Fig. 2.2). Rational prescribing ultimately rests on continuous monitoring of the balance between the risks and benefits of drug therapy. Common examples are ACE inhibitors (negative impact on renal function versus blood pressure-lowering), cancer chemotherapy (bone marrow suppression versus tumour regression) and disease-modifying anti-rheumatic drugs (liver toxicity versus anti-inflammatory effect). Advances in therapeutics have also led to increasing complexity of ongoing monitoring requirements. The recognition that hospital specialist clinics cannot take on the responsibility for monitoring of all chronic disease therapy has led to the development of shared care protocols that aim to share monitoring activities between specialists and primary care physicians with the aim of promoting efficient use of health-care resources and convenience for patients.

Clinical and surrogate endpoints

Ideally, clinical endpoints should be measured directly, and the drug dosage titrated to achieve the therapeutic goal and avoid toxicity. Sometimes this is impractical because the drug is being used prophylactically and the clinical endpoint is preventing a future event. In these circumstances, it may be possible to select a surrogate endpoint that will predict success or failure. This may be an intermediate step in the pathophysiological process, such as serum cholesterol as a surrogate for risk of myocardial infarction, or a measurement that follows the pathophysiology, such as serum C-reactive protein as a surrogate for resolution of inflammation in chest infection. These surrogates are usually termed biomarkers of response.

Considerations for monitoring of drug concentrations in blood

The following criteria must be met to justify routine monitoring of drug concentrations in blood:

- Clinical endpoints and other pharmacodynamic (surrogate) effects are difficult to monitor.
- The relationship between blood concentration and clinical effects is predictable.
- The therapeutic index is low. For drugs with a high therapeutic index, any variability in plasma concentrations is likely to be irrelevant clinically.

Some examples of drugs that fulfil these criteria are listed in Box 2.23.

Measurement of blood concentration may be useful in planning adjustments of drug dose and frequency of administration; to explain an inadequate therapeutic response (by identifying subtherapeutic concentration or incomplete adherence); to establish whether a suspected ADR is likely to be caused by the drug; and to assess and avoid potential drug interactions.

When monitoring blood concentrations, it is important to remember that the concentration of drug rises and falls during the dosage interval (see Fig. 2.4B). Measurements made during the initial absorption and distribution phases are unpredictable because of the rapidly changing concentration, so samples are usually taken at the end of the dosage interval (a trough or pre-dose concentration). This measurement is normally made in steady state, which usually takes 5 half-lives to achieve after the drug is introduced or the dose changed (unless a loading dose has been given).

When undertaking blood monitoring, a target range is provided for many drugs, based on average thresholds for therapeutic benefit and toxicity. Inter-individual variability means that these can be used only as a guide. For instance, a patient who describes symptoms that could be consistent with toxicity, with drug concentration in the top half of the target range, should be suspected to have toxic effects. Another important consideration is that some drugs are heavily protein-bound but only the unbound drug is pharmacologically active. Patients with hypoalbuminaemia may, therefore, have a therapeutic or even toxic concentration of unbound drug, despite a low total concentration.

Stopping drug therapy

It is also always important to review long-term treatment at regular intervals to assess whether continued treatment is required. Elderly patients are keen to reduce their medication burden and are often prepared to compromise on the original goals of long-term preventative therapy to achieve this.

Prescribing in special circumstances

Renal impairment

Patients with renal impairment are identified by a low estimated glomerular filtration rate (eGFR <60 mL/min/1.73 m^2), based on their serum creatinine, age, sex and ethnic group (see Box 18.1). This group includes a large proportion of elderly patients. If a drug (or its active metabolites) is eliminated predominantly by the kidneys, it will tend to accumulate and so the maintenance dose must be reduced. For some drugs, renal impairment makes patients more sensitive to their adverse pharmacodynamic effects. Examples of drugs that require extra caution in patients with renal disease are listed in Box 2.24.

Hepatic disease

The liver has a large capacity for drug metabolism and hepatic insufficiency has to be advanced before drug dosages need to be modified. Patients who may have impaired metabolism include those with jaundice, ascites, hypoalbuminaemia, malnutrition or encephalopathy. Hepatic drug clearance may also be reduced in acute hepatitis, in patients with liver congestion due to cardiac failure and in the presence of intrahepatic arteriovenous shunting. There are no good tests of hepatic drug-metabolising capacity or of biliary excretion, so dosage should be guided by the therapeutic response and careful monitoring for adverse effects. The presence of liver disease also increases the susceptibility to adverse pharmacological effects of drugs. Some drugs that require extra caution in patients with hepatic disease are listed in Box 2.24.

Older patients

The issues around prescribing in old age are discussed in Box 2.25.

2.23 Drugs commonly monitored by plasma drug concentration

Drug	Half-life (hrs)*	Comment
Digoxin	36	Steady state takes several days to achieve. Samples should be taken 6 hrs post dose. Measurement is useful to confirm the clinical impression of toxicity or non-adherence but clinical effectiveness is better assessed by ventricular heart rate. Risk of toxicity increases progressively at concentrations >1.5 μg/L, and is likely at concentrations >3.0 μg/L (toxicity is more likely in the presence of hypokalaemia)
Gentamicin	2	Measure pre-dose trough concentration (should be <1 mg/L) to ensure that accumulation (and the risk of nephrotoxicity and ototoxicity) is avoided; see Figure 7.19
Lithium	24	Steady state takes several days to achieve. Samples should be taken 12 hrs post dose. Target range 0.4–1 mmol/L
Phenytoin	24	Measure pre-dose trough concentration (should be 10–20 mg/L) to ensure that accumulation is avoided. Good correlation between concentration and toxicity. Concentration may be misleading in the presence of hypoalbuminaemia
Theophylline (oral)	6	Steady state takes 2–3 days to achieve. Samples should be taken 6 hrs post dose. Target concentration is 10–20 mg/L but its relationship with bronchodilator effect and adverse effects is variable
Vancomycin	6	Measure pre-dose trough concentration (should be 10–15 mg/L) to ensure clinical efficacy and that accumulation and the risk of nephrotoxicity are avoided

*Half-lives vary considerably with different formulations and between patients.

2.24 Some drugs that require extra caution in patients with renal or hepatic disease

Kidney disease	Liver disease
Pharmacodynamic effects enhanced	
ACE inhibitors and ARBs (renal impairment, hyperkalaemia)	Warfarin (increased anticoagulation because of reduced clotting factor synthesis)
Metformin (lactic acidosis)	Metformin (lactic acidosis)
Spironolactone (hyperkalaemia)	Chloramphenicol (bone marrow suppression)
NSAIDs (impaired renal function)	NSAIDs (gastrointestinal bleeding, fluid retention)
Sulphonylureas (hypoglycaemia)	Sulphonylureas (hypoglycaemia)
Insulin (hypoglycaemia)	Benzodiazepines (coma)
Pharmacokinetic handling altered (reduced clearance)	
Aminoglycosides	Phenytoin
Vancomycin	Rifampicin
Other antibiotics	Propranolol
Digoxin	Warfarin
Lithium	Diazepam
Atenolol	Lidocaine
Allopurinol	Opioids
Cephalosporins	
Methotrexate	
Opioids	

(ACE = angiotensin-converting enzyme; ARB = angiotensin receptor blocker; NSAID = non-steroidal anti-inflammatory drug)

2.25 Prescribing in old age

- **Reduced drug elimination**: partly due to impaired renal function.
- **Increased sensitivity to drug effects**: notably in the brain (leading to sedation or delirium) and as a result of comorbidities.
- **More drug interactions**: largely as a result of polypharmacy.
- **Lower starting doses and slower dose titration**: often required, with careful monitoring of drug effects.
- **Drug adherence**: may be poor because of cognitive impairment, difficulty swallowing (dry mouth) and complex polypharmacy regimens. Supplying medicines in pill organisers (e.g. dosette boxes or calendar blister packs), providing automatic reminders, and regularly reviewing and simplifying the drug regimen can help.
- Some drugs that require extra caution, and their mechanisms:
    - *Digoxin*: increased sensitivity of Na^+/K^+ pump; hypokalaemia due to diuretics; renal impairment favours accumulation → increased risk of toxicity.
    - *Antihypertensive drugs*: reduced baroreceptor function → increased risk of postural hypotension.
    - *Antidepressants, hypnotics, sedatives, tranquillisers*: increased sensitivity of the brain; reduced metabolism → increased risk of toxicity.
    - *Warfarin*: increased tendency to falls and injury and to bleeding from intra- and extracranial sites; increased sensitivity to inhibition of clotting factor synthesis → increased risk of bleeding.
    - *Amitriptyline, diltiazem, lidocaine, metoprolol, morphine, propranolol, theophylline*: metabolism reduced → increased risk of toxicity.
    - *Non-steroidal anti-inflammatory drugs*: poor renal function → increased risk of renal impairment; susceptibility to gastrotoxicity → increased risk of upper gastrointestinal bleeding.

Pregnancy and breastfeeding

Prescribing in pregnancy should be avoided wherever possible to minimise the risk of adverse effects on the fetus. Drug therapy in pregnancy may, however, be required either for a pre-existing problem or for problems that arise during pregnancy, such as morning sickness, gestational diabetes or hypertension. About 35% of women take drug therapy at least once during pregnancy and 6% take drug therapy during the first trimester (excluding iron, folic acid and vitamins). The most commonly used drugs are simple analgesics, antibacterial drugs and antacids. Some considerations when prescribing in pregnancy are listed in Box 2.26. Drugs that are excreted in breast milk may cause adverse effects in the baby. Prescribers should always consult the SPC for each drug or a reliable formulary when treating a pregnant woman or breastfeeding mother.

2.26 Prescribing in pregnancy

- **Teratogenesis**: a potential risk, especially when drugs are taken between 2 and 8 weeks of gestation (4–10 weeks from last menstrual period). Common teratogens include isotretinoin, cytotoxic drugs, angiotensin-converting enzyme inhibitors, sodium valproate and warfarin. If there is inadvertent exposure, then the timing of conception should be established, counselling given and investigations undertaken for fetal abnormalities.
- **Adverse fetal effects in late gestation**: Tetracyclines may stain growing teeth and bones; sulphonamides displace fetal bilirubin from plasma proteins, potentially causing kernicterus; opioids given during delivery may be associated with respiratory depression in the neonate.
- **Altered maternal pharmacokinetics**: extracellular fluid volume and V_d increase. Plasma albumin falls but other binding globulins for thyroid and steroid hormones increase. Glomerular filtration increases by approximately 70%, enhancing renal clearance. Placental metabolism contributes to increased clearance, e.g. of levothyroxine and glucocorticoids. The overall effect is a fall in plasma concentration of many drugs.
- **In practice**:
    - Avoid any drugs unless the risk:benefit analysis is in favour of treatment
    - Use drugs for which there is some record of safety in humans.
    - Use the lowest dose for the shortest time possible.
    - Choose the least harmful drug if alternatives are available.

High-risk prescribing moments

See Box 2.15.

Further information

Websites

medicinescomplete.com *Medicines Complete offers a collection of reliable resources intended to support prescribers and other health-care professionals to deliver safe and effective drug treatment. These resources include the British National Formulary (BNF), a key reference resource for UK NHS prescribers, with a list of licensed drugs, chapters on prescribing in renal failure, liver disease, pregnancy and during breastfeeding, and appendices on drug interactions.*

cochranelibrary.com *The Cochrane Collaboration is a leading international body that provides evidence-based reviews (around 7000 so far).*

icp.org.nz *The Interactive Clinical Pharmacology site is designed to increase understanding of principles in clinical pharmacology.*

medicines.org.uk/emc/ *The electronic medicines compendium (emc) contains up-to-date, easily accessible information about medicines licensed by the UK Medicines and Healthcare Products Regulatory Agency (MHRA) and the European Medicines Agency (EMA).*

nice.org.uk *The UK National Institute for Health and Care Excellence makes recommendations to the UK NHS on new and existing medicines, treatments and procedures. This site also includes access to the BNF and Clinical Knowledge Summaries (CKS).*

who.int/health-topics/medicines *The World Health Organization essential medicines and pharmaceutical policies.*

realisticmedicine.scot *The Realistic Medicine website is dedicated to introducing the delivery of 'realistic medicine' and supporting the delivery of shared decision-making between health-care professionals and patients.*

Multiple Choice Questions

2.1. Which of the following drugs for type 2 diabetes acts on a transporter protein?

A. Gliclazide
B. Dapagliflozin
C. Metformin hydrochloride
D. Pioglitazone
E. Sitagliptin

Answer: B.

Dapagliflozin is a sodium-glucose co-transporter 2 inhibitor that is indicated for the treatment of type 2 diabetes mellitus. Dapagliflozin improves glycaemic control by inhibiting glucose re-absorption in the proximal tubule of the nephron leading to excretion of excess glucose in the urine (glycosuria).

2.2. Which of the following is a prodrug that depends on hepatic metabolism for conversion to its active form?

A. Amlodipine
B. Clopidogrel
C. Metoprolol
D. Simvastatin
E. Tramadol

Answer: B.

Clopidogrel binds specifically and irreversibly to the platelet P2RY12 purinergic receptor to inhibit ADP-mediated platelet activation and aggregation. Clopidogrel is a prodrug that is absorbed in the intestine and activated in the liver. The conversion of clopidogrel to its active metabolite involves two sequential oxidation reactions that involve various cytochrome P450 isoforms (CYP1A2, CYP2B6, CYP2C9, CYP2C19 and CYP3A4/5).

2.3. A 52-year-old man who is being treated with azathioprine 150 mg orally daily to maintain remission from Crohn disease presents to hospital with severe pancytopenia. Which of his other current medicines (listed below) is most likely to have interacted with azathioprine to cause this adverse drug reaction?

A. Allopurinol 200 mg orally daily
B. Atorvastatin 20 mg orally daily
C. Indapamide 2.5 mg orally daily
D. Metronidazole 400 mg orally three times daily
E. Omeprazole 20 mg orally daily

Answer: A.

Allopurinol inhibits the enzyme xanthine oxidase (XO), which is one of the three enzymes responsible for inactivating 6-mercaptopurine, its active purine metabolite. Normally, XO is needed to convert the purine base hypoxanthine to xanthine and then xanthine to uric acid. Allopurinol is a structural analogue of hypoxanthine and binds to XO, thereby inhibiting its effect on purine metabolism.

2.4. Which of the following regular medicines is most likely to require a dose reduction in a patient who develops chronic renal impairment (chronic kidney disease stage 3)?

A. Bendroflumethiazide 2.5 mg orally daily
B. Digoxin 125 micrograms orally daily
C. Fluoxetine 20 mg orally daily
D. Simvastatin 20 mg orally nightly
E. Verapamil hydrochloride m/r 120 mg orally daily

Answer: B.

Digoxin is mainly eliminated by renal excretion and there is a risk of toxicity if the dosage is not reduced as renal function deteriorates. Bendroflumethiazide becomes less effective as renal function deteriorates but does not require a dose reduction (unless there is evidence that dehydration is a contributory factor). Simvastatin should be used with caution if the eGFR falls below 30 mL/min/1.73 m^2. Verapamil is eliminated by hepatic metabolism. Fluoxetine does not require dose adjustment.

2.5. Which of the following aspects of a new drug is not considered by drug regulators but is considered by organisations concerned with health technology assessments such as the UK National Institute for Health Care and Excellence?

A. Manufacturing standards
B. Safety profile
C. Efficacy in treating the clinical indication
D. Cost-effectiveness
E. Patient information

Answer: D.

The role of national drug regulatory authorities is to ensure that any new medicine meets minimum acceptable standards of quality, safety and efficacy prior to being granted a market authorisation. It is not the role of the regulator to assess cost-effectiveness, which is devolved to national or local health technology assessments that may compare the new drug with other available treatment options.

Genomics and clinical practice 51
- Genomics and health care 51
- Treatment of genetic disease 54
- Ethics in a genomic age 55

We have entered a genomic era. Powerful new technologies are driving forward transformational change in health care. Genetic sequencing has evolved from the targeted sequencing of a single gene to the parallel sequencing of multiple genes or even the whole genome (an organism's complete set of genetic information). In addition to improving the chances of identifying a genetic cause of rare diseases, these technologies are increasingly directing therapies and, in the future, are likely to be used in the diagnosis and prevention of common diseases such as diabetes. In this chapter we explore the fundamentals of genomics, the basic principles underlying these new genomic technologies and how the data generated can be applied safely for patient benefit. We will review the use of genomic technology across a breadth of medical specialties, including obstetrics, paediatrics, oncology and infectious disease, and consider how health care is being transformed by these new genomic technologies. Finally, we will consider the ethical impact that these technologies are likely to have, both for the individual and for their wider family.

The fundamental principles of genomics

The packaging of genes: DNA, chromatin and chromosomes

Genes are functional units encoded in double-stranded deoxyribonucleic acid (DNA), packaged as chromosomes and located in the nucleus of the cell: a membrane-bound compartment found in all cells except erythrocytes and platelets (Fig. 3.1). DNA consists of a linear sequence of four bases: adenine (A), cytosine (C), thymine (T) and guanine (G). It forms a 'double helix', a twisted ladder-like structure formed from two complementary strands of DNA joined by hydrogen bonds between bases on the opposite strand. These bonds can form only between a C and a G base or an A and a T base. It is this feature of DNA that enables faithful DNA replication and is the basis for many of the technologies designed to interrogate the genome: when the DNA double helix 'unzips', one strand can act as a template for the creation of an identical strand.

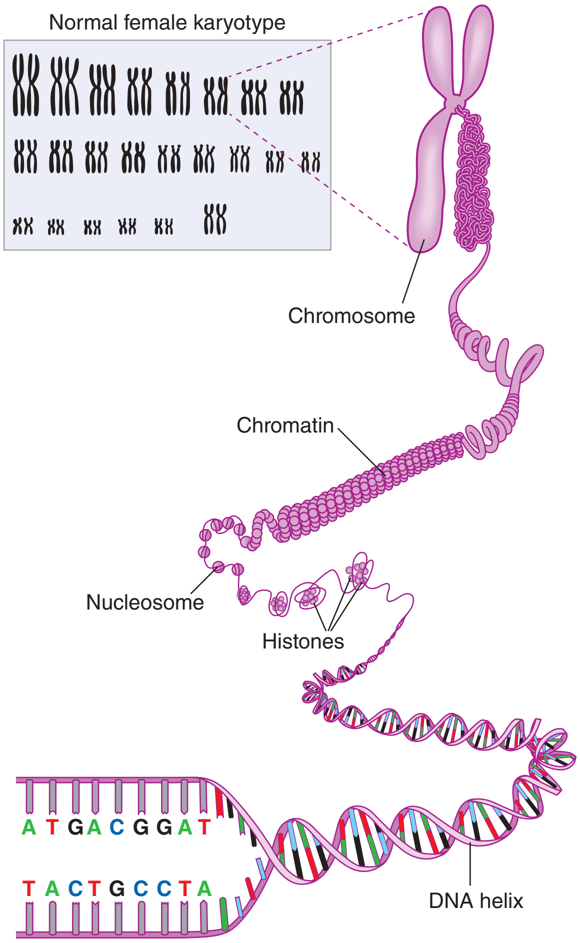

Fig. 3.1 The packaging of DNA, genes and chromosomes. From bottom to top: the double helix and the complementary DNA bases; chromatin; and a normal female chromosome pattern – the karyotype.

A single copy of the human genome comprises approximately 3.1 billion base pairs of DNA, wound around proteins called histones. The unit consisting of 147 base pairs wrapped around four different histone proteins is called the nucleosome. Sequences of nucleosomes (resembling a string of beads) are wound and packaged to form chromatin. Tightly wound, densely packed chromatin which stains deeply is called heterochromatin and open, less tightly wound chromatin which stains poorly is called euchromatin (the differences between them are discussed below).

The chromatin is finally packaged into the chromosomes. Humans are diploid organisms which means that the nucleus contains two copies of the genome. These are visible microscopically as 23 chromosome pairs (known as the karyotype). Chromosomes 1 through to 22 are known as the autosomes and consist of chromosome pairs which carry the same genes arranged in the same order. The 23rd 'pair' of chromosomes are the two sex chromosomes: females have two X chromosomes and males an X and Y chromosome. A normal female karyotype is therefore written as 46,XX and a normal male is 46,XY.

From DNA to protein

Genes are functional elements within the chromosome that are capable of transmitting information from the DNA template via the production of messenger ribonucleic acid (mRNA) to the production of proteins. Proteins carry out all the functions necessary for life, acting as biochemical catalysts, hormones, enzymes, structural support, and in the synthesis of new cellular constituents and the initiation of cell death. The human genome contains over 20 000 genes, although many of these are inactive or silenced in different cell types, reflecting the variable gene expression responsible for cell-specific characteristics. Gene expression in its simplest sense means that a gene produces a corresponding protein. The central dogma is the pathway describing the basic steps of protein production: transcription, splicing, translation and protein modification (Fig. 3.2). Although this is now recognised as an over-simplification (contrary to this linear relationship, a single gene will often encode many different proteins), it remains a useful starting point to explore protein production.

Transcription: DNA to messenger RNA

Transcription is the first step in protein production. In transcription, the information in DNA is transferred into another chemical form: ribonucleic acid (RNA).

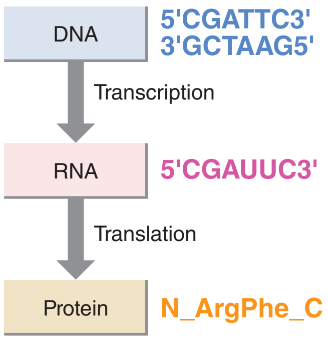

Fig. 3.2 The central dogma of protein production. Double-stranded DNA as a template for single-stranded RNA, which codes for the production of a peptide chain of amino acids. Each of these chains has an orientation. For DNA and RNA, this is 5′ to 3′. For peptides, this is N-terminus to C-terminus.

As in DNA, the information in RNA is also written in the form of a nucleotide sequence. However, RNA differs from DNA in three main ways:

- RNA is single-stranded. This makes it less stable than DNA.
- The sugar residue within the nucleotide is ribose, rather than deoxyribose.
- It contains uracil (U) in place of thymine (T). This means that uracil forms base pairs with adenine.

Transcription begins when an enzyme called RNA polymerase binds to a segment of DNA at the start of the gene: this is called the promoter. The RNA polymerase opens and unwinds a small section of the DNA double helix to expose the bases on each DNA strand. One of the strands then acts as a template for the synthesis of an RNA molecule, so that the incoming ribonucleotide is complementary to the DNA template. In protein-coding genes this is known as messenger RNA (mRNA).

The RNA polymerase moves stepwise along the DNA, unwinding the DNA to expose a new region of the template strand for complementary base-pairing, and catalyses the formation of the phosphodiester bonds that link the nucleotides together. In this way, the RNA chain – the transcript – grows by one nucleotide at a time.

A DNA sequence close to the end of the gene, called the polyadenylation signal, acts as a signal for termination of the RNA transcript (Fig. 3.3).

The activity of RNA polymerase is regulated by transcription factors. These proteins bind to specific DNA sequences at the promoter or to enhancer elements that may be many thousands of base pairs (bp) away from the promoter; a loop in the chromosomal DNA brings the enhancer close to the promoter, enabling the bound proteins to interact. The human genome encodes more than 1200 different transcription factors. Damaging gene variants (also referred to as pathogenic variants or mutations) within transcription factors, promoters and enhancers can cause disease. For example, the blood disorder alpha-thalassaemia is usually caused by gene deletions (see Box 3.6). However, it can also result from a pathogenic variant in an enhancer located more than 100 000 bp from the α-globin gene promoter, leading to greatly reduced transcription.

Gene activity, or expression, is influenced by a number of complex interacting factors, including the accessibility of the gene promoter to transcription factors. DNA can be modified by the addition of a methyl group (CH$_3$) to cytosine molecules (methylation). If DNA methylation occurs in promoter regions, transcription is silenced, as methyl cytosines are usually not available for transcription factor binding.

A second mechanism determining promoter accessibility is the structural configuration of chromatin, which is determined by a process called histone modification: The histone protein tail is a floppy peptide region at the start of each histone protein. If certain molecules, such as methyl groups (CH$_3$) or acetyl groups (CH$_3$CO) bind to specific amino acid residues in the histone protein tail, these can either disrupt or strengthen histone–DNA interactions.

If the modification disrupts the histone–DNA interactions, nucleosomes will unwind into euchromatin. Since euchromatin has an open structure, gene promoters become accessible to RNA polymerase and transcription factors and are transcriptionally active. This can be compared to the pages of a book, which move freely and are therefore possible to read.

If the modification strengthens histone–DNA interactions, tightly packed heterochromatin is produced. This is densely packed (like book pages that are stuck together) and therefore transcriptionally silent. Euchromatin is prevalent in cells that are active in the transcription of many of their genes while heterochromatin is most abundant in cells that are less active or inactive.

Modifications of DNA and histone protein tails are termed epigenetic ('epi-' meaning 'above' the genome), as they do not alter the primary sequence of the DNA code but have biological significance in chromosomal function. Abnormal epigenetic changes are increasingly recognised as important events in the progression of cancer, allowing expression of normally silenced genes that result in cancer cell de-differentiation and proliferation. They also afford therapeutic targets. For instance, the histone deacetylase inhibitor vorinostat has been successfully used to treat cutaneous T-cell lymphoma due to the re-expression of genes that had previously been silenced in the tumour. These genes encode transcription factors that promote T-cell differentiation as opposed to proliferation, thereby causing tumour regression.

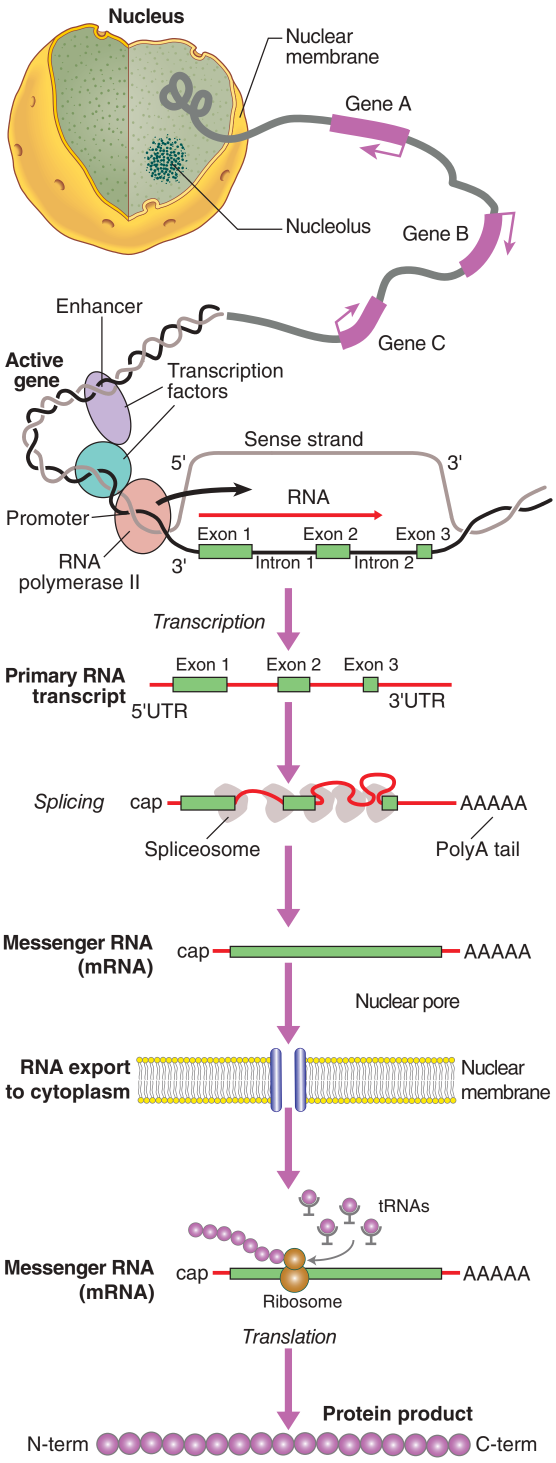

Fig. 3.3 RNA synthesis and its translation into protein. Gene transcription involves binding of RNA polymerase II to the promoter of genes being transcribed with other proteins (transcription factors) that regulate the transcription rate. The primary RNA transcript is a copy of the whole gene and includes both introns and exons, but the introns are removed within the nucleus by splicing and the exons are joined to form the messenger RNA (mRNA). Prior to export from the nucleus, a methylated guanosine nucleotide is added to the 5′ end of the RNA ('cap') and a string of adenine nucleotides is added to the 3′ ('polyA tail'). This protects the RNA from degradation and facilitates transport into the cytoplasm. In the cytoplasm, the mRNA binds to ribosomes and forms a template for protein production. (tRNA = transfer RNA; UTR = untranslated region)

RNA splicing, editing and degradation

Transcription produces an RNA molecule that is a copy of the whole gene, termed the primary or nascent transcript. This nascent transcript then undergoes splicing, whereby regions not required to make protein (the intronic regions) are removed while those segments that are necessary for protein production (the exonic regions) are retained and rejoined (Fig. 3.3).

Splicing is a highly regulated process that is carried out by a multimeric protein complex called the spliceosome. Following splicing, the mRNA molecule is exported from the nucleus and used as a template for protein synthesis. Many genes produce more than one form of mRNA (and thus protein) by a process termed alternative splicing, in which different combinations of exons are joined together. Different proteins from the same gene can have entirely distinct functions. For example, in thyroid C cells the calcitonin gene produces mRNA encoding the osteoclast inhibitor calcitonin, but in neurons the same gene produces an mRNA with a different complement of exons via alternative splicing that encodes a neurotransmitter, calcitonin-gene-related peptide.

Translation and protein production

During translation, the mRNA is ‘read’ according to the genetic code, which relates the DNA sequence to the amino acid sequence in proteins. The segment of mRNA containing the code that directs synthesis of a protein product is called the open reading frame (ORF).

Each group of three bases in mRNA makes up a codon, and each codon specifies a particular amino acid (hence, it is a triplet code). The mRNA sequence is thus used as a template to assemble the chain of amino acids that form a protein.

There are 64 different codons with some redundancy in the system: 61 codons encode one of the 20 amino acids, and the remaining three codons – UAA, UAG and UGA (known as stop codons) – cause termination of the growing polypeptide chain. These codons are shown in Figure 3.4. The ORF contains the whole genetic code for making a protein up to the stop codon – you can think of it a bit like an open book that you keep reading until you see ‘The End’ (the stop codon). The ORFs in humans most commonly start with the amino acid methionine. All mRNA molecules have domains before and after the ORF called the 5′ (pronounced ‘5 prime’) untranslated region (UTR) and 3′UTR, respectively. The start of the 5′UTR contains a cap structure that protects mRNA from enzymatic degradation, while other elements within the 5′UTR are required for efficient translation. The 3′UTR also contains elements that regulate efficiency of translation and mRNA stability, including a stretch of adenine bases known as a polyA tail (see Fig. 3.3).

Fig. 3.4 The genetic code. The figure shows the code for translating each nucleotide triplet in mRNA into an amino acid or a termination signal (stop codon) in a protein. The AUG codon usually serves as the start codon to initiate translation of a protein and codes for methionine. Three-letter short codes signify the following amino acids: Ala – alanine; Arg – arginine; Asn – asparagine; Asp – aspartic acid; Cys – cysteine; Gln – glutamine; Glu – glutamic acid; Gly – glycine; His – histidine; Ile – isoleucine; Leu – leucine; Lys – lysine; Met – methionine; Phe – phenylalanine; Pro – proline; Ser – serine; Thr – threonine; Trp – tryptophan; Tyr – tyrosine; Val – valine. UAA, UAG and UGA code for termination of the protein (stop codons).

After transcription, the mRNAs leave the nucleus via nuclear pores and associate with ribosomes, which are the sites of protein production (see Fig. 3.3). Ribosomes are made of protein and RNA and each ribosome consists of two subunits, one small (40S) and one large (60S). During protein synthesis, the ribosome attaches to the membrane of the endoplasmic reticulum (ER), a complex tubular structure that surrounds the nucleus. Ribosomes bind to the mRNA molecules and translate the codons in mRNA into the amino acid sequence needed to make the corresponding protein. During translation, a different RNA molecule known as transfer RNA (tRNA) binds a specific amino acid via an anticodon of three nucleotides that is complementary to the codon in mRNA. Having bound the amino acid, it delivers it to the ribosome so that the newly synthesised protein can be assembled in a stepwise fashion. The ribosome moves along the mRNA, continuing to add one amino acid at a time to the growing polypeptide chain. When the amino acid attached to each tRNA molecule is added to the chain, the tRNA is released back into the cytosol (see Fig. 3.3).

Proteins synthesised on these ribosomes are translocated into the lumen of the ER, where they undergo folding and processing. From here, the protein may be transferred to the Golgi apparatus, where it undergoes post-translational modifications, such as glycosylation (covalent attachment of sugar moieties), to form the mature protein that can be exported into the cytoplasm or packaged into vesicles for secretion. The clinical importance of post-translational modification of proteins is shown by the severe developmental, neurological, haemostatic and soft tissue abnormalities that are associated with the many different congenital disorders of glycosylation. Post-translational modifications can also be disrupted by the synthesis of proteins with abnormal amino acid sequences. For example, the most common *CFTR* gene variant that causes cystic fibrosis (ΔF508) results in an abnormal protein that cannot be exported from the ER and Golgi.

Non-coding RNA

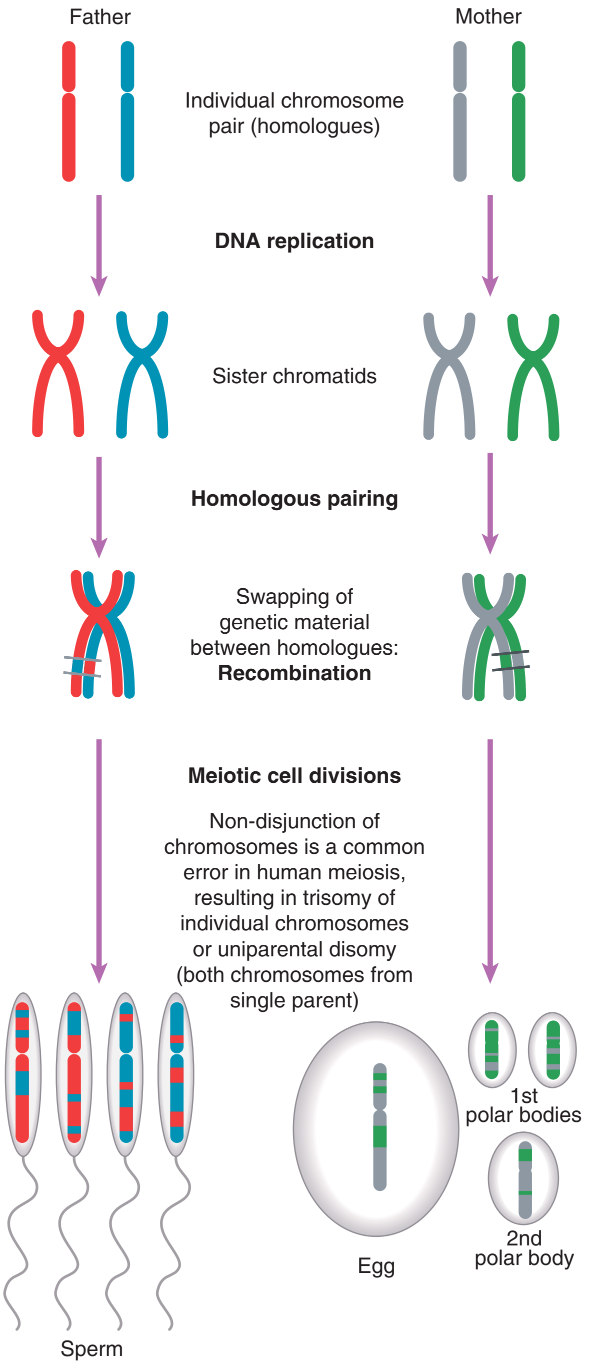
Approximately 4500 genes in humans encode non-coding RNAs (ncRNAs) rather than proteins. There are various categories of ncRNA, including transfer RNA (tRNA), ribosomal RNA (rRNA), ribozymes and microRNA (miRNA). The miRNAs, which number over 1000, have a role in post-translational gene expression: they bind to mRNAs, typically in the 3′UTR, promoting target mRNA degradation and gene silencing. Together, miRNAs affect over half of all human genes and have important roles in normal development, cancer and common degenerative disorders. This is the subject of considerable research interest at present.

Cell division, differentiation and migration

In normal tissues, molecules such as hormones, growth factors and cytokines provide the signal to activate the cell cycle: a controlled programme of biochemical events that culminates in cell division. In all cells of the body, except the gametes (the sperm and egg cells, also known as the germline), mitosis completes cell division, resulting in two diploid daughter cells. In contrast, the sperm and egg cells complete cell division with meiosis, resulting in four haploid (containing one set of chromosomes) daughter cells (Fig. 3.5).

The stages of cell division in somatic cells (not the cells that make egg and sperm) are shown below:

- Cells not committed to mitosis are said to be in G_0.
- Cells committed to mitosis must go through the preparatory phase of interphase consisting of G_1, S and G_2:



Father
Mother
Individual chromosome pair (homologues)
DNA replication
Sister chromatids
Homologous pairing
Swapping of genetic material between homologues: Recombination
Meiotic cell divisions
Non-disjunction of chromosomes is a common error in human meiosis, resulting in trisomy of individual chromosomes or uniparental disomy (both chromosomes from single parent)
1st polar bodies
Egg
2nd polar body
Sperm

Fig. 3.5 Meiosis and gametogenesis. The main chromosomal stages of meiosis in both males and females. A single homologous pair of chromosomes is represented in different colours. The final step is the production of haploid germ cells. Each round of meiosis in the male results in four sperm cells; in the female, however, only one egg cell is produced, as the other divisions are sequestered on the periphery of the mature egg as peripheral polar bodies.

  - G_1 (first gap): synthesis of the cellular components necessary to complete cell division
  - S (synthesis): DNA replication producing identical copies of each chromosome called the sister chromatids
  - G_2 (second gap): repair of any errors in the replicated DNA before proceeding to mitosis.
- *Mitosis* (M) consists of four phases:
  - Prophase: the chromosomes condense and become visible, the centrioles move to opposite ends of the cell and the nuclear membrane disappears.
  - Metaphase: the centrioles complete their migration to opposite ends of the cell and the chromosomes – consisting of two identical sister chromatids – line up at the equator of the cell.
  - Anaphase: spindle fibres attach to the chromosome and pull the sister chromatids apart.
  - Telophase: the chromosomes decondense, the nuclear membrane reforms and two daughter cells – each with 46 chromosomes – are formed.

The progression from one phase to the next is tightly controlled by cell-cycle checkpoints. For example, the checkpoint between G_2 and mitosis ensures that all damaged DNA is repaired prior to segregation of the chromosomes. Failure of these control processes is a crucial driver in the pathogenesis of cancer, as discussed on page 160.

- Meiosis is a special, gamete-specific, form of cell division (see Fig. 3.5). Like mitosis, meiosis consists of four phases (prophase, metaphase, anaphase and telophase) but differs from mitosis in the following ways:
  - It consists of two separate cell divisions known as meiosis I and meiosis II.
  - It reduces the chromosome number from the diploid to the haploid number so that when a sperm cell fertilises the egg, the resulting zygote will return to a diploid, 46, chromosome complement. This reduction to the haploid number occurs at the end of meiosis II.
  - The 92 chromosome stage consists of 23 homologous pairs of sister chromatids, which then swap genetic material, a process known as recombination. This occurs at the end of MI prophase and ensures that the chromosome that a parent passes to his or her offspring is a mix of the chromosomes that the parent inherited from his or her own mother and father.

The individual steps in meiotic cell division are similar in males and females. However, the timing of the cell divisions is very different. In females, meiosis begins in fetal life but does not complete until after ovulation. A single meiotic cell division can therefore take more than 40 years to complete. As women become older, the separation of chromosomes at meiosis II becomes less efficient. That is why the risk of trisomies (p. 42) due to non-disjunction grows greater with increasing maternal age. In males, meiotic division does not begin until puberty and continues throughout life. In the testes, both meiotic divisions are completed in a matter of days.

Mitochondria

The mitochondrion is the main site of energy production within the cell. Mitochondria have a distinctive structure with functionally distinct inner and outer membranes (Fig. 3.6A). Each mitochondrion contains 2–10 copies of a 16-kilobase (kB) double-stranded circular DNA molecule (mtDNA). This mtDNA contains 13 protein-coding genes, all involved in the respiratory chain, as well as the ncRNA genes required for production of transfer RNA (tRNA) and ribosomal RNA (rRNA), both of which are required for protein synthesis within the mitochondria (Fig. 3.6B). The mutational rate of mtDNA is relatively high due to the lack of protection by chromatin. Several mtDNA diseases characterised by defects in adenosine triphosphate (ATP) production have been described. Mitochondria are most numerous in cells with high metabolic demands, such as muscle, retina and the basal ganglia, and these tissues tend to be the ones most severely affected in mitochondrial diseases, which are discussed later in this chapter. While some mitochondrial diseases are caused by pathogenic variants in mtDNA, others are caused by pathogenic variants in nuclear genes, which encode proteins that are imported into the mitochondrion and play critical roles in energy production. Mitochondria produce energy in the form of ATP. The ATP is mostly derived from the metabolism of glucose and fat (Fig. 3.6C). Glucose cannot enter mitochondria directly but is first metabolised to pyruvate via glycolysis. Pyruvate is then imported into the mitochondrion and metabolised to acetyl-co-enzyme A (acetyl-CoA). The membranes create two compartments: the inter-membrane compartment, which plays a crucial role in the electron transport chain, and the inner compartment (or matrix), which contains mitochondrial DNA and the enzymes responsible for the citric acid (Krebs) cycle and the fatty acid β-oxidation cycle. **B** Mitochondrial DNA. The mitochondrion contains several copies of a circular double-stranded DNA molecule, which has a non-coding region, and a coding region that encodes the genes responsible for energy production, mitochondrial transfer RNA (tRNA) molecules and mitochondrial ribosomal RNA (rRNA) molecules. **C** Mitochondrial energy production. Fatty acids (FA) enter the mitochondrion conjugated to carnitine by carnitine-palmityl transferase type 1 (CPT I) and, once inside the matrix, are unconjugated by CPT II to release free fatty acids (FFA). These are broken down by the β-oxidation cycle to produce acetyl-co-enzyme A (acetyl-CoA). Pyruvate can enter the mitochondrion directly and is metabolised by pyruvate dehydrogenase (PDH) to produce acetyl-CoA. The acetyl-CoA enters the citric acid (Krebs cycle), leading to the production of NADH and the reduced form of flavine adenine dinucleotide ($FADH_2$), which are used by proteins in the electron transport chain to generate a hydrogen ion gradient across the inter-membrane compartment. Oxidation of NADH and $FADH_2$ by proteins I and II, respectively, releases electrons (e), and the energy released is used to pump protons into the inter-membrane compartment. Co-enzyme Q_{10}/ubiquinone (Q) is an intensely hydrophobic electron carrier that is mobile within the inner membrane. As electrons are exchanged between proteins in the chain, more protons are pumped across the membrane until the electrons reach complex IV (cytochrome oxidase), which uses the energy to reduce oxygen to water. The hydrogen ion gradient is used to produce ATP by the enzyme ATP synthase, which consists of a proton channel and catalytic sites for the synthesis of ATP from ADP. When the channel opens, hydrogen ions enter the matrix down the concentration gradient, and energy is released that is used to make ATP. (ATP = adenosine triphosphate; Cyt C = cytochrome c; $FADH_2$ = the reduced form of flavine adenine dinucleotide; NADH = the reduced form of nicotinamide adenine dinucleotide; PDH = pyruvate dehydrogenase)

and are transported into the mitochondria and sequentially catabolised by a process called β-oxidation to also produce acetyl-CoA. The acetyl-CoA from both pyruvate and fatty acid oxidation is used in the citric acid (Krebs) cycle – a series of enzymatic reactions that ultimately produces CO_2, the reduced form of nicotinamide adenine dinucleotide (NADH) and the reduced form of flavine adenine dinucleotide ($FADH_2$). Both NADH and $FADH_2$ then donate electrons to the respiratory chain. Here these electrons are transferred via a complex series of reactions, resulting in the formation of a proton gradient across the inner mitochondrial membrane. The gradient is used by an inner mitochondrial membrane protein, ATP synthase, to produce ATP, which is then transported to other parts of the cell. Dephosphorylation of ATP produces the energy required for many cellular processes.

Cell death, apoptosis and senescence

With the exception of stem cells, human cells have only a limited capacity for cell division. The Hayflick limit (named after the anatomist who discovered this) is the number of divisions a cell population can go through in culture before division stops and enters a state known as senescence. Senescence is a potent anti-tumour mechanism since it prevents abnormal cells from replicating; however, senescent cells are not dead and may persist until they are removed by immune processes. If their presence is prolonged, they may have a deleterious effect on tissues. This ‘biological clock’ is of great interest in the study of the normal ageing process. Rare human diseases associated with premature ageing, called progeroid syndromes, have been very helpful in identifying the importance of DNA repair mechanisms in senescence. For example, in Werner syndrome, a DNA helicase (an enzyme that separates the two DNA strands) is mutated, leading to failure of DNA repair and premature ageing.

Cell death can be broadly classified into programmed cell death and unprogrammed or necrotic cell death. While necrotic cell death is a disordered process resulting from injury or attack, programmed cell death occurs when cells are no longer needed and is mediated through activation of an ordered intracellular death programme called apoptosis. Apoptosis occurs in normal tissues and plays an important role in development, tissue remodelling and the immune response. The signal that triggers apoptosis is specific to each tissue or cell type. This signal activates enzymes, called caspases, which actively destroy cellular components, including chromosomal DNA. This degradation results in cell death, but the cellular corpse contains characteristic vesicles called apoptotic bodies. The cell corpse is then recognised and removed by phagocytic cells of the immune system, such as macrophages, in a manner that does not provoke an inflammatory response.

In contrast to apoptosis, necrosis is a pathological process of cell death in which the cellular environment loses one or more of the components necessary for cell viability. In necrosis, cells swell and then rupture, often leading to the cell contents causing inflammation in nearby cells. Hypoxia is probably the most common cause of necrosis.

Genomics, health and disease

Classes of genetic variant

There are many different classes of variation in the human genome, categorised by the size of the DNA segment involved and/or by the mechanism giving rise to the variation.

Nucleotide substitutions, insertions and deletions

The substitution of one nucleotide for another is the most common type of genomic variation. This is caused by misincorporation of a nucleotide during DNA synthesis or by chemical modification of the base. Insertion/deletion variants occur when one or more nucleotides are inserted or lost in a DNA sequence. When these variants occur within the ORF of a protein-coding gene, there are several potential consequences:

- *Synonymous variants*. These result in a change in the codon that doesn't alter the amino acid. This is particularly common when the third base of a codon is changed. For example, AAG and AAA both encode the amino acid lysine, as illustrated in Figure 3.4 and Figure 3.7A.
- *Non-synonymous (also known as a missense) variant*. These result in a change in the codon and the encoded amino acid. An example would be a change from AAG to CAG, changing the amino acid from lysine (Fig. 3.7A) to glutamine (Fig. 3.7C).
- *Insertion and deletion (indel) variants*. These variants occur when one or more nucleotides are inserted or lost in a DNA sequence. If an indel change affects one or two nucleotides within the ORF of a protein-coding gene, this can have serious consequences because the triplet nucleotide sequence of the codons is totally disrupted, resulting in a frameshift variant. The effect of such a variant is typically severe because the amino acid sequence is totally disrupted, as shown in Box 3.1 and Figure 3.7D. However, if a multiple of three nucleotides is involved, this is 'in frame' and does not disturb the triplet nucleotide sequence, meaning that the next codon can be read as normal. The effect of these variants on the gene may therefore be minor.
- *Stop-gain (or nonsense) variant*. These variants introduce a premature stop codon, resulting in truncation of the protein. An example would be AAG to TAG changing a lysine (Fig. 3.7A) to a stop codon (Fig. 3.7E). These variants may not only cause an abnormal truncated protein but also result in nonsense mediated RNA decay (NMD), resulting in haploinsufficiency due to degradation of the abnormal allele. This is a common mechanism of disease in type I osteogenesis imperfecta (Ch. 25).
- *Splice-site variants*. These variants occur at the junction between exons and introns and can affect either the splice donor site or the splice acceptor site. In almost all cases the splice donor site at the start

Fig. 3.7 Different types of genetic variant affecting coding exons. **A** Normal sequence. **B** A synonymous nucleotide substitution changing the third base of a codon; the resulting amino acid sequence is unchanged. **C** A missense variant in which the nucleotide substitution results in a change in a single amino acid from the normal sequence (AAG) encoding lysine to glutamine (CAG). **D** Insertion of a G residue (boxed) causes a frameshift variant, completely altering the amino acid sequence downstream. This usually results in a loss-of-function variant. **E** A nonsense variant resulting in a single nucleotide change from a lysine codon (AAG) to a premature stop codon (TAG). See Figure 3.4 for the amino acids corresponding to the three-letter short codes.

i 3.1 Classes of genetic variant

The classes of genetic variant can be illustrated using the sentence‘THE FAT FOX WAS ILL COS SHE ATE THE OLD CAT’

Synonymous	
Silent polymorphism with no amino acid change	THE FAT FOX WAS ILL COS SHE ATE THE OLD KAT where the C is replaced with a K but the meaning remains the same
Non-synonymous	
Causing an amino acid change	THE FAT BOX WAS ILL COS SHE ATE THE OLD CAT where the F of FOX is replaced by B and the original meaning of the sentence is lost
Stop-gain (also called a nonsense variant)	
Causing the generation of a premature stop codon	THE CAT where the F of FAT is replaced by a C, generating a premature stop codon
Indel	
Where the bases are either inserted or deleted; disruption of the reading frame is dependent on the number of bases inserted or deleted	THE FAT FOX WAS ILL ILL COS SHE ATE THE OLD CAT where the insertion of three bases results in maintenance of the reading frame THE FAT FOX WAW ASI LLC OSS HEA TET HEO LDC AT where the insertion of two bases results in disruption of the reading frame

of an intron is a GT sequence and the acceptor site at the end of an intron is an AG sequence, as illustrated in Figure 3.8. Pathogenic variants affecting either the splice donor or splice acceptor site can stop the introns being removed and the exons being joined together normally. This can lead to exons being completely removed (exon skipping) or to an abnormal or a truncated protein being produced, as shown in Figure 3.8B. In some instances where a premature stop codon is introduced as the result of a splice-site variant, the nonsense-mediated mRNA decay (NMD) pathway may be activated and the abnormal RNA degraded to prevent production of an abnormal and potentially harmful protein, as described for stop gain (or nonsense) variants in exons.

Simple tandem repeat variants

Variations in the length of simple tandem repeats of DNA are thought to arise as the result of slippage of DNA during meiosis. These are termed microsatellite (small) or minisatellite (larger) repeats. These repeats are unstable and can expand or contract in different generations. This instability is proportional to the size of the original repeat, in that longer repeats tend to be more unstable. Many microsatellites and minisatellites occur in introns or in chromosomal regions between genes and have no obvious adverse effects. However, some genetic diseases are caused by microsatellite repeats that result in duplication of amino acids within the affected gene product or affect gene expression (Box 3.2).

Copy number variations

Variation in the number of copies of an individual segment of the genome from the usual diploid (two copies) content can be categorised by the size of the segment involved. Rarely, individuals may gain or lose a whole chromosome, which is called aneuploidy. Having only one of a particular chromosome is called monosomy and having an extra one is called trisomy. Such numerical chromosome anomalies most commonly occur by a process known as non-disjunction, where pairs of homologous chromosomes do not separate at meiosis II (p. 38). Common trisomies include Down syndrome (trisomy 21), Edwards syndrome (trisomy 18) and Patau syndrome (trisomy 13). Monosomy of the autosomes (present in all the cells, as opposed to in a mosaic distribution) is not compatible with life, but Turner syndrome, in which there is monosomy for the X chromosome, affects approximately 1 in 2500 live births (Box 3.3).

Large insertions or deletions of chromosomal DNA also occur and are usually associated with a learning disability and/or congenital malformations. Such structural chromosomal anomalies usually arise as the result of one of two different processes, explained below:

- non-homologous end-joining
- non-allelic homologous recombination.

Random double-stranded breaks in DNA are a necessary process in meiotic recombination and also occur during mitosis at a predictable rate. The rate of these breaks is dramatically increased by exposure to ionising radiation. When such breaks take place, they are usually repaired accurately by DNA repair mechanisms within the cell. However, in a proportion of breaks, segments of DNA that are not normally contiguous will be joined (‘non-homologous end-joining’). If the joined fragments are from different chromosomes, this results in a translocation. If they are from the same chromosome, this will result in inversion, duplication or deletion of a chromosomal fragment (Fig. 3.9). Large insertions and deletions may be cytogenetically visible as chromosomal deletions or duplications. If the anomalies are too small to be detected by microscopy (smaller than around 5 million base pairs), they are termed microdeletions and microduplications. Many microdeletion syndromes have been described and most result from ‘non-allelic homologous recombination’ between repeats of highly similar DNA sequences. This means that recurrent chromosome anomalies – and clinical syndromes – occur in unrelated individuals (see Fig. 3.9 and Box 3.3).

Consequences of genomic variation

The consequence of an individual genomic variant depends on many factors, including the variant type, the nature of the gene product and the position of the variant in the protein. Variants can have profound or subtle effects on gene and cell function. Variants that have profound effects are responsible for ‘classical’ genetic diseases, whereas those with subtle effects may contribute to the pathogenesis of common disease where there is a genetic component, such as diabetes.

- *Neutral variants* have no effect on quality or type of protein produced.
- *Loss-of-function variants* result in loss or reduction in the normal protein function. Whole-gene deletions are the archetypal loss-of-function variants but stop-gain or indel variants (early in the ORF), missense variants affecting a critical domain and splice-site variants can also result in loss of protein function.
- *Gain-of-function variants* result in a gain of protein function. They are typically non-synonymous variants that alter the protein structure, leading to activation/alteration of its normal function either by causing it to interact with a novel substrate or by changing its normal function.
- *Dominant negative variants* are the result of non-synonymous substitutions or in-frame deletions/duplications but may also be caused by triplet repeat expansions. Dominant negative variants are heterozygous (present on one allele) changes that result in the production of an abnormal protein that interferes with the function of the normal protein.

Normal genomic variation

We each have 3–5 million variants in our genome, occurring approximately every 300 bases. These variants are mostly polymorphisms, arising in more than 1% of the population; they have no or subtle effects on gene and cell function and are not associated with an increased risk of disease. Polymorphisms can occur within exons, introns or the

Fig. 3.8 Splice-site variants. **A** The normal sequence is shown, illustrating two exons, and intervening intron (blue) with splice donor (GT) and splice acceptor sites (AG) underlined. Normally, the intron is removed by splicing to give the mature messenger RNA that encodes the protein. **B** In a splice-site variant the donor site is mutated. As a result, splicing no longer occurs, leading to read-through of the mRNA into the intron which contains a premature termination codon downstream of the variant. Splice-site mutations can also lead to complete loss of one or more exons (exon skipping). See Figure 3.4 for the amino acids corresponding to the three-letter short codes.

3.2 Diseases associated with triplet and other repeat expansions*

	Repeat	No. of repeats		Gene	Gene location	Inheritance
		Normal	Mutant			
Coding repeat expansions						
Huntington disease	[CAG]	6–34	> 35	*Huntingtin*	4p16	AD
Spinocerebellar ataxia (type 1)	[CAG]	6–39	> 40	*Ataxin*	6p22–23	AD
Spinocerebellar ataxia (types 2, 3, 6, 7)	[CAG]	Various	Various	Various	Various	AD
Dentatorubral-pallidoluysian atrophy	[CAG]	7–25	> 49	*Atrophin*	12p12–13	AD
Machado–Joseph disease	[CAG]	12–40	> 67	*MJD*	14q32	AD
Spinobulbar muscular atrophy	[CAG]	11–34	> 40	Androgen receptor	Xq11–12	XL recessive
Non-coding repeat expansion						
Myotonic dystrophy	[CTG]	5–37	> 50	*DMPK-3′ UTR*	19q13	AD
Friedreich ataxia	[GAA]	7–22	> 200	*Frataxin-intronic*	9q13	AR
Progressive myoclonic epilepsy	[CCCCGCCCCGCG]$_{4-8}$	2–3	> 25	*Cystatin B-5′ UTR*	21q	AR
Fragile X mental retardation	[CGG]	5–52	> 200	*FMR1–5′ UTR*	Xq27	XL dominant
Fragile site mental retardation 2 (FRAXE)	[GCC]	6–35	> 200	*FMR2*	Xq28	XL, probably recessive

*The triplet repeat diseases fall into two major groups: those with disease stemming from expansion of [CAG]n repeats in coding DNA, resulting in multiple adjacent glutamine residues (polyglutamine tracts), and those with non-coding repeats. The latter tend to be longer. Unaffected parents usually display 'pre-mutation' allele lengths that are just above the normal range. (AD/AR = autosomal dominant/recessive; UTR = untranslated region; XL = X-linked)

intergenic regions that comprise 98%–99% of the human genome. The most frequent variants are single nucleotide polymorphisms, or SNP (pronounced 'snip'), describing the substitution of a single base. When considering human genetic variation, it is also important to bear in mind that the human genome is present in two copies in our germline cells. An allele is one of the two copies of DNA sequence at a given genomic location. Genetic variations can therefore be present on one or both alleles.

Polygenic inheritance

Polygenic inheritance refers to the situation whereby susceptibility to a disease is caused by the combined action of multiple individual genetic variants, each with a small effect on disease susceptibility as compared to a monogenic or familial disease that is caused by a pathogenic variant in a single gene. This is discussed in more detail later in the chapter.

3.3 Chromosome and contiguous gene disorders

Disease	Locus	Incidence	Clinical features
Numerical chromosomal abnormalities			
Down syndrome (trisomy 21)	47,XY,+21 or 47,XX+21	1 in 800	Characteristic facies, IQ usually < 50, congenital heart disease, reduced life expectancy
Edwards syndrome (trisomy 18)	47,XY,+18 or 47,XX,+18	1 in 6000	Early lethality, characteristic skull and facies, frequent malformations of heart, kidney and other organs
Patau syndrome (trisomy 13)	47,XY,+13 or 47,XX,+13	1 in 15 000	Early lethality, cleft lip and palate, polydactyly, small head, frequent congenital heart disease
Klinefelter syndrome	47,XXY	1 in 1000	Phenotypic male, infertility, gynaecomastia, small testes
XYY	47,XYY	1 in 1000	Usually asymptomatic, some impulse control problems
Triple X syndrome	47,XXX	1 in 1000	Usually asymptomatic, may have reduced IQ
Turner syndrome	45,X	1 in 5000	Phenotypic female, short stature, webbed neck, coarctation of the aorta, primary amenorrhoea
Recurrent deletions, microdeletions and contiguous gene defects			
Di George/velocardiofacial syndrome	22q11.2	1 in 4000	Cardiac outflow tract defects, distinctive facial appearance, thymic hypoplasia, cleft palate and hypocalcaemia. Major gene seems to be *TBX1* (cardiac defects and cleft palate)
Prader–Willi syndrome	15q11–q13	1 in 15 000	Distinctive facial appearance, hyperphagia, small hands and feet, distinct behavioural phenotype. Imprinted region, deletions on paternal allele in 70% of cases
Angelman syndrome	15q11–q13	1 in 15 000	Distinctive facial appearance, absent speech, electroencephalogram (EEG) abnormality, characteristic gait. Imprinted region, deletions on maternal allele encompassing *UBE3A*
Williams syndrome	7q11.23	1 in 10 000	Distinctive facial appearance, supravalvular aortic stenosis, learning disability and infantile hypercalcaemia. Major gene for supravalvular aortic stenosis is *elastin*
Smith–Magenis syndrome	17p11.2	1 in 25 000	Distinctive facial appearance and behavioural phenotype, self-injury and rapid eye movement (REM) sleep abnormalities. Major gene seems to be *RAI1*

Fig. 3.9 Chromosomal analysis and structural chromosomal disorders. A Human chromosomes can be classed as metacentric if the centromere is near the middle, or acrocentric if the centromere is at the end. The bands of each chromosome are given a number, starting at the centromere and working out along the short (p) arm and long (q) arm. Translocations and inversions are balanced structural chromosome anomalies where no genetic material is missing but it is in the wrong order. Translocations can be divided into reciprocal (direct swap of chromosomal material between non-homologous chromosomes) and Robertsonian (fusion of acrocentric chromosomes). Deletions and duplications can also occur due to non-allelic homologous recombination (illustrated in part B). Deletions are classified as interstitial if they lie within a chromosome, and terminal if the terminal region of the chromosome is affected. Duplications can be either in tandem (where the duplicated fragment is inserted next to the region that is duplicated and orientated in the correct direction) or inverted (where the duplicated fragment is in the wrong direction). (N = normal; A = abnormal) B A common error of meiotic recombination, known as non-allelic homologous recombination, can occur (right panel), resulting in a deletion on one chromosome and a duplication in the homologous chromosome. The error is induced by tandem repeats in the DNA sequences (green), which can misalign and bind to each other, thereby ‘fooling’ the DNA into thinking the pairing prior to recombination is correct.

Evolutionary selection

Genetic variants play an important role in evolutionary selection, with advantageous variants resulting in positive selection via improved reproductive fitness, and variations that decrease reproductive fitness becoming excluded through evolution. Given this simple paradigm, it would be tempting to assume that common variants are all advantageous and all rare variants are deleterious. Unfortunately, it is often difficult to classify any single common variant as either advantageous or deleterious – or, indeed, neutral. Variants that are advantageous in early life and thus enhance reproductive fitness may be deleterious in later life. There may be variants that are advantageous for survival in particular conditions (for example famine or pandemic) that may be disadvantageous in more benign circumstances by causing a predisposition to obesity or autoimmune disorders.

Familial genetic disease

Familial genetic disease, also known as monogenic disease, is caused by constitutional variants which are inherited through the germline. It has been estimated that about 1% of the human population carries constitutional variants that are pathogenic and can directly cause disease or play a major role in the pathogenesis of disease.

It should be noted that different pathogenic variants can have different consequences, depending on the genetic mechanism underlying the disease. The variants that cause familial genetic disease can also vary in penetrance. Penetrance is defined as the proportion of individuals that carry a specific variant who develop the disease phenotype. A variant is said to be fully penetrant if all individuals who inherit that variant develop the disease. Inherited variants may show differences in expressivity. Expressivity describes the level of severity of each aspect of the disease phenotype. Both penetrance and expressivity can influence the number of affected individuals and the clinical manifestations of disease in each generation. Huntington disease is an example of a condition that is fully penetrant since everyone with a pathogenic expansion in the *HTT* gene will go on to develop the condition, if they live long enough. By contrast, pathogenic variants in the *BRCA2* gene tend not to be fully penetrant, such that some variants only cause tumours in about 50% of people. An example of variable expressivity is Marfan syndrome, caused by variants in the *FBN1* gene. Some people with pathogenic *FBN1* variants may have mild expression, such as being tall with long, slender fingers, while others who may carry the same variant can develop life-threatening aortopathy. This is thought to be due to an interaction with environmental factors or the effects of modifying genetic variants that influence the phenotype. An example of variable penetrance and expressivity of the autosomal codominant disease is α1-antitrypsin deficiency caused by loss-of-function variants in *SERPINA1* (Box 3.4). The severity of the disease is worse in homozygotes for the Z variant where α1-antitrypsin levels are much reduced as compared with compound heterozygotes for the Z/S variant. Another example of a difference in penetrance resulting from different pathogenic variants in the same gene is provided by Duchenne muscular dystrophy (DMD) and Becker muscular dystrophy (BMD), both of which are X-linked recessive disorders. Originally these were considered to be different diseases, but they are actually allelic disorders caused by different variants in the same gene, which encodes the dystrophin protein. In DMD, virtually no functional dystrophin is produced, resulting in progressive muscle weakness and early loss of ambulation, whereas in BMD, reduced levels of a truncated dystrophin protein are produced, which retains function, causing a much milder disorder (Box 3.5).

Constructing a family tree

The family tree – or pedigree – is a fundamental tool of the clinical geneticist, who will routinely take a three-generation family history, on both sides of the family, enquiring about details of all medical conditions in family members, consanguinity (literally 'with blood' meaning relatedness of parents), dates of birth and death, and any history of pregnancy loss or infant death.

3.4 Alpha-1-antitrypsin deficiency

Inheritance pattern

- Autosomal co-dominant

Genetic cause

- Two common variants in the *SERPINA1* gene: p.Glu342Lys and p.Glu264Val

Prevalence

- 1 in 1500–3000 of European ancestry

Clinical presentation

- Variable presentation from neonatal period through to adulthood
- Neonatal period: prolonged jaundice with conjugated hyperbilirubinaemia or (rarely) liver disease
- Adulthood: pulmonary emphysema and/or cirrhosis. Rarely, the skin disease, panniculitis, develops

Disease mechanism

- *SERPINA1* encodes α1-antitrypsin, which protects the body from the effects of neutrophil elastase. The symptoms of α1-antitrypsin deficiency result from the effects of this enzyme attacking normal tissue

Disease variants

- M variant: if an individual has normal *SERPINA1* genes and produces normal levels of α1-antitrypsin, they are said to have an M variant
- S variant: p.Glu264Val variant results in α1-antitrypsin levels reduced to about 40% of normal
- Z variant: p.Glu342Lys variant results in α1-antitrypsin levels reduced to about 10% of normal
- PiZZ: individuals who are homozygous for the p.Glu342Lys variant are likely to have α1-antitrypsin deficiency and the associated symptoms
- PiZS: individuals who are compound heterozygous for p.Glu342Lys and p.Glu264Val are likely to be affected, especially if they smoke, but usually to a milder degree

3.5 Duchenne and Becker muscular dystrophies

Inheritance pattern

- X-linked recessive

Genetic cause

- Pathogenic variants which disrupt the ORF of the dystrophin gene located at Xp21, resulting in a truncated protein that lacks the cysteine rich and C-terminal domains

Prevalence

- 1 in 3000–4000 live male births

Clinical presentation

- Delayed motor milestones
- Speech delay
- Grossly elevated creatine kinase levels (in the thousands)
- Ambulation is usually lost between the ages of 7 and 13 years
- Lifespan is reduced, with a mean age of death, usually from respiratory failure, in the mid-twenties
- Cardiomyopathy affects almost all boys with Duchenne muscular dystrophy and some female carriers

Disease mechanism

- *DMD* encodes dystrophin, a major structural component of muscle
- Dystrophin links the internal cytoskeleton to the extracellular matrix

Disease variants

- Becker muscular dystrophy is also caused by pathogenic variants in *DMD*, but these are in-frame deletions that result in production of a truncated dystrophin, which retains function but is expressed at lower and more variable levels than full-length dystrophin

Patterns of disease inheritance

The basic symbols and nomenclature used in drawing a pedigree are shown in Figure 3.10A. Examples of pedigrees with autosomal dominant, autosomal recessive and X-linked recessive and mitochondrial patterns of inheritance are illustrated in Figure 3.10B–E. Examples of human diseases with all these types of inheritance discussed in more detail elsewhere in this book are shown in Box 3.6.

Autosomal dominant inheritance

An example of autosomal inheritance is shown in Figure 3.10B. Here, the disease is inherited through four generations with affected individuals in each generation. Both males and females are affected in approximately equal numbers and the risk of passing the disease from an affected individual in one generation to offspring in the next generation is 50% independent of gender.

Autosomal recessive inheritance

In this case, both copies (alleles) of a gene must be mutated before the disease is manifest in an individual. An example of autosomal recessive inheritance is shown in Figure 3.10C. An affected individual inherits one mutant allele from each of their parents, who are unaffected carriers for the condition. Approximately 25% of children born to carriers of an autosomal recessive condition will be affected. The chances of an unaffected child who is not a carrier is 50% and the chances of a child who is a carrier is 25%. An autosomal recessive condition should be suspected in a family with the following features:

- Males and females are affected in roughly equal proportions.
- Parents are consanguineous. Where there is consanguinity, the variants are usually homozygous, meaning the same mutant allele is inherited from both parents.
- More than one sibling born to healthy parents is affected and so the condition may appear to have arisen 'out of the blue'.

The pattern of autosomal codominant inheritance is similar to autosomal recessive inheritance. Autosomal codominant inheritance is the term used to describe the situation whereby two different alleles of a gene are expressed, but each version makes a different protein. The combination of both alleles influences the characteristics of the genetic condition. A good example of autosomal codominance is in α1-antitrysin deficiency, where the Z and S protein variants may be inherited, resulting in different degrees of disease severity (see Box 3.4).

X-linked inheritance

An example of X-linked recessive inheritance is shown in Figure 3.10D. Here the disease only occurs in males but is transmitted from the mother, who is an unaffected carrier. Affected males cannot transmit the condition to their sons (but all their daughters are carriers). The chance of a female carrier having an affected child is 25% or half of her male offspring. This is because with each conception, she has a 50% chance of passing on the pathogenic variant but only males are affected. This type of inheritance occurs because males have only one X chromosome, whereas females have two (see Fig. 3.1). Note that female carriers may occasionally exhibit signs and symptoms of an X-linked disease due to a phenomenon called skewed X-inactivation. All female embryos, at about 100 cells in size, stably inactivate one of their two X chromosomes in each cell. Where this inactivation is random, approximately 50% of the cells will express the genes from one X chromosome and 50% of cells will express genes from the other. Where there is a pathogenic variant, there is often skewing away from the affected X chromosome, resulting in an unaffected female carrier. However, if, by chance, there is a disproportionate inactivation of the

Fig. 3.10 Pedigree diagrams, symbols and patterns of inheritance. **A** The main symbols used to represent pedigrees in diagrammatic form. **B** Autosomal dominant inheritance. The disease is transmitted to approximately 50% of offspring independent of gender. **C** Autosomal recessive inheritance. Affected individuals inherit one pathogenic allele from each of their parents, who are carriers of the condition. Consanguinity is common in recessively inherited diseases. **D** X-linked recessive inheritance. Affected males inherit a pathogenic allele from unaffected females, who carry the pathogenic allele but who are usually unaffected. Male-to-male transmission does not occur, but daughters of affected males are carriers. **E** Mitochondrial inheritance. Both sexes are affected but transmission occurs only from affected females. All offspring of an affected woman are expected to inherit the condition.

3.6 Patterns of inheritance for selected familial genetic diseases

Name of condition	Gene	Reference
Autosomal dominant conditions		
Autosomal dominant polycystic kidney disease (ADPKD)	*PKD1* (85%), *PKD2* (15%)	p. 620 Box 18.28

*Autosomal recessive and X-linked recessive forms of osteogenesis imperfecta have also been described.

normal X chromosome with skewing towards the mutant allele, then an affected female carrier may be clinically affected (albeit more mildly than males). An example of this is in DMD, where cardiomyopathy may be observed in some female carriers (see Box 3.5).

Mitochondrial inheritance

An example of mitochondrial inheritance is shown in Figure 3.10E. In this case the disease is transmitted only by females, but males and females are generally equally affected. Unlike the inheritance patterns mentioned above, mitochondrial inheritance has nothing to do with meiosis but reflects the fact that mitochondrial DNA is transmitted by oocytes: sperm do not contribute mitochondria to the zygote. Mitochondrial disorders tend to be variable in penetrance and expressivity within families, and this is mostly accounted for by the fact that only a proportion of multiple mtDNA molecules within mitochondria contain the pathogenic variant (the degree of mtDNA heteroplasmy). Some examples of mitochondrial disease are shown in Box 3.7. As mitochondria are most numerous in cells with high metabolic demands, such as muscle, retina and the basal ganglia, these tissues tend to be the ones most severely affected in mitochondrial diseases. It is important to remember that a mitochondrial pattern of inheritance only applies when the pathogenic variant directly affects the mitochondrial genome. Some mitochondrial diseases are due to pathogenic variants in nuclear genes like *RRM2B*, where the gene product is transported into the mitochondrion to maintain mtDNA. In such cases the disease may be inherited in an autosomal manner.

Imprinting

In several chromosomal regions (loci), gene expression is dependent on the parent of origin. These are called imprinted loci. Within these loci, the paternally inherited allele may be active while the maternally inherited allele may be silenced, or vice versa. Variants within imprinted loci lead to an unusual pattern of inheritance where the phenotype is manifest only if inherited from the parent who contributes the transcriptionally active allele. Examples of imprinting disorders are given in Box 3.8.

Somatic genetic disease

Somatic variants are not inherited but instead occur during post-zygotic mitotic cell divisions at any point from embryonic development to late adult life. An example of this phenomenon is polyostotic fibrous dysplasia (McCune–Albright syndrome), in which somatic gain-of-function variants in the *GNAS* gene in embryonic development cause constitutive activation of G protein signalling. This influences hormone regulation and many other cell functions, resulting in focal lesions in the skeleton and endocrine dysfunction.

The most important example of human disease caused by somatic variants is cancer (Ch. 8). Here, 'driver mutations' occur within genes that are involved in regulating cell division or apoptosis, resulting in abnormal cell growth and tumour formation. The two general categories of cancer-causing variants are gain-of-function variants in growth-promoting genes (oncogenes) and loss-of-function variants in growth-suppressing genes (tumour suppressor genes). Whichever mechanism is operative, most tumours require an initiating variant in a single cell that can then escape from normal growth controls. This cell replicates more frequently or fails to undergo programmed death, resulting in clonal expansion. As the size of the clone increases, one or more cells may acquire additional variants that confer a further growth advantage, leading to proliferation of these subclones, which may ultimately result in aggressive metastatic cancer. The cell's complex self-regulating machinery means that more than one variant is usually required to produce a malignant tumour (see Fig. 8.3). For example, if a variant results in activation of a growth factor gene or receptor, then that cell will replicate more frequently due to autocrine stimulation. However, this mutant cell will still be subject to normal cell-cycle checkpoints to promote DNA integrity in its progeny.

3.7 Diseases, phenotypes and causes of some primary mitochondrial disorders

Condition	Main clinical features	Genetic causes
Kearns–Sayre syndrome	Ophthalmoplegia < age 20 y Pigmentary retinopathy Cerebellar ataxia Heart block Deafness Myopathy	Usually caused by a large-scale deletion of mitochondrial DNA. A third are caused by a common 4977 bp deletion. Pathogenic variants in mtDNA encompassing tRNA genes, or in nuclear genes involved in mtDNA maintenance such as *RRM2B* have also been described
Leigh syndrome	Infantile onset Subacute relapsing encephalopathy Cerebellar and brain stem signs	Usually caused by pathogenic variants in nuclear genes, causing a defect in aerobic energy production. The identified genes encode either one of the subunits of the pyruvate dehydrogenase (PDH) complex, one of the subunits of respiratory complexes I or II, or a protein involved in the assembly of respiratory complex IV. Between 10% and 30% have mtDNA variants, most commonly the *MTATP6* gene encoding a subunit of ATP synthase
MELAS	Stroke-like episodes at age < 40 yrs Seizures Dementia in adolescence/early adulthood	The mt tRNA variant m.3243A>G is responsible for 80% of cases Variants in the nuclear gene *POLG1* have also been described
MERFF	Seizures Myoclonus Myopathy Cerebellar ataxia Optic atrophy Deafness	More than 80% of individuals carrying the m.8344A>G variant in the lysine transfer RNA (tRNA Lys) gene *(MTTK)*
Pearson syndrome	Sideroblastic anaemia of childhood Pancytopenia Exocrine pancreatic failure	Mt-DNA deletion, usually including 1+ tRNA gene
MIDD	Sensorineural hearing impairment and diabetes mellitus. Initially the diabetes can be controlled with oral hypoglycaemic drugs, but insulin may be required	Most commonly caused by the m.3243A>G variant, located in the leucine transfer RNA gene (tRNA Leu) gene (*MTTL1)*

(MELAS = mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes; MERFF = myoclonic epilepsy with ragged-red fibres; MIDD = maternally inherited diabetes and deafness)

3.8 Imprinting disorders

Disorder	Locus	Genes	Notes
Beckwith–Wiedemann syndrome	11p15	*CDKN1C, IGF2, H19*	Increased growth, macroglossia, hemihypertrophy, abdominal wall defects, ear lobe pits/creases and increased susceptibility to developing childhood tumours
Prader–Willi syndrome	15q11–q13	*SNRPN*, *Necdin* and others	Obesity, hypogonadism and learning disability. Lack of paternal contribution (due to deletion of paternal 15q11–q13, or inheritance of both chromosome 15q11–q13 regions from the mother)
Angelman syndrome (AS)	15q11–q13	*UBE3A*	Severe mental retardation, ataxia, epilepsy and inappropriate laughing bouts. Due to loss-of-function variants in the maternal *UBE3A* gene. The neurological phenotype results because most tissues express both maternal and paternal alleles of *UBE3A*, whereas the brain expresses predominantly the maternal allele
Pseudohypoparathyroidism	20q13	*GNAS1*	Inheritance of the variant from the mother results in hypocalcaemia, hyperphosphataemia, raised parathyroid hormone (PTH) levels, ectopic calcification, obesity, delayed puberty and shortened 4th and 5th metacarpals (the syndrome known as Albright hereditary osteodystrophy, AHO). When the gene variant is inherited from the father, PTH, calcium and phosphate levels are normal but the other features are present. These differences are due to the fact that, in the kidney (the main target organ through which PTH regulates serum calcium and phosphate), the paternal allele is silenced and the maternal allele is expressed, whereas both alleles are expressed in other tissues

If additional variants in the same cell result in defective cell-cycle checkpoints, however, it will rapidly accumulate further genomic variants, which may allow completely unregulated growth and/or separation from its matrix and cellular attachments and/or resistance to apoptosis. As cell growth becomes increasingly dysregulated, cells de-differentiate, lose their response to normal tissue environment and cease to ensure appropriate mitotic chromosomal segregation. These processes combine to generate the classical malignant characteristics of disorganised growth, variable levels of differentiation and numerical and structural chromosome abnormalities. An increase in somatic variant rate can occur from exposure to external mutagens, such as ultraviolet light or cigarette smoke, or if the cell has defects in DNA repair systems. Accordingly, cancer is a disease that affects the fundamental processes of molecular and cell biology.

Interrogating the genome: the changing landscape of genomic technologies

Looking at chromosomes

For decades, the analysis of metaphase chromosomes by light microscopy was the mainstay of clinical cytogenetic analysis, the aim being to detect gains or losses of whole chromosomes (aneuploidy) or large chromosomal segments (>4 million bp). More recently, genome-wide microarrays (array comparative genomic hybridisation or array CGH and SNP arrays) have replaced chromosome analysis, allowing rapid and precise detection of segmental gain or loss of DNA throughout the genome (see Box 3.3). Microarrays consist of grids of multiple wells containing short DNA sequences (reference DNA) that are complementary to known sequences in the genome. In array CGH, patient and reference DNA are each labelled with a coloured fluorescent dye (generally, patient DNA is labelled with a green fluorescent dye and reference DNA with a red fluorescent dye) and added to the microarray grid. Where there is an equal quantity of patient and reference DNA bound to the spot, this results in yellow fluorescence. Where there is too much patient DNA (representing a duplication of a chromosome region), the spot will be greener; it will be more red (appears orange) where there is 2:1 ratio of the control to patient DNA (representing heterozygous deletion of a chromosome region (Fig. 3.11).

Array CGH and other array-based approaches can detect small chromosomal deletions and duplications. They are also generally more sensitive than conventional karyotyping at detecting mosaicism (where there are two or more populations of cells, derived from a single fertilised egg, with different genotypes). However, array-based approaches will not detect balanced chromosome rearrangements where there is no loss or gain of genes/chromosome material, such as balanced reciprocal translocations, or a global increase in copy number, such as triploidy (where there are three copies of each chromosome rather than two).

The widespread use of array-based approaches has brought a number of challenges for clinical interpretation, including the identification of copy number variants (CNVs) of uncertain clinical significance, CNVs of variable penetrance and incidental findings. A CNV of uncertain clinical significance describes a loss or gain of chromosome material where there are insufficient data to conclude whether or not it is associated with a learning disability and/or medical problems. While this uncertainty can be difficult to prepare families for, and can be associated with considerable anxiety, it is likely that there will be greater clarity in the future as we generate larger CNV datasets.

A CNV of variable penetrance, also known as a neurosusceptibility locus, describes a chromosome deletion or duplication associated with a lower threshold for manifesting a learning disability or autistic spectrum disorder. These CNVs of variable penetrance are therefore identified at greater frequencies among individuals with a learning disability and/or autistic spectrum disorder than in the general population. The current understanding is that additional genetic and environmental modifying factors must influence the phenotypic expression of these neurosusceptibility loci.

Finally, an incidental CNV finding describes a deletion or duplication encompassing a gene or genes that are causative of a phenotype or risk unrelated to the presenting complaint. For instance, if, through the array CGH investigation for an intellectual disability, a deletion encompassing the *BRCA1* gene were identified, this would be considered an incidental finding.

Looking at genes

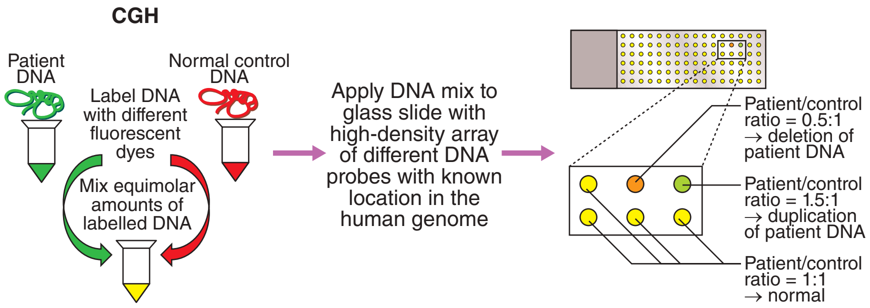
Gene amplification: polymerase chain reaction

The polymerase chain reaction (PCR) is a fundamental laboratory technique that amplifies targeted sections of the human genome for further analysis – most commonly, DNA sequencing. The method uses thermal cycling: repeated cycles of heating and cooling allow the initial separation of double-stranded DNA into two single strands (known as denaturation) followed by DNA amplification, using DNA polymerase (under cooled conditions). Since DNA polymerase is only able to add a nucleotide to an existing $3'$OH group, specially designed primers (short segments of nucleotides) are used to anneal to the DNA template and target the region for amplification. This cycle of heating/cooling and denaturation/replication is repeated many times, resulting in the exponential amplification of DNA between primer sites (Fig. 3.12).

Gene sequencing

In the mid-1970s, a scientist called Fred Sanger pioneered a DNA sequencing technique (Sanger sequencing) that could determine the precise order and nucleotide type (thymine, cytosine, adenine and guanine) in a particular molecule of DNA. Modern Sanger sequencing uses fluorescently labelled, chain-terminating nucleotides that are sequentially incorporated into the newly synthesised DNA, thus generating multiple DNA chains of different lengths. Capillary electrophoresis then separates these DNA chains, allowing the fragments to be 'read' by a laser and producing a sequence chromatogram that corresponds to the target sequence (Fig. 3.13). Although transformative, Sanger sequencing was difficult and costly to scale, as exemplified by the Human Genome Project, which used this technology, taking 12 years to sequence the entire human genome at a cost approaching US$3 billion. Recently, DNA sequencing has been transformed again by a group of technologies collectively known as 'next-generation sequencing' (NGS; Fig. 3.14). This refers to a family of post-Sanger sequencing technologies that use the same five basic principles:

- *Library preparation*: DNA samples are fragmented (by enzyme cleavage or ultrasound) and then modified with a custom adapter sequence.



CGH
Patient DNA
Normal control DNA
Label DNA with different fluorescent dyes
Mix equimolar amounts of labelled DNA
Apply DNA mix to glass slide with high-density array of different DNA probes with known location in the human genome
Patient/control ratio = 0.5:1 → deletion of patient DNA
Patient/control ratio = 1.5:1 → duplication of patient DNA
Patient/control ratio = 1:1 → normal

Fig. 3.11 Detection of chromosome abnormalities by comparative genomic hybridization. Comparative genomic hybridization (CGH) is used to detect deletions and duplications in DNA. These are detected by looking for deviation from the 1:1 ratio of patient and control DNA in a microarray. Ratios in excess of 1 indicate duplications, whereas ratios below 1 indicate deletions.

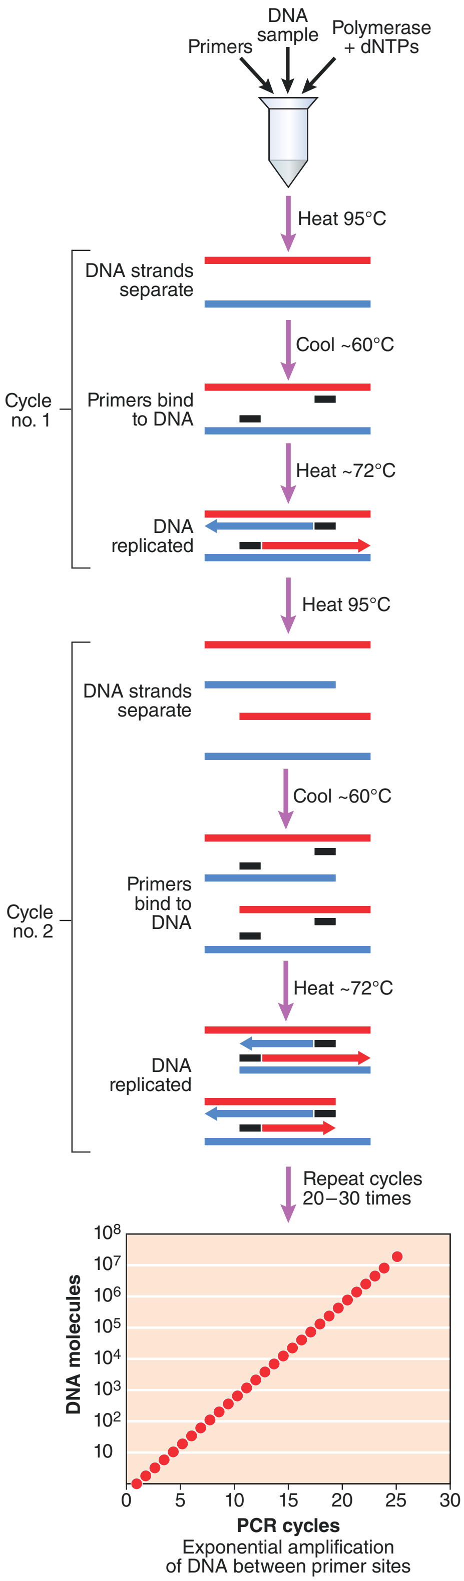


Fig. 3.12 The polymerase chain reaction. The polymerase chain reaction (PCR) involves adding a tiny amount of the patient's DNA to a reaction containing primers (short oligonucleotides 18–21 bp in length, which bind to the DNA flanking the region of interest), and deoxynucleotide phosphates (dATP, dCTP, dGTP, dTTP), which are used to synthesise new DNA and a heat-stable polymerase. The reaction mix is first heated to 95°C, which causes the double-stranded DNA molecules to separate. The reaction is then cooled to 50–60°C, which allows the primers to bind to the target DNA. The reaction is then heated to 72°C, at which point the polymerase starts making new DNA strands. These cycles are repeated 20–30 times, resulting in exponential amplification of the DNA fragment between the primer sites. The resulting PCR products can then be used for further analysis – most commonly, DNA sequencing (see Fig. 3.13).

- *Amplification*: the library fragment is amplified to produce DNA clusters, each originating from a single DNA fragment. Each cluster will act as a single sequencing reaction.
- *Capture*: if an entire genome is being sequenced, this step will not be included. The capture step is required if targeted resequencing is necessary, such as for a panel gene test or an exome (Box 3.9).
- *Sequencing*: each DNA cluster is simultaneously sequenced and the data from each captured; this is known as a 'read' and is usually between 50 and 300 bases long. See Box 3.10 for a detailed description of the three most commonly used sequencing methods: synthesis, ligation and ion semiconductor sequencing.
- *Alignment and variant identification*: specialised software analyses read sequences and compares the data to a reference template. This is known as alignment or mapping and, although there are approximately 3 billion bases in the human genome, allows the remarkably accurate determination of the genomic origin where a read consists of 25 nucleotides or more. Variants are identified as differences between the read and the reference genome (this is called variant calling). For instance, if there is a different nucleotide in half the reads at a given position compared to the reference genome, this is likely to represent a heterozygous base substitution. The number of reads that align at a given point is called the depth or coverage. The higher the read depth, the more accurate the variant call. However, in general, a depth of 30 or more reads is generally accepted as producing diagnostic-grade results.

Rather than sequencing only one small section of DNA at a time, NGS allows the analysis of many hundreds of thousands of DNA strands in a single experiment and so is also commonly referred to as multiple parallel sequencing technology. Today's NGS machines can sequence the entire human genome in a single day at a cost of less than US$1000.

Next-generation sequencing capture

Although we now have the capability to sequence the entire genome in a single experiment, whole-genome sequencing is not always the optimal use of NGS. NGS capture refers to the 'pull-down' of targeted regions of the genome and may constitute several to several hundred genes associated with a given phenotype (a gene panel), the exons of all known coding genes (an exome), or the exons of all coding genes known to be associated with disease (a clinical exome). Each of these targeted resequencing approaches is associated with a number of advantages and disadvantages (see Box 3.9). In order for NGS to be used for optimal patient benefit, it is essential for the clinician to have a good understanding of which test is the best one to request in any given clinical presentation.

Challenges of next-generation sequencing technologies

Genomic technologies are transforming the way that we practise medicine, and ever faster and cheaper DNA sequencing offers increasing opportunities to prevent, diagnose and treat disease. However, genomic technologies are not without their challenges: for instance, storing the enormous quantities of data generated by NGS. While the A, C, T and G of our genomic code could be stored on the memory of a smartphone, huge computers, able to store several petabytes of data (where 1 petabyte is 1 million gigabytes of data), are required to store the information needed to generate each individual's genome.

Even if we can store and handle these huge datasets successfully, we then need to be able to sift through the millions of normal variants to identify the single (or, rarely, several) pathogenic, disease-causing variant. While this can, to an extent, be achieved through the application of complex algorithms, these take time and considerable expertise to develop and are not infallible.

Furthermore, even after these data have been sifted by bioinformaticians, it is highly likely that clinicians will be left with some variants for which there are insufficient data to enable their definitive categorisation as either pathogenic or benign. This may be because we simply do not know enough about the gene: because the particular variant has not previously been reported and/or it is identified in an unaffected parent. These variants

Fig. 3.13 **Sanger sequencing of DNA.** Sanger sequencing of DNA is widely used in DNA diagnostics. It is performed using polymerase chain reaction (PCR)-amplified fragments of DNA corresponding to the gene of interest. The sequencing reaction is carried out with a combination dNTP and fluorescently labelled di-deoxy-dNTP (ddATP, ddTTP, ddCTP and ddGTP), which become incorporated into the newly synthesised DNA, causing termination of the chain at that point. The reaction products are then subject to capillary electrophoresis and the different-sized fragments are detected by a laser, producing a sequence chromatogram that corresponds to the target DNA sequence.

must be interpreted with caution and, more usually, their interpretation will require input from a genetics expert in the context of the clinical presentation, where an ‘innocent until proven guilty’ approach should be adopted.

Finally, if the entire genome or even the exome is interrogated, it is foreseeable that we will routinely identify incidental or secondary findings – in other words, findings not related to the initial diagnostic question. Whether or not to report these incidental findings is a topic of much debate, although there is general agreement that clinicians should feed back incidental findings where there is an intervention that could slow or halt development/progress of the associated disease. Some argue that any clinically relevant pathogenic variants should be fed back to patients, even when no intervention is possible and that to withhold any such information is paternalistic. However, such an approach is problematic since, even if patients consent to receiving incidental findings, the breadth of possible outcomes means that meaningful consent is likely to be impossible to achieve. Where children are having testing, returning such findings may violate their right to autonomy and an open future. It is also much harder to interpret variants where there is no associated phenotype, so seemingly pathogenic novel variants may not actually cause a condition in a particular individual or family (see the end of this chapter for more discussion of ethical considerations in genomics).

Uses of next-generation sequencing

Next-generation sequencing is frequently used within diagnostic laboratories to identify base substitutions and indels (although the latter were initially problematic). Previously NGS could not reliably detect large deletions or duplications spanning several hundreds or thousands of bases. Similarly, copy number variants, or triplet repeat disorders such as those that cause Huntington disease, myotonic dystrophy and fragile X syndrome (see Box 3.2), were previously difficult to detect by NGS. Increasingly, however, disorders caused by both copy number variants and triplet repeat expansions are being diagnosed with NGS using sophisticated computational methods. Additional potential uses of NGS include detection of balanced and unbalanced translocations and mosaicism: NGS has proved remarkably sensitive at detecting the latter when there is high read coverage for a given region. Of note, however, NGS is still not able to interrogate the epigenome and so will not identify conditions caused by a disruption of imprinting, such as Beckwith–Wiedemann, Silver–Russell, Angelman and Prader–Willi syndromes (see Boxes 3.8 and 3.2).

Long read sequencing

Increasingly, long read sequencing, also called third-generation, or single-molecule sequencing, is entering the diagnostic arena. As with NGS, a number of different platforms are commercially available. One of the most successful is SMRT technology (single-molecule sequencing in real time). This system uses a single-stranded DNA molecule (as compared to the amplified clusters used in NGS), which acts as a template for the sequential incorporation of fluorescently labelled nucleotides. As each complementary nucleotide is added, the fluorescence (and therefore the identity of the nucleotide) is recorded in real time before it is removed and another nucleotide added.

A key advantage of third-generation sequencing is the long length of the read it generates. Whereas NGS cannot exceed read lengths of 1 kilobase pairs, long read sequencing technologies typically use read lengths between 10 kilobase pairs and 100 kilobase pairs. This makes it much easier, quicker and cheaper to assemble full genomes; it can also detect structural variation and copy number variation. As well as this, it is better for sequencing repetitive DNA (for example, with respect to the triplet repeat disorders). With NGS, since smaller reads need to be reassembled using bioinformatics software, repeats may be overlooked or duplicated.

Another advantage is in analysis of epigenetic changes. Because this technology targets native unamplified templates, the DNA and RNA molecules retain base modifications, allowing epigenomic changes to be detected. Given these inherent advantages, long read sequencing is likely to supersede NGS in the near future. Given the many terms used for NGS and long read sequencing, these technologies are increasingly referred to collectively as ‘massively parallel sequencing’.

Genomics and clinical practice

Genomics and health care

Genomics in rare neurodevelopmental disorders

Although, by definition, the diagnosis of a rare disorder is made infrequently, rare diseases collectively affect about 3 million (1 in 17) people in the UK, the majority of whom are children. NGS has transformed

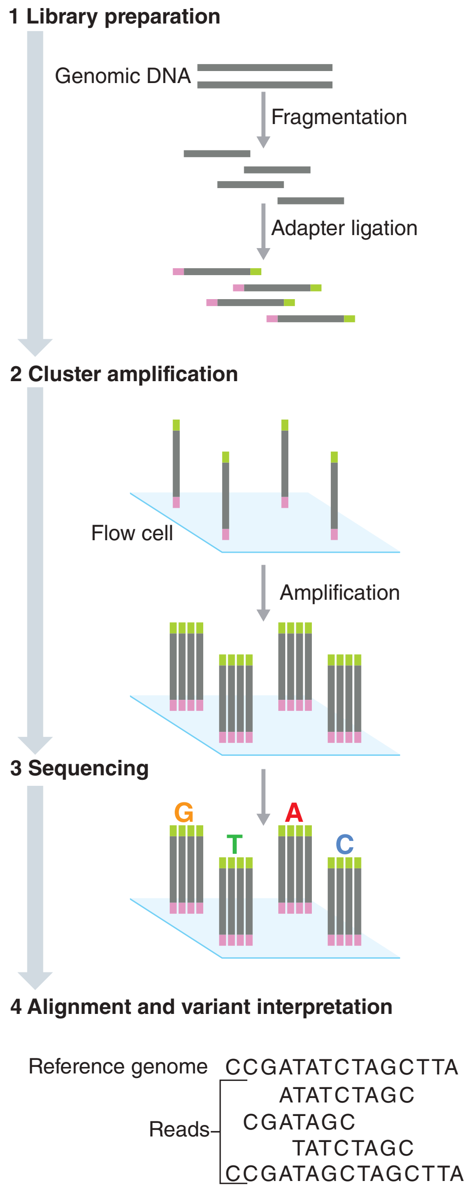

Fig. 3.14 Sequencing by synthesis as used in the Illumina system. (1) Library preparation: DNA is fragmented and specialist adapters are ligated to the fragmented ends. (2) Cluster amplification: the library is loaded to a flow cell and the adapters hybridise to the flow-cell surface. Each bound fragment is hybridised. (3) Sequencing. (4) Alignment and variant interpretation: reads are aligned to a reference sequence using complex software and differences between reference and case genomes are identified.

the ability to diagnose individuals affected by a rare disease. Whereas previously, when we were restricted to the sequential analysis of single genes, a clinician would need to make a clinical diagnosis in order to target testing, NGS instead allows the interrogation of multiple genes in a single experiment. This might be done through a gene panel, a clinical exome or whole exome/genome sequencing (see Box 3.9 and p. 50), and has increased the diagnostic yield in neurodevelopmental disorders to 35%–50%. Not only does the identification of the genetic cause of a rare disorder potentially provide families with answers, prognostic information, the opportunity to meet and derive support from other affected families, and in some cases, access to targeted treatments, it can provide valuable information for those couples planning more children and wishing to consider prenatal testing in the future.

3.9 The advantages and disadvantages of whole-genome sequencing, whole-exome sequencing and gene panels

Test	Advantages	Disadvantages
Whole-genome sequencing (WGS)	The most comprehensive analysis of the genome available More even coverage of genes, allowing better identification of dosage abnormalities Will potentially detect all gene variants, including intronic variants	More expensive to generate and store Will detect millions of variants in non-coding DNA, which can be very difficult to interpret Associated with a greater risk of identifying incidental findings Shallow sequencing (few reads per gene) and so less sensitive and less able to detect mosaicism
Whole-exome sequencing (WES)	Cheaper than whole-genome sequencing Analysis is not restricted to only those genes known to cause a given condition Fewer variants detected than in WGS and so easier interpretation Deeper sequencing than WGS increases sensitivity and detection of mosaicism	Less even coverage of the genome and so dosage abnormalities are more difficult to detect Less comprehensive analysis (1%–2% of the genome) than WGS Increased risk of identifying incidental findings over targeted gene sequencing
Gene panels	Cost-effective Very deep sequencing, increasing the chances of mosaicism being detected Fewer variants detected and so data easier to interpret As analysis is restricted to known genes, the likelihood of a variant being pathogenic is greatly increased	Will only detect variation in genes known to cause a given condition Difficult to add new genes to the panel as they are discovered

Polygenic diseases

Most common disorders are determined by interactions between a number of genes and the environment. In this situation, the genetic contribution to disease is termed polygenic. Until recently, very little progress had been made in identifying the genetic variants that predispose to common disorders, but this has been changed by the advent of genome-wide association studies (GWAS). A GWAS typically involves genotyping many (> 500 000) genetic markers (SNPs) spread across the genome in a large group of individuals with the disease and in controls. By comparing the SNP genotypes in cases and controls, it is possible to identify regions of the genome, and therefore genes, more strongly associated with a given SNP profile and therefore more likely to contribute to the disease under study. Increasingly there is a move to develop disease-specific polygenic risk scores (PRS) in order to stratify individual risk and determine personalised management strategies. Whilst not yet in mainstream practice, it is likely that PRS will be integrated into clinical management in the next few years.

Genomics and obstetrics

Prenatal genetic testing may be performed where a pregnancy is considered at increased risk of being affected with a genetic condition, either because of the ultrasound/biochemical screening results or because of the family history. While invasive tests, such as amniocentesis and chorionic villus sampling, have been the mainstay of prenatal diagnosis for many years, they are increasingly being superseded by non-invasive testing of cell-free fetal DNA (cffDNA), originating from placental

3.10 Next-generation sequencing methods

Sequencing by synthesis

- The most frequently used NGS method, as illustrated in Figure 3.14
- Used in Illumina systems (commonly used in diagnostic laboratories)
- Uses fluorescently labelled, terminator nucleotides that are sequentially incorporated into a growing DNA chain
- Library DNA samples (fragmented DNA flanked by DNA adapter sequences) are anchored to a flow cell by hybridisation of the DNA adapter sequence to probes on the flow-cell surface
- Amplification occurs by washing the flow cell in a mixture containing all four fluorescently labelled terminator nucleotides: A, C, T and G
- Once the nucleotide, complementary to the first base of the DNA template, is incorporated, no further nucleotides can be added until the mixture is washed away
- The nucleotide terminator is shed and the newly incorporated nucleotide reverts to a regular, non-fluorescent nucleotide that can be extended
- The process is then repeated with the incorporation of a second base etc.
- Sequencing by synthesis is therefore space- and time-dependent: a sensor will detect the order of fluorescent emissions for each spot on the plate (representing the cluster) and determine the sequence for that read

Sequencing by ligation

- Used in SOLiD systems
- Uses DNA ligase rather than DNA polymerase (as is used in sequencing by synthesis) and short oligonucleotides (as opposed to single nucleotides)
- Library DNA samples are washed in a mixture containing oligonucleotide probes representing 4–16 dinucleotide sequences. Only one nucleotide in the probe is fluorescently labelled
- The complementary oligo probes will hybridise, using DNA ligase, to the target sequence, initially at a primer annealed to the anchor site and then progressively along the DNA strand
- After incorporation of each probe, fluorescence is measured and the dye is cleaved off
- Eventually, a new strand is synthesised (composed of a series of the oligo probes)
- A new strand is then synthesised but is offset by one nucleotide
- The process is repeated a number of times (5 rounds in the SOLiD system), providing overlapping templates that are analysed and a composite of the target sequence determined

Ion semiconductor sequencing

- When a nucleotide is incorporated into a growing DNA strand, a hydrogen ion is released that can be detected by an alteration in the pH of the solution. This hydrogen ion release forms the basis of ion semiconductor sequencing
- Each amplified DNA cluster is located above a semiconductor transistor, capable of detecting differences in the pH of the solution
- The DNA cluster is washed in a mixture containing only one type of nucleotide
- If the correct nucleotide, complementary to the next base on the DNA template, is in the mixture and incorporated, a hydrogen ion is released and detected
- If a homopolymer (sequence of two or more identical nucleotides) is present, this will be detected as a decrease in pH proportionate to the number of identical nucleotides in the sequence

trophoblasts and detectable in the maternal circulation from 4–5 weeks' gestation; it is present in sufficient quantities for testing by 9 weeks.

- *Non-invasive prenatal testing (NIPT)*. This refers to the sequencing and quantification, using NGS, of cffDNA chromosome-specific DNA sequences to identify trisomy 13, 18 or 21. The accuracy of NIPT in detecting pregnancy-specific aneuploidy approaches 98%. A false-negative result can occur when there is too little cffDNA (possibly due to early gestation or high maternal body mass index) or when aneuploidy has arisen later in development and is confined to the embryo and not represented in the placenta. False positives can occur with confined placental mosaicism (describing aneuploidy in the placenta, not the fetus) or with an alternative cause of aneuploidy in the maternal circulation, such as cell-free tumour DNA.
- *Non-invasive prenatal diagnosis (NIPD)*. This refers to the identification of a fetal single-gene defect that either has been paternally inherited or has arisen *de novo* and so is not identifiable in the maternal genome. Examples of conditions that are currently amenable to NIPD include achondroplasia and the craniosynostoses. Increasingly, however, NIPD is being used for autosomal recessive conditions such as cystic fibrosis, where parents are carriers for different gene variants. Research is underway to perform more agnostic fetal gene sequencing through whole-exome or whole-genome sequencing on cffDNA.

Where a genetic diagnosis is known in a family, a couple may opt to undertake pre-implantation genetic testing for monogenic disorders (PGT-M, previously known as PGD or pre-implantation genetic diagnosis). PGT-M is used as an adjunct to in vitro fertilisation and involves the genetic testing of a single cell from a developing embryo in very early life, prior to transfer to the uterus.

Genomics and oncology

Until recently, individuals were stratified to genetic testing if they presented with a personal and/or family history suggestive of an inherited cancer predisposition syndrome (Box 3.11). Relevant clinical information included the age of cancer diagnosis and number/type of tumours. For example, the diagnosis of bilateral breast cancer in a woman in her thirties with a mother who had ovarian cancer in her forties is suggestive of *BRCA1/2*-associated familial breast/ovarian cancer. In many familial cancer syndromes, somatic gene variants act together with an inherited variant to cause specific cancers (p. 47). Familial cancer syndromes may be due to germline loss-of-function variants in tumour suppressor genes encoding DNA repair enzymes or gain-of-function variants in proto-oncogenes, which have important roles in cell growth and survival. Some variants can cause constitutive activation, transforming a proto-oncogene into an oncogene, and allowing cells to grow inappropriately.

At the cellular level, loss of one copy of a tumour suppressor gene does not have any functional consequences, as the cell is protected by the remaining normal copy. However, a somatic variant affecting the normal allele is likely to occur in one cell at some point during life, resulting in complete loss of tumour suppressor activity and a tumour developing by clonal expansion of that cell. This two-hit mechanism (one inherited, one somatic) for cancer development is known as the Knudson, or two-hit hypothesis. It explains why tumours may not develop for many years (or ever) in some members of these cancer-prone families. In DNA repair diseases, the inherited variants increase the somatic mutation rate. Autosomal dominant variants in genes encoding components of specific DNA repair systems are relatively common causes of familial colon cancer and breast cancer.

Increasingly, genetics is moving into the mainstream, becoming integrated into routine care as new gene-specific treatments are introduced. Diagnostic testing for a genetic predisposition to cancer in patients who have already developed a tumour has therefore largely moved from the domain of clinical genetics to oncology, where it is often informing their immediate management. This is exemplified by *BRCA1* and *BRCA2* *(BRCA1/2)*-related breast cancer. Previously, women with a pathogenic variant in either the *BRCA1* or *BRCA2* gene would have received similar first-line chemotherapy to women with a sporadic breast cancer without a known genetic association. More recently, it has been shown that *BRCA1/2* mutation-positive tumours are sensitive to poly ADP ribose polymerase (PARP) inhibitors which block the single-strand break-repair pathway. In a *BRCA1/2* mutation-positive tumour – with compromised double-strand break repair – the additional loss of the single-strand break-repair pathway will drive the cell towards apoptosis. Indeed, PARP inhibitors have been shown to be so effective at destroying *BRCA1/2* mutation-positive tumour cells, that *BRCA1/2* gene testing is increasingly determining patient management. It is likely, with a growing understanding of the genomic architecture of tumours, increasing accessibility of NGS and an expanding portfolio of gene-directed therapies, that testing

3.11 Inherited cancer predisposition syndromes

Syndrome name	Gene	Associated cancers	Additional clinical features
Birt–Hogg–Dubé syndrome	*FLCN*	Renal tumour (oncocytoma, chromophobe (and mixed), renal cell carcinoma)	Fibrofolliculoma Trichodiscoma Pulmonary cysts
Breast/ovarian hereditary susceptibility	*BRCA1* *BRCA2*	Breast carcinoma Ovarian carcinoma Pancreatic carcinoma Prostate carcinoma	
Cowden syndrome	*PTEN*	Breast carcinoma Thyroid carcinoma Endometrial carcinoma	Macrocephaly Intellectual disability/autistic spectrum disorder Trichilemmoma Acral keratosis Papillomatous papule Thyroid cyst Lipoma Haemangioma Intestinal hamartoma
Gorlin syndrome/basal cell naevus syndrome	*PTCH1*	Basal cell carcinoma Medulloblastoma	Odontogenic keratocyst Palmar or plantar pits Falx calcification Rib abnormalities (bifid, fused or missing ribs) Macrocephaly Cleft lip/palate
Li–Fraumeni syndrome	*TP53*	Sarcoma (osteosarcoma, chondrosarcoma, rhabdomyosarcoma) Breast carcinoma Brain cancer (esp. glioblastoma) Adrenocortical carcinoma Brain	
Lynch syndrome/hereditary non-polyposis colon cancer	*MLH1* *MSH2* *MSH6* *PMS2*	Colorectal tumours (majority right-sided) Endometrial carcinoma Gastric carcinoma Cholangiocarcinoma Ovarian carcinoma (esp. mucinous)	
Multiple endocrine neoplasia 1	*MEN1*	Parathyroid tumour Endocrine pancreatic tumour Anterior pituitary tumour	Lipoma Facial angiofibroma
Multiple endocrine neoplasia 2a and 2b (formerly known as type 2 and 3, respectively)	*RET*	Medullary thyroid tumour Phaeochromocytoma Parathyroid tumour	
Polyposis, familial adenomatous (FAP)	*APC*	Colorectal adenocarcinoma (FAP is characterised by thousands of polyps from the second decade; without colectomy, malignant transformation of at least one of these polyps is inevitable) Duodenal carcinoma Hepatoblastoma	Desmoid tumour Congenital hypertrophy of the retinal pigment epithelium (CHRPE)
Polyposis, MYH-associated	*MYH (MUTYH)*	Colorectal adenocarcinoma Duodenal adenocarcinoma	
Retinoblastoma, familial	*RB1*	Retinoblastoma Osteosarcoma	

for many of the other inherited cancer susceptibility genes will, in time, move into the mainstream. Pre-symptomatic testing for unaffected relatives remains in the sphere of clinical genetics, where it informs cascade screening of wider family members and surveillance/prophylactic management.

Genomics in infectious disease

Genomic technologies are also transforming infectious disease. Given that a microbial genome can be sequenced within a single day at a current cost of under US$100, microbiologists are able to identify a causative microorganism and target effective treatment rapidly and accurately. Moreover, microbial genome sequencing enables the effective surveillance of infections to reduce and prevent transmission. Finally, an understanding of the microbial genome will drive the development of vaccines and antibiotics, essential in an era characterised by increasing microbial resistance to established antibiotic agents. This was exemplified during the COVID-19 pandemic, when rapid sequencing of the virus enabled the development of fast-tracked vaccines.

Treatment of genetic disease

Pharmacogenomics

Pharmacogenomics is the science of dissecting the genetic determinants of drug kinetics and effects using information from the human genome. For more than 50 years it has been appreciated that polymorphic variants within genes can affect individual responses to some drugs. For example, loss-of-function variants in a gene called *CYP2D6* present in 3% of the population cause hypersensitivity to debrisoquine, an adrenergic-blocking medication formerly used for the treatment of hypertension. This gene is part of a large family of highly polymorphic genes encoding cytochrome P450 proteins, mostly expressed in the liver, which determine the metabolism of a host of specific drugs. Polymorphisms in the *CYP2D6* gene also determine codeine activation, while those in the *CYP2C9* gene affect warfarin inactivation. Polymorphisms in these and other drug metabolic genes determine the persistence of drugs and, therefore, should provide information about dosages and toxicity. With the increasing use of NGS, genetic testing for assessment of drug response is beginning to be employed routinely, and it is becoming more and more possible to predict the best specific drugs and dosages for individual patients based on genetic profiling: so-called 'personalised medicine'. An example is the enzyme thiopurine methyltransferase (TPMT), which catabolises azathioprine, a drug that is used in the treatment of autoimmune diseases and in cancer chemotherapy. Genetic screening for polymorphic variants of TPMT can be useful in identifying patients who have increased sensitivity to the effects of azathioprine and who can be treated with lower doses than normal.

Gene therapy and genome editing

Replacing or repairing mutated genes (gene therapy) is challenging in humans, but in recent years significant strides have been made in the treatment of genetic disorders. The most exciting development in genetics for a generation has been the discovery of accurate, efficient and specific techniques to enable editing of the genome in cells and organisms. This technology is known as CRISPR/Cas9 (clustered regularly interspaced short palindromic repeats and CRISPR-associated protein 9) genome editing. Ex vivo gene therapy approaches can be used for conditions that affect tissues that are straightforward to remove and replace into the body, such as the blood. For example, in a one-off gene therapy named exagamglogene autotemcel (Casgevy), blood stem cells are removed from the body of patients with haemoglobinopathies beta-thalassaemia and sickle-cell disorder. The stem cells are edited in a laboratory using CRISPR technology, and the treated cells are then returned to the patient via an infusion. In vivo correction is also available via certain groundbreaking drugs, such as voretigene neparvovec (Luxturna), which treats *RPE65*-related retinal dystrophy via a retinal injection; and onasemnogene abeparvovec (Zolgensma), which treats spinal muscular atrophy type 1, a muscle-wasting disorder that usually results in death in the first year of life.

In vivo gene therapies are required when the affected tissue cannot be removed. For in vivo therapies, the new genetic material or genome-editing molecules need to be packaged inside a delivery vehicle (called a vector), often a virus, that can deliver them into a cell.

Downsides of virally delivered gene therapy have been oncogenic integration of the exogenous DNA into the genome and severe immune response to the virus. Alternative vectors such as plasmid DNA (small, extrachromosomal DNA molecules which replicate independently) are in use but they may also result in immunogenicity.

Antisense oligonucleotides (ASOs) show much promise in the treatment of genetic disorders and, at the time of writing, are already used in licensed treatments for spinal muscular atrophy and SOD1-amyotrophic lateral sclerosis (also known as motor neuron disease), a fatal degenerative disorder of nerve cells in the brain and spinal cord. ASOs are single strands of DNA or RNA that are complementary to a specific sequence of mRNA. They work by binding to a targeted region of RNA and blocking the translation of certain proteins, thereby altering gene expression. ASOs' small size means they can easily penetrate cell membranes and target both nuclear- and cytoplasmic-located RNAs. Downsides of ASOs include off-target effects, where they bind to unintended RNA sequences and cause unwanted biological effects.

Other therapies for genetic disease include *PTC124*, a compound that can 'force' cells to read through a stop-gain variant that results in a premature termination codon in an ORF with the aim of producing a near-normal protein product. This therapeutic approach could potentially be applied to any genetic disease caused by stop-gain variants.

Induced pluripotent stem cells and regenerative medicine

Adult stem cell therapy has been in wide use for decades in the form of bone marrow transplantation. The identification of adult stem cells for other tissues, coupled with the ability to purify and maintain such cells in vitro, now offers exciting therapeutic potential for other diseases. It was recently discovered that many different adult cell types can be trans-differentiated to form cells (induced pluripotent stem cells or iPS cells) with almost all the characteristics of embryonal stem cells derived from the early blastocyst. In mammalian model species, such cells can be taken and used to regenerate differentiated tissue cells, such as in heart and brain. They have great potential both for the development of tissue models of human disease and for regenerative medicine.

Pathway medicine

The ability to manipulate pathways that have been altered in genetic disease has tremendous therapeutic potential for Mendelian disease, but this requires a firm understanding of both disease pathogenesis and drug action at a biochemical level. One example is the development of drugs that can interact with the abnormal CFTR proteins in cystic fibrosis and partially restore their function either by opening the chloride channel or allowing the abnormal protein to reach the cell surface. Another example is the use of burosumab, a monoclonal antibody to FGF23 which is a highly effective treatment for X-linked hypophosphataemic rickets (XLH). While XLH is caused by pathogenic variants in the *PHEX* gene, raised levels of FGF23 are responsible for the hypophosphataemia. Accordingly, burosumab works by targeting the pathways that are disrupted by *PHEX* rather than targeting the gene itself (Ch. 25).

Ethics in a genomic age

As genomic technology is increasingly moving into mainstream clinical practice, it is essential for clinicians from all specialties to appreciate the complexities of genetic testing and consider whether genetic testing is the right thing to do in a given clinical scenario. To exemplify the ethical considerations associated with genetic testing, it may be helpful to think about them in the context of a clinical scenario. As you read the scenario, try to think what counselling/ethical issues might arise:

A 32-year-old woman is referred to discuss *BRCA2* testing; she is currently pregnant with her second child (she already has a 2-year-old daughter) and has an identical twin sister. Her mother, a healthy 65-year-old with Ashkenazi Jewish ancestry, participated in direct-to-consumer (DTC) testing for 'a bit of fun' and a *BRCA2* gene variant – common in the Ashkenazi Jewish population – was identified. There is no significant cancer family history of note.

Consider the following issues:

- *Pre-symptomatic/predictive testing*. Although predictive testing could be considered for the unaffected patient, in the current scenario, any testing would also have implications for her identical twin sister. This needs to be fully explored with the patient and her sister prior to testing. There is also the potential issue of predictive testing in the patient's first child. A fundamental tenet in clinical genetics is that predictive genetic testing should be avoided in childhood for adult-onset conditions. This is because, if no benefit to the patient is accrued through childhood testing, it is better to retain the child's right to decide for herself, when she is old enough, whether she wishes to participate in genetic testing or not.

- *Prenatal testing*. The principles behind predictive genetic testing in childhood can be extended to prenatal testing. That is, if a pregnancy is being continued, a baby should not be tested for an adult-onset condition that cannot be prevented or treated in childhood. However, prenatal testing itself is hugely controversial and there is much debate as to how severe a condition should be to justify prenatal diagnosis, which would determine ongoing pregnancy decisions.
- *Direct-to-consumer testing*. While direct-to-consumer (DTC) testing can be interesting and empowering for individuals wishing to find out more about their genetic backgrounds, it also has several drawbacks. Perhaps the main one is that, unlike face-to-face genetic counselling (which usually precedes any genetic testing), DCT may uncover abnormalities which have serious implications for the individual and their family, such as pathogenic variants in *BRCA1/2*. Also, DTC testing is undertaken in isolation with no direct access to professional support. Furthermore, in addition to some (common) single-gene variants, such as the founder *BRCA1/2* variants frequently identified in the Ashkenazi Jewish population and discussed in this example, current DTC packages use a series of SNPs to determine an overall risk profile; they evaluate the number of detrimental and protective SNPs for a given disease. However, given that only a minority of the risk SNPs have so far been characterised, this is often inaccurate. Individuals may be falsely reassured that they are not at increased risk of a genetic condition despite a family history suggesting otherwise, resulting in inadequate surveillance and/or treatment.

The ethical considerations listed in this clinical scenario give just a flavour of some of the issues frequently encountered in clinical genetics. They are not meant to be an exhaustive summary and whole textbooks and meetings are devoted to the discussion of hugely complex ethical issues in genetics. However, a guiding principle is that, although each counselling situation will be unique with specific communication and ethical challenges, a genetic result is permanent and has implications for the whole family, not just the individual. Where possible, therefore, an informed decision regarding genetic testing should be taken by a competent adult following counselling by an experienced and appropriately trained clinician.

Multiple Choice Questions

3.1. Which of the following best describes a missense or non-synonymous variant?

A. A base substitution that results in the introduction of a premature stop codon
B. A base substitution that results in a different codon and different amino acid
C. The deletion of two bases that results in a shift of reading frame and the introduction of a downstream premature stop codon
D. A base substitution that introduces a cryptic splice site
E. A base substitution that results in a different codon but same amino acid

Answer: B.

The most common type of genomic variation is the substitution of one nucleotide for another, caused by either misincorporation of a nucleotide during DNA synthesis or chemical modification of the base. If a nucleotide substitution occurs within the open reading frame of a protein-coding gene, it will affect a codon within that gene. A missense/non-synonymous variant refers to a nucleotide substitution in which the effect on the codon in which it occurs is to cause it to encode a different amino acid.

3.2. Approximately how many genes are there in the average human genome?

A. 2000
B. 20 000
C. 200 000
D. 2 000 000
E. 20 000 000

Answer: B.

The human genome contains about 20 000 genes. Many of these are inactive or silenced in different cell types, reflecting the variable gene expression responsible for cell-specific characteristics.

3.3. Which of the following is a cardinal feature of an X-linked recessive disorder?

A. Male-to-male transmission
B. Affected individuals in each generation
C. Increased frequency in consanguineous unions
D. Predominantly males affected
E. There is characteristically highly variable penetrance and expressivity in the same family

Answer: D.

In X-linked recessive diseases, females who carry a copy of the mutant allele on one of their X chromosomes (unaffected carriers) will pass the allele on to 50% of their offspring. Only the male offspring will be affected, because they have only one X chromosome. The female offspring will be carriers, as they will inherit a 'normal' X chromosome from their fathers. The overall risk of a female carrier having an affected child is therefore 25%, or half of her male offspring.

Male-to-male transmission of an X-linked recessive condition does not occur because fathers will pass on their Y chromosome to their sons (not the X chromosome with mutant allele). The presence of affected individuals in each generation is a characteristic feature of autosomal dominant inheritance with full penetrance, in which half of the offspring of an affected parent will be affected irrespective of their sex. Increased frequency in consanguineous unions would suggest an autosomal recessive disorder, because the chance of both the female and the male parent carrying the same mutant allele would be increased by consanguinity. Highly variable penetrance and expressivity in the same family is a feature of mitochondrial disorders.

3.4. Which type of genomic variant will an array comparative genomic hybridisation (CGH) best detect?

A. A balanced chromosome translocation
B. A frameshift variant
C. A 2 Mb deletion
D. A missense variant
E. An essential splice variant

Answer: C.

Array CGH allows rapid and precise detection of segmental gain or loss of DNA throughout the genome. Microarrays consist of grids of multiple wells containing short DNA sequences (reference DNA) that are complementary to known sequences in the genome. Patient and reference DNA are each labelled with a coloured fluorescent dye (generally, patient DNA is labelled with a green fluorescent dye and reference DNA with a red fluorescent dye) and added to the microarray grid. Where there is an equal quantity of patient and reference DNA bound to the spot, this results in yellow fluorescence. Where there is too much patient DNA (representing a duplication of a chromosome region), the spot will be greener; and it will be more red (appears orange) where there is a 2:1 ratio of the control:patient DNA (representing heterozygous deletion of a chromosome region).

Array CGH can detect small chromosomal deletions and duplications and is also more sensitive than conventional karyotyping at detecting mosaicism. However, array CGH and other array-based approaches will not detect balanced chromosome rearrangements where there is no loss or gain of genes/chromosome material, such as balanced reciprocal translocations, or a global increase in copy number, such as triploidy. In addition, an array CGH will not detect small insertions/deletions or single nucleotide substitutions.

3.5. Which of the following is an imprinted condition?

A. Huntington disease
B. Patau syndrome
C. Neurofibromatosis type 1
D. Pseudohypoparathyroidism
E. Alpha-1-antitrypsin deficiency

Answer: D.

Several chromosomal regions (loci) have been identified where gene expression is inherited in a parent-of-origin-specific manner; these are called imprinted loci. Within these loci the paternally inherited gene may be active while the maternally inherited may be silenced, or vice versa. Variants within imprinted loci lead to an unusual pattern of inheritance where the phenotype is manifest only if inherited from the parent who contributes the transcriptionally active allele.

Pseudohypoparathyroidism (PHP) is caused by the maternal inheritance of a *GNAS1* variant (located at 20q13) and is characterised by hypocalcaemia, hyperphosphataemia, raised parathyroid hormone (PTH) levels, ectopic calcification, obesity, delayed puberty and shortened 4th and 5th metacarpals (the syndrome also known as Albright hereditary osteodystrophy, AHO). When the gene variant is inherited from the father, PTH, calcium and phosphate levels are normal but the other (skeletal) features are present and the condition is known as pseudpseudohypoparathyroidism (PPHP). *GNAS1* encodes Gsα, which is primarily expressed from the maternal allele in the kidney, pituitary, thyroid and gonadal cells (and their disruption is the cause of the biochemical defects), whereas both alleles are expressed in other tissues (responsible for the skeletal features). Therefore, where a *GNAS1* variant is maternally inherited the individual will have both biochemical and skeletal features (PHP) but where it is paternally inherited they will not have the biochemical features (PPHP).

The immune system has evolved to identify and destroy pathogens while minimising damage to host tissue. Despite the ancient observation that recovery from an infectious disease frequently results in protection against that condition, the existence of the immune system as a functional entity was not recognised until the end of the 19th century. More recently, it has become clear that the immune system not only protects against infection, but also regulates tissue repair following injury, and when dysregulated, governs the responses that can lead to autoimmune and autoinflammatory diseases. Dysfunction or deficiency of the immune response can lead to a wide variety of diseases that can potentially involve every organ system in the body.

The aim of this chapter is to provide a general understanding of the immune system, how it contributes to human disease and how manipulation of the immune system can be put to therapeutic use. A review of the key components of the immune response is followed by sections that illustrate the clinical presentation of the most common forms of immune dysfunction: immune deficiency, inflammation, autoimmunity and allergy. More detailed discussion of individual conditions can be found in the relevant organ-specific, emergency and critical care medicine chapters.

Functional anatomy and physiology

The immune system consists of an intricately linked network of lymphoid organs, cells and proteins that are strategically placed to protect against infection (Fig. 4.1). Immune defences are normally categorised into the innate immune response, which provides immediate protection against an invading pathogen, and the adaptive or acquired immune response, which takes more time to develop but confers exquisite specificity and long-lasting protection. Innate and adaptive immunity do not work in isolation, but rather in concert, largely driven by cytokines produced by the specific immune cell populations.

The innate immune system

Innate defences against infection include anatomical barriers, phagocytic cells, soluble molecules such as complement and acute phase proteins, and natural killer cells. The innate immune system recognises generic microbial structures present on non-mammalian tissue and can be mobilised within minutes. A specific stimulus will elicit essentially identical responses in different individuals, in contrast with adaptive antibody and T-cell responses, which vary greatly between individuals.

Physical barriers

The tightly packed keratinised cells of the skin physically limit colonisation by microorganisms. The hydrophobic oils that are secreted by sebaceous glands further repel water and microorganisms, and microbial growth is inhibited by the skin's low pH and low oxygen tension. Sweat also contains lysozyme, an enzyme that destroys the structural integrity of bacterial cell walls; ammonia, which has antibacterial properties; and several antimicrobial peptides such as defensins. Similarly, the mucous membranes of the respiratory, gastrointestinal and genitourinary tracts provide a physical barrier to infection. Secreted mucus traps invading pathogens, and immunoglobulin A (IgA), generated by the adaptive immune system, prevents bacteria and viruses attaching to and penetrating epithelial cells. As in the skin, lysozyme and antimicrobial peptides within mucosal membranes directly kill invading pathogens, and lactoferrin acts to starve invading bacteria of iron. Within the respiratory tract, cilia directly trap pathogens and contribute to removal of mucus, assisted by physical manœuvres such as sneezing and coughing. In the gastrointestinal tract, hydrochloric acid and salivary amylase chemically destroy bacteria, while normal peristalsis and induced vomiting or diarrhoea assist clearance of invading organisms.

Fig. 4.1 Anatomy of the immune system.

The microbiome, which is made up of endogenous commensal bacteria, provides an additional constitutive defence against infection. Approximately 10^{14} bacteria normally reside at epithelial surfaces in symbiosis with the human host. They compete with pathogenic microorganisms for scarce resources, including space and nutrients, and produce fatty acids and bactericidins that inhibit the growth of many pathogens. In addition, recent research has demonstrated that commensal bacteria help to shape the immune response by inducing specific regulatory T cells within the intestine. Eradication of the normal flora with broad-spectrum antibiotics commonly results in opportunistic infection by organisms such as *Clostridioides* (formerly *Clostridium*) *difficile*, which rapidly colonise an undefended ecological niche.

These constitutive barriers are highly effective, but if external defences are breached by a wound or pathogenic organism, the specific soluble proteins and cells of the innate immune system are activated.

Phagocytes

Phagocytes ('eating cells') are specialised cells that ingest and kill microorganisms, scavenge cellular and infectious debris, and produce inflammatory molecules that regulate other components of the immune system. They include neutrophils, monocytes and macrophages, and are particularly important for defence against bacterial and fungal infections. Phagocytes express a wide range of surface receptors, including pattern recognition receptors (PRRs), which recognise pathogen-associated molecular patterns (PAMPs) on invading microorganisms. These PAMPs consist of molecular motifs that are not expressed by mammalian cells, including bacterial cell wall components like lipopolysaccharides (LPS), bacterial DNA and viral double-stranded RNA allowing their identification. The PRRs expressed by phagocytes include Toll-like receptors, nucleotide oligomerisation domain (NOD) protein-like receptors (Fig. 4.2A) and mannose receptors (not shown). Interaction between the PRRs and their PAMPs leads to activation of nuclear factor kappa B (NFκB), which stimulates expression of pro-inflammatory genes, and of nucleotide-binding oligomerisation domain (NOD)-like receptor proteins (NLRP), which form complexes with other intracellular proteins to form the inflammasome (see Fig. 4.2A). The inflammasome results in activation of interleukin-1 beta (IL-1β), which is excreted extracellularly and plays a key pathogenic role in systemic autoinflammatory disorders (p. 74) and acute gout (Ch. 25). While phagocytes can recognise microorganisms through PRRs alone, engulfment of microorganisms is greatly enhanced by opsonisation. Opsonins include acute phase proteins produced by the liver, such as C-reactive protein and complement component C3b. Antibodies generated by the adaptive immune system also act as opsonins. They bind both to the pathogen and to phagocyte receptors, acting as a bridge between the two to facilitate phagocytosis (Fig. 4.2B). This is followed by intracellular pathogen destruction within lysozymes.

Neutrophils

Neutrophils, also known as polymorphonuclear leucocytes, are derived from the bone marrow and circulate freely in the blood. They are short-lived cells with a half-life of 6 hours and are produced at the rate of 10^{11} cells daily. Their functions are to kill microorganisms, to facilitate rapid transit of cells through tissues and to amplify the immune response non-specifically. These functions are mediated by enzymes contained in granules, which also provide an intracellular milieu for the killing and degradation of microorganisms. Two main types of granule are recognised: primary or azurophil granules, and the more numerous secondary or specific granules. Primary granules contain myeloperoxidase and other enzymes important for intracellular killing and digestion of ingested microbes. Secondary granules are

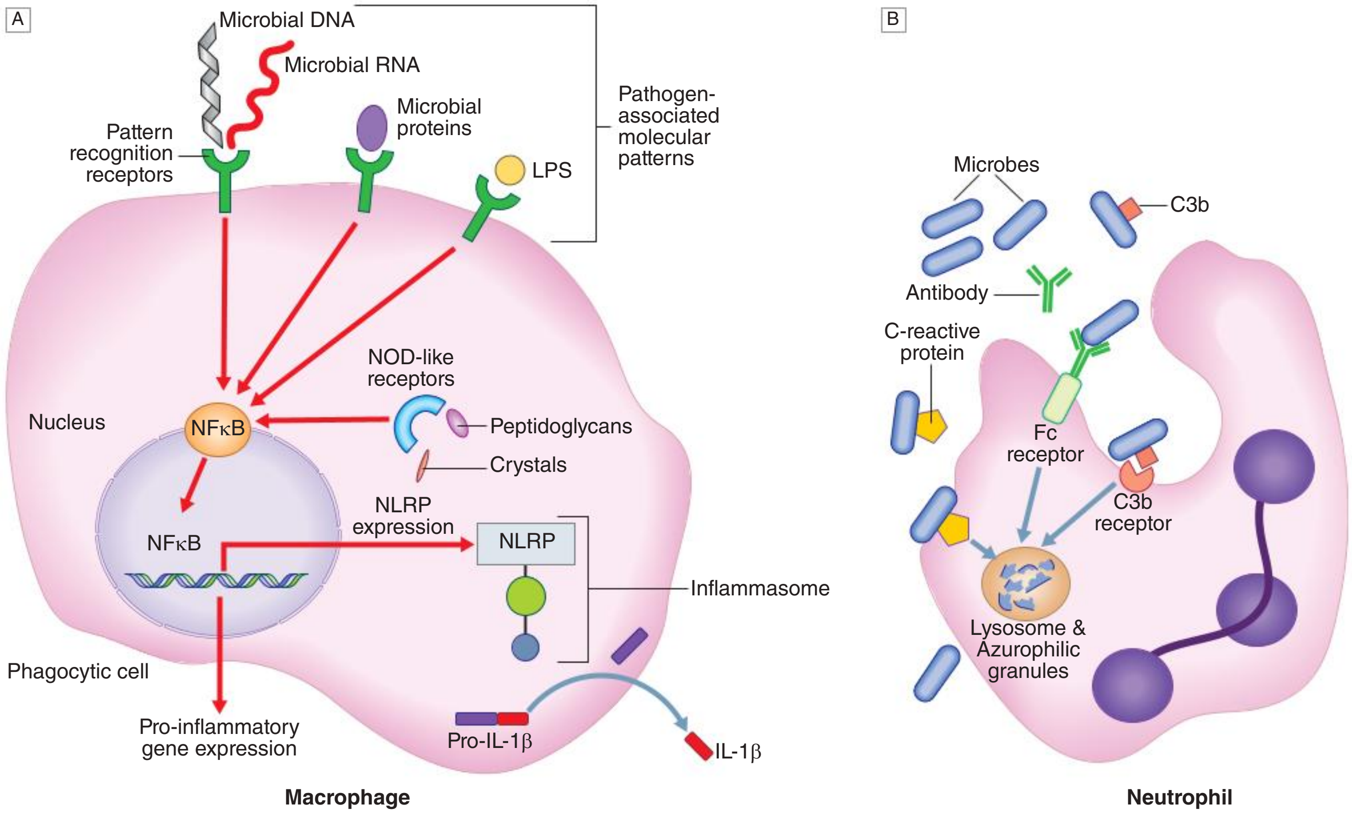

Fig. 4.2 Phagocytosis and opsonisation. A Phagocytes recognise components of microbes, such as lipopolysaccharide, peptidoglycans, DNA and RNA, collectively known as pathogen-associated molecular patterns (PAMPs). These activate pattern recognition receptors (PRRs), such as Toll-like receptors and nucleotide oligomerisation domain (NOD)-like receptors, which promote inflammatory gene expression through the nuclear factor kappa B (NFκB) pathway. Uric acid and other crystals can also promote inflammation through the NOD pathway. B Phagocytosis of microbes can be augmented by several opsonins, such as C-reactive protein, antibodies and complement fragments like C3b, which enhance the ability of phagocytic cells to engulf microorganisms and destroy them in intracellular organelles like lysozymes and azurophilic granules. (IL = interleukin; LPS = lipopolysaccharide; NLRP = nucleotide-binding oligomerisation domain, leucine rich repeat and pyrin domain containing proteins)

smaller and contain lysozyme, collagenase and lactoferrin, which can be released into the extracellular space. Enzyme production is increased in response to infection, which is reflected by more intense granule staining on microscopy, known as 'toxic granulation'.

Changes to damaged or infected cells trigger local production of inflammatory molecules and cytokines. These cytokines stimulate the production and maturation of neutrophils in the bone marrow, and their release into the circulation. Neutrophils are recruited to specific sites of infection by chemotactic agents, such as interleukin-8 (IL-8), and by activation of local endothelium. Up-regulation of cellular adhesion molecules on neutrophils and the endothelium also facilitates neutrophil migration. The transit of neutrophils through the blood stream is responsible for the rise in neutrophil count that occurs in early infection. Once present within infected tissue, activated neutrophils seek out and engulf invading microorganisms. These are initially enclosed within membrane-bound vesicles, which fuse with cytoplasmic granules to form the phagolysosome. Within this protected compartment, killing of the organism occurs through a combination of oxidative and non-oxidative killing. Oxidative killing, also known as the respiratory burst, is mediated by the nicotinamide adenine dinucleotide phosphate (NADPH)–oxidase enzyme complex, which converts oxygen into reactive oxygen species such as hydrogen peroxide and superoxide that are lethal to microorganisms. The myeloperoxidase enzyme within neutrophils produces hypochlorous acid, which is a powerful oxidant and antimicrobial agent. Non-oxidative (oxygen-independent) killing occurs through the release of bactericidal enzymes into the phagolysosome. Each enzyme has a distinct antimicrobial spectrum, providing broad coverage against bacteria and fungi.

An additional form of neutrophil-mediated killing is neutrophil extracellular trap (NET) formation. Activated neutrophils can release chromatin with granule proteins such as elastase to form an extracellular matrix that binds to microbial proteins. This can immobilise or kill microorganisms without requiring phagocytosis. The process of phagocytosis and NET formation (NETosis) depletes neutrophil glycogen reserves and is followed by neutrophil death. As the cells die, their contents are released and lysosomal enzymes degrade collagen and other components of the interstitium, causing liquefaction of closely adjacent tissue. The accumulation of dead and dying neutrophils results in the formation of pus, which, if extensive, may lead to abscess formation.

Monocytes and macrophages

Monocytes are the precursors of tissue macrophages. They are produced in the bone marrow and enter the circulation, where they constitute about 5% of leucocytes. From the blood stream they migrate to peripheral tissues, where they differentiate into tissue macrophages and reside for long periods. Specialised populations of tissue macrophages include Kupffer cells in the liver, alveolar macrophages in the lung, mesangial cells in the kidney and microglial cells in the brain. Macrophages, like neutrophils, are capable of phagocytosis and killing of microorganisms but also play an important role in the amplification and regulation of the inflammatory response (Box 4.1). They are particularly important in tissue surveillance and constantly survey their immediate surroundings for signs of tissue damage or invading organisms.

Dendritic cells

Dendritic cells are specialised antigen-presenting cells that are present in tissues in contact with the external environment, such as the skin and mucosal membranes. They can also be found in an immature state in the blood. They sample the environment for foreign particles and, once activated, carry microbial antigens to regional lymph nodes, where they interact with T cells and B cells to initiate and shape the adaptive immune response.

4.1 Functions of macrophages

Amplification of the inflammatory response

- Stimulate the acute phase response (through production of IL-1 and IL-6)
- Activate vascular endothelium (IL-1, TNF-α)
- Stimulate neutrophil maturation and chemotaxis (IL-1, IL-8)
- Stimulate monocyte chemotaxis

Killing of microorganisms

- Phagocytosis
- Microbial killing through oxidative and non-oxidative mechanisms

Clearance, resolution and repair

- Scavenging of necrotic and apoptotic cells
- Clearance of toxins and other inorganic debris
- Tissue remodeling (elastase, collagenase, matrix proteins)
- Down-regulation of inflammatory cytokines
- Wound healing and scar formation (IL-1, platelet-derived growth factor, fibroblast growth factor)

Link between innate and adaptive immune systems

- Activate T cells by presenting antigen in a recognisable form
- T cell–derived cytokines increase phagocytosis and microbicidal activity of macrophages in a positive feedback loop

(IL = interleukin; TNF = tumour necrosis factor)

Cytokines

Cytokines are signalling proteins produced by cells of the immune system and a variety of other cell types. More than 100 have been identified. Cytokines have complex and overlapping roles in cellular communication and regulation of the immune response. Subtle differences in cytokine production, particularly at the initiation of an immune response, can have a major impact on outcome. Cytokines bind to specific receptors on target cells and activate downstream intracellular signalling pathways, ultimately leading to changes in gene transcription and cellular function. Three important signalling pathways are illustrated in Figure 4.3. The nuclear factor kappa B (NFκB) pathway is activated by tumour necrosis factor (TNF), superfamily members and by Toll-like receptors like TLR4. In the case of TNF superfamily members, receptor binding causes the inhibitor of kappa B kinase (IKK) complex of three proteins to be recruited to the receptor by binding TNF receptor–associated proteins (TRAF). This activates IKK, which in turn leads to phosphorylation of the inhibitor of nuclear factor kappa B protein (IκB), causing it to be degraded by the proteasome, allowing NFκB to translocate to the nucleus and activate gene transcription. A similar sequence of events takes place on activation of TLR4 by lipopolysaccharide although the intermediate signalling proteins differ. The Janus kinase/signal transducers and activators of transcription (JAK-STAT) pathway is involved in transducing signals downstream of many cytokine receptors, including those for IL-2, IL-6 and interferon-gamma (IFN-γ). On receptor binding, JAK proteins are recruited to the intracellular portion of the receptor and are phosphorylated. These in turn phosphorylate STAT proteins, which translocate to the nucleus and activate gene transcription, altering cellular function. The function and disease associations of several important cytokines are shown in Box 4.2. Cytokine inhibitors are now routinely used in the treatment of autoimmune diseases, most of which are monoclonal antibodies to cytokines or their receptors. In addition, small-molecule inhibitors have been developed that inhibit the intracellular signalling pathways used by cytokines. These include the Janus kinase inhibitors tofacitinib, baricitinib, upadacitinib and filgotinib, which are used in the treatment of various inflammatory rheumatic diseases and inflammatory bowel disease, and the tyrosine kinase inhibitor imatinib, which is used in chronic myeloid leukaemia and other haematological malignancies.

Integrins

Integrins are transmembrane proteins that play important roles in cell–cell and cell–matrix interactions. They are expressed on lymphocytes as well as a variety of other cell types and mediate attachment of cells to the endothelium and the extracellular matrix, affecting cell migration and

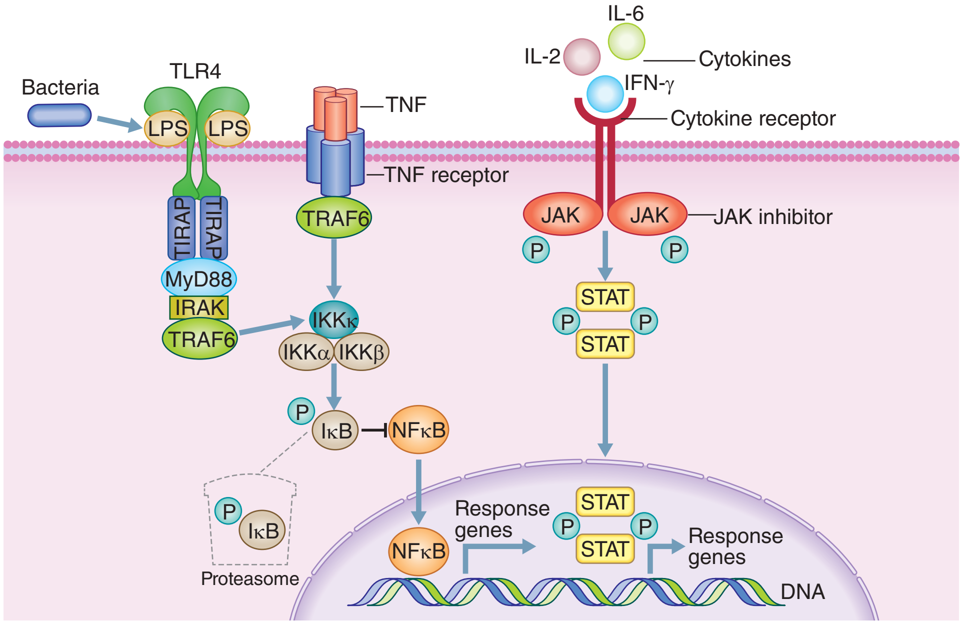

Fig. 4.3 **Signalling pathways and the immune response.** Cytokines and PAMPs activate the immune response through binding to specific receptors that activate a variety of intracellular signalling pathways, three of which are shown. Toll-like receptors such as TLR4 recognise PAMPs, activating intracellular signalling through adaptor proteins including MyD88, IRAK and TRAF6 to activate nuclear factor kappa B (NFκB). Similar mechanisms are employed by the NOD receptors which are present intracellularly (see Fig. 4.2A). Members of the tumour necrosis factor (TNF) superfamily also signal through the NFκB pathway to activate pro-inflammatory response genes. Several other cytokines, including IL-2, IL-6 and interferons, employ the Janus kinase/signal transducer and activator of transcription (JAK-STAT) pathway to activate pro-inflammatory responses. These are targets for JAK inhibitors, which are used in the treatment of a range of inflammatory diseases. (IFN = interferon; IκB = inhibitor of kappa B; IKK = I kappa B kinase; IL = interleukin; IRAK = interleukin 1 receptor-associated kinase; LPS = lipopolysaccharide; MYD88 = myeloid differentiation primary response protein 88; P = phosphorylation of the signalling protein; TRAF = tumour necrosis factor receptor-associated factor)

signal transduction. Their role in autoimmune disease has been extensively studied and therapeutic agents are now being developed which modify binding of integrins to their targets. For example, natalizumab is a monoclonal antibody which targets the α4 integrin which is expressed on lymphocytes. Natalizumab prevents α4β1 integrin binding to vascular cell adhesion molecule 1 (VCAM1) and the α4β7 integrin binding to mucosal vascular addressin cell adhesion molecule 1 (MAdCAM1), resulting in an anti-inflammatory effect. It is an effective treatment for multiple sclerosis, which works by preventing immune cells from entering the central nervous system by interfering with lymphocyte binding the α4β1 integrin. This treatment is not without risk, however, since there are reports of progressive multifocal leucoencephalopathy (PML) in multiple sclerosis (MS) treated patients, as a result of JC virus infection of the central nervous system. Similarly, vedolizumab, a monoclonal antibody directed against the α4/β7 integrin, is an effective treatment for Crohn disease and ulcerative colitis which works selectively by preventing lymphocytes entering gut endothelium by inhibiting the interaction with MAdCAM-1.

Complement

The complement system comprises a group of more than 20 tightly regulated, functionally linked proteins that act to promote inflammation and eliminate invading pathogens. Complement proteins are produced in the liver and are present in inactive form in the circulation. When the complement system is activated, it sets in motion a rapidly amplified biological cascade analogous to the coagulation cascade.

There are three mechanisms by which the complement cascade can be activated (Fig. 4.4):

- *The alternate pathway* is triggered directly by binding of C3 to bacterial cell-wall components, such as lipopolysaccharide of gram-negative bacteria and teichoic acid of gram-positive bacteria.
- *The classical pathway* is initiated when two or more IgM or IgG antibody molecules bind to antigen. The associated conformational change exposes binding sites on the antibodies for the first protein in the classical pathway, C1, which is a multiheaded molecule that can bind up to six antibody molecules. Once two or more 'heads' of a C1 molecule are bound to antibody, the classical cascade is triggered. An important inhibitor of the classical pathway is C1 inhibitor (C1inh), as illustrated in Figure 4.4.
- *The lectin pathway* is activated when mannose-binding lectin interacts with microbial cell surface carbohydrates. Mannose-binding lectin (MBL) is an acute phase protein produced by the liver. It binds to carbohydrates such as mannose or N-acetylglucosamine on the surface of pathogens such as bacteria, viruses, parasites and fungi. When MBL binds to its target, MBL-associated proteases are recruited to the complex and these activate C4 and C2 directly. This stimulates the classical pathway bypassing the need for immune complex formation.

Activation of complement by any of these pathways results in activation of C3. This in turn activates the final common pathway, in which the complement proteins C5–C9 assemble to form the membrane attack complex (MAC). This can puncture the cell wall, leading to osmotic lysis of target cells. This step is particularly important in the defense against encapsulated bacteria such as *Neisseria* spp. and *Haemophilus influenzae*.

Complement fragments generated by activation of the cascade can also act as opsonins, rendering microorganisms more susceptible to phagocytosis by macrophages and neutrophils (see Fig. 4.2B). In addition, they are chemotactic agents, promoting leucocyte trafficking to sites of inflammation. Some fragments act as anaphylatoxins, binding to complement receptors on mast cells and triggering release of histamine, which increases vascular permeability. The products of complement activation also help to target immune complexes to antigen-presenting cells, providing a link between the innate and the adaptive immune systems. Finally, activated complement products dissolve the immune complexes that triggered the cascade, minimising bystander damage to surrounding tissues.

There are a number of regulatory proteins within the complement system that prevent activation on host cells, thereby preventing host

4.2 Important cytokines in the regulation of the immune response

Cytokine	Source	Actions	Biologic therapies
Interferon-alpha (IFN-α)	T cells and macrophages	Antiviral activity Activates NK cells, CD8$^+$ T cells and macrophages	Recombinant IFN-α used in hepatitis C and some malignancies
Interferon-gamma (IFN-γ)	T cells and NK cells	Increases antimicrobial activity of macrophages Regulates cytokine production by T cells and macrophages	Interferon-γ used in chronic granulomatous disease
Tumour necrosis factor alpha (TNF-α)	Macrophages, NK cells and others, including T cells	Pro-inflammatory Increases expression of other cytokines and adhesion molecules Causes apoptosis of some target cells Directly cytotoxic	TNF-α inhibitors used in rheumatoid arthritis, inflammatory bowel disease, psoriasis and many other inflammatory conditions
Interleukin-1 (IL-1)	Macrophages and neutrophils	Stimulates neutrophil recruitment, fever, and T-cell and macrophage activation as part of the inflammatory response	IL-1 inhibitors used in systemic juvenile rheumatoid arthritis, systemic autoinflammatory syndromes and acute gout
Interleukin-2 (IL-2)	CD4$^+$ T cells	Stimulates proliferation and differentiation of antigen-specific T lymphocytes	IL-2 inhibitors used in the treatment of transplant rejection
Interleukin-4 (IL-4)	CD4$^+$ T cells	Stimulates maturation of B and T cells, and production of IgE antibody	Antibodies to IL-4 receptor used in severe atopic dermatitis
Interleukin-5 (IL-5)	CD4$^+$ T cells, mast cells, eosinophils and basophils	Growth and differentiation factor for B cells and eosinophils	Antibodies to IL-5 or the IL-5 receptor used in treatment refractory eosinophilic asthma and eosinophilic granulomatosis with polyangiitis
Interleukin-6 (IL-6)	Monocytes and macrophages	Stimulates neutrophil recruitment, fever, and T-cell and macrophage activation as part of the inflammatory response, stimulates maturation of B cells into plasma cells	Antibodies to IL-6 receptor used in rheumatoid arthritis and giant cell arteritis
Interleukin-12 (IL-12)	Monocytes and macrophages	Stimulates IFN-γ and TNF-α release by T cells Activates NK cells	Antibody to p40 subunit of IL-12 used in psoriasis and psoriatic arthritis
Interleukin-17 (IL-17)	Th17 cells (T helper), NK cells, NK-T cells	Pro-inflammatory cytokine Involved in mucosal immunity and control of extracellular pathogens, synergy with IL-1 and TNF	Antibody to IL-17 used in psoriasis, psoriatic arthritis and axial spondyloarthritis
Interleukin-22 (IL-22)	Th17 cells	Induction of epithelial cell proliferation and antimicrobial proteins in keratinocytes	
Interleukin-23 (IL-23)	Activated macrophages and dendritic cells in peripheral tissues	Pro-inflammatory cytokine, proliferation of Th17 T cells with induction of IL-17	Antibody to IL-23 used in psoriasis, psoriatic arthritis and inflammatory bowel disease

(IgE = immunoglobulin E; NK = natural killer)

cell damage, some of which are membrane bound, and others soluble, such as C1 inhibitor. Factor H is an important regulatory protein which controls the alternate pathway. Deficiency in factor H is associated with activation of the alternate pathway and can lead to atypical haemolytic uraemic syndrome. The CD59 and CD55 proteins are important in the terminal complement pathway. Both are glycosylphosphatidylinositol-anchored cell surface proteins; CD59 inhibits formation of C3 convertases whereas CD55 (also known as decay-accelerating factor or DAF) prevents polymerisation of the membrane attack complex. Deficiency of either can lead to paroxysmal nocturnal haemoglobulinuria as a result of complement-mediated haemolysis. A monoclonal antibody directed against the central complement molecule C5, eculizumab, has been developed for therapeutic use in these conditions. Invasive infection, including meningococcal sepsis, has been reported with eculizumab therapy, highlighting the importance of the complement system in preventing such infections.

Mast cells and basophils

Mast cells and basophils are bone marrow–derived cells that play a central role in allergic disorders. Mast cells reside predominantly in tissues exposed to the external environment, such as the skin and gut, while basophils circulate in peripheral blood and are recruited into tissues in response to inflammation. Both contain large cytoplasmic granules that enclose vasoactive substances such as histamine. Mast cells and basophils express IgE receptors on their cell surface, which bind IgE antibody. On encounter with specific antigen, the cell is triggered to release histamine and other mediators present within the granules and to synthesise additional mediators, including leukotrienes, prostaglandins and cytokines. An inflammatory cascade is initiated that increases local blood flow and vascular permeability, stimulates smooth muscle contraction and increases secretion at mucosal surfaces.

Natural killer cells

Natural killer (NK) cells are large granular lymphocytes that play a major role in defense against tumours and viruses. They exhibit features of both the adaptive and the innate immune systems in that they are morphologically similar to lymphocytes and recognise similar ligands, but they are not antigen-specific and cannot generate immunological memory. NK cells express a variety of cell surface receptors, some of which are stimulatory and others inhibitory. The effects of inhibitory receptors normally predominate. These recognise human leucocyte antigen (HLA) molecules that are expressed on normal nucleated cells, preventing NK cell–mediated attack, whereas the stimulatory receptors recognise molecules that are expressed primarily when cells are damaged. This allows

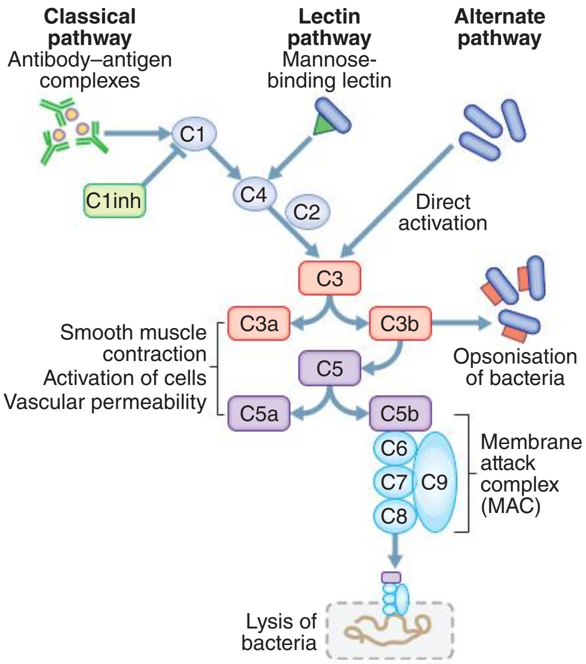

Fig. 4.4 **The complement pathway.** The classical pathway is activated by binding of antigen–antibody complexes to C1 but is blocked by C1 inhibitor (C1inh), whereas mannose-binding lectins, which are macromolecules that bind to carbohydrates on the surface of various microorganisms, activate the pathway by binding C4. Bacteria can directly activate the pathway through C3, which plays a pivotal role in complement activation through all three pathways.

NK cells to remain tolerant to healthy cells but not to damaged ones. When cells become infected by viruses or undergo malignant change, expression of HLA class I molecules on the cell surface can be down-regulated. This is an important mechanism by which these cells then evade adaptive T-lymphocyte responses. In this circumstance, however, NK cell defenses become important, as down-regulation of HLA class I abrogates the inhibitory signals that normally prevent NK activation. The net result is NK attack on the abnormal target cell. NK cells can also be activated by binding of antigen–antibody complexes to surface receptors. This physically links the NK cell to its target in a manner analogous to opsonisation and is known as antibody-dependent cellular cytotoxicity (ADCC).

Activated NK cells can kill their targets in various ways. They secrete pore-forming proteins such as perforin into the membrane of the target cell, and proteolytic enzymes called granzymes into the target cell, which cause apoptosis. In addition, NK cells produce a variety of cytokines such as TNF-α and IFN-γ, which have direct antiviral and anti-tumour effects.

The adaptive immune system

If the innate immune system fails to provide effective protection against an invading pathogen, the adaptive immune system is mobilised (see Fig. 4.1). This has three key characteristics:

- It has exquisite specificity and can discriminate between very small differences in molecular structure.
- It is highly adaptive and can respond to an almost unlimited number of molecules.
- It possesses immunological memory, and changes consequent to initial activation by an antigen allow a more effective immune response on subsequent encounters.

There are two major arms of the adaptive immune response. Humoral immunity involves the production of antibodies by B lymphocytes, and cellular immunity involves the activation of T lymphocytes, which synthesise and release cytokines that affect other cells, as well as directly killing target cells. These interact closely with each other and with the components of the innate immune system to maximise effectiveness of the immune response.

Lymphoid organs

The primary lymphoid organs are involved in lymphocyte development. They include the bone marrow, where T and B lymphocytes differentiate from haematopoietic stem cells and where B lymphocytes also mature, and the thymus, the site of T-cell maturation (see Fig. 4.1). After maturation, lymphocytes migrate to the secondary lymphoid organs. These include the spleen, lymph nodes and mucosa-associated lymphoid tissue. These trap and concentrate foreign substances and are the major sites of interaction between naïve lymphocytes and microorganisms.

The thymus

The thymus is a bilobed structure in the anterior mediastinum and is organised into cortical and medullary areas. The cortex is densely populated with immature T cells, which migrate to the medulla to undergo selection and maturation. The thymus is most active in the fetal and neonatal period, and involutes after puberty. Failure of thymic development is associated with profound T-cell immune deficiency but surgical removal of the thymus in childhood (usually during major cardiac surgery) is not associated with significant immune dysfunction.

The spleen

The spleen is the largest of the secondary lymphoid organs. It is highly effective at filtering blood and is an important site of phagocytosis of senescent erythrocytes, bacteria, immune complexes and other debris, and of antibody synthesis. It is important for defense against encapsulated bacteria, and asplenic individuals are at risk of overwhelming *Streptococcus pneumoniae* and *H. influenzae* infection (see Box 4.5 below).

Lymph nodes

These are positioned to maximise exposure to lymph draining from sites of external contact and are highly organised (see Fig. 4.1). The *cortex* contains primary lymphoid follicles, which are the site of B-lymphocyte interactions. When B cells encounter antigen, they undergo intense proliferation, forming germinal centres.

- The *paracortex* is rich in T lymphocytes and dendritic cells.
- The *medulla* is the major site of antibody-secreting plasma cells.
- Within the medulla there are many *sinuses*, which contain large numbers of macrophages.

Mucosa-associated lymphoid tissue

Mucosa-associated lymphoid tissue (MALT) consists of diffusely distributed lymphoid cells and follicles present along mucosal surfaces. Unlike lymph nodes, they are not encapsulated, but rather embedded directly in the submucosa of the organs in which they are found. They include the tonsils, adenoids and Peyer patches. MALT has a similar function to the more organised lymph nodes, but antigens are collected directly from the mucosal surface across specialised epithelial cells. Dendritic cells are found immediately below this epithelium, with B cells forming follicles underneath the dendritic cell layer, while T-cell zones occupy the space between the follicles.

Lymphatics

Lymphoid tissue is connected by a network of lymphatics, with three major functions: lymphatics provide access to lymph nodes, return interstitial fluid to the venous system and transport fat from the small intestine to the blood stream (see Fig. 19.12). The lymphatics begin as blind-ending capillaries, which come together to form lymphatic ducts, entering and leaving regional lymph nodes as afferent and efferent ducts, respectively. They eventually coalesce and drain into the thoracic duct and left subclavian vein. Lymphatics may be either deep or superficial and follow the distribution of major blood vessels.

Humoral immunity

Humoral immunity is mediated by B lymphocytes, which differentiate from haematopoietic stem cells in the bone marrow. Their major functions are to produce antibody and interact with T cells, but they are also involved in antigen presentation. Mature B lymphocytes can be found in the bone marrow, lymphoid tissue, spleen and, to a lesser extent, the blood stream. They express a unique receptor on their cell surface, the B-cell receptor (also known as the immunoglobulin receptor), which binds to soluble antigen targets (Fig. 4.5). Encounters with antigen usually occur within lymph nodes. If provided with appropriate cytokines and other signals from nearby T lymphocytes, antigen-specific B cells respond by rapidly proliferating in a process known as clonal expansion (see Fig. 4.5). This is accompanied by a highly complex series of genetic rearrangements known as somatic hypermutation, which generates B-cell populations that express receptors with greater affinity for antigen than the original. These cells differentiate into either long-lived memory cells, which reside in the lymph nodes, or plasma cells, which produce antibody. Memory cells allow production of a more rapid and more effective response on subsequent exposure to that pathogen.

Immunoglobulins

Immunoglobulins (Ig) play a central role in humoral immunity. They are soluble proteins produced by plasma cells and are made up of two heavy and two light chains (Fig. 4.6). The heavy chain determines the antibody class or isotype, such as IgG, IgA, IgM, IgE or IgD (Box 4.3). Subclasses of IgG and IgA also occur. The antigen is recognised by the antigen-binding regions (Fab) of both heavy and light chains, while the consequences of antibody binding are determined by the constant region of the heavy chain (Fc) (Fig. 4.6). Antibodies have several functions. They facilitate phagocytosis by acting as opsonins (see Fig. 4.2B) and facilitate cell killing by cytotoxic cells, particularly NK cells by antibody-dependent cellular cytotoxicity. Binding of antibodies to antigen can trigger activation of the classical complement pathway (see Fig. 4.4). In addition, antibodies can directly neutralise the biological activity of their antigen target. This is a particularly important feature of IgA antibodies, which act predominantly at mucosal surfaces.

The humoral immune response is characterised by immunological memory, in which the antibody response to successive exposures to an antigen is qualitatively and quantitatively improved from the first exposure. When a previously unstimulated or 'naïve' B lymphocyte is activated by antigen, the first antibody to be produced is IgM, which appears in the serum after 5–10 days. Depending on additional stimuli provided by T lymphocytes, other antibody classes (IgG, IgA and IgE) are produced 1–2 weeks later. If the memory B cell is subsequently re-exposed to the same antigen, the lag time between exposure and production of antibody is decreased to 2–3 days, the amount of antibody produced is increased, and the response is dominated by IgG antibodies of high affinity. Furthermore, in contrast to the initial antibody response, secondary antibody responses do not require additional input from T lymphocytes. This allows the rapid generation of highly specific responses on re-exposure to a pathogen and is an important mechanism in vaccine efficacy.

Cellular immunity

Cellular immunity is mediated by T lymphocytes, which play important roles in defense against viruses, fungi and intracellular bacteria. They also play an important immunoregulatory role, by orchestrating and regulating the responses of other components of the immune system. T-lymphocyte precursors differentiate from haematopoietic stem cells in the bone marrow and are exported to the thymus when they are still immature (see Fig. 4.1). Individual T cells express a unique receptor called the T-cell receptor that is highly specific for a single antigen (Fig. 4.7). Within the thymus T cells undergo a process of stringent selection to ensure that autoreactive cells are destroyed. Mature T lymphocytes leave the thymus and expand to populate other organs of the immune system. It has been estimated that an individual possesses 10^7–10^9 T-cell clones, each with a unique T-cell receptor, ensuring at least partial coverage for any antigen encountered.

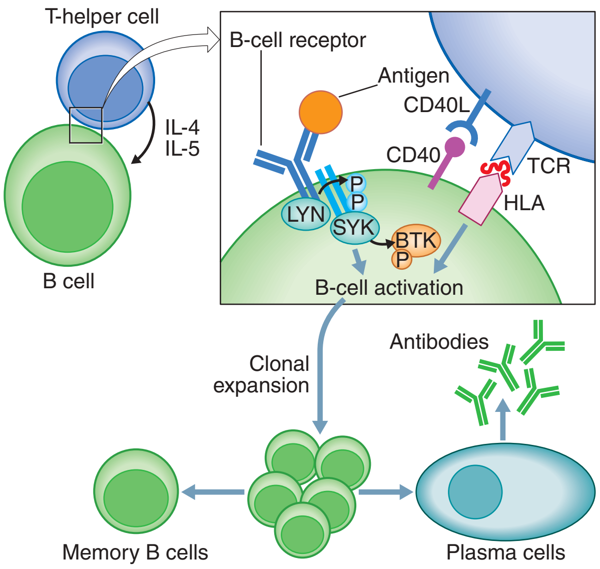

Fig. 4.5 B-cell activation. Activation of B cells is initiated through binding of an antigen with the B-cell receptor on the cell surface. Proteins immediately downstream of the B-cell receptor (BCR) include the Lyn and Syk tyrosine kinases, which lead to phosphorylation (P) of the Bruton tyrosine kinase (BTK). For activation to proceed, an interaction with T-helper cells is also required, providing additional signals through binding of CD40 ligand (CD40L) to CD40; an interaction between the T-cell receptor (TCR) and processed antigenic peptides presented by human leucocyte antigen (HLA) molecules on the B-cell surface; and cytokines released by the T-helper cells. Fully activated B cells undergo clonal expansion with differentiation towards plasma cells that produce antibody. Following activation, memory cells are generated that allow rapid antibody responses when the same antigen is encountered on a second occasion. (IL = interleukin)

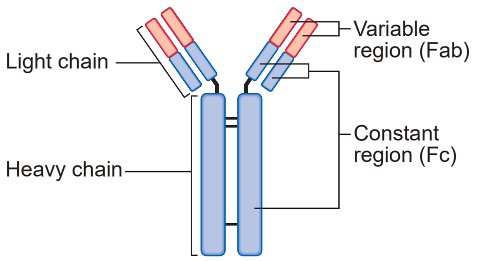

Fig. 4.6 The structure of an immunoglobulin (antibody) molecule. The variable region is responsible for antigen binding, whereas the constant region can interact with immunoglobulin receptors expressed on immune cells.

Unlike B cells, T cells cannot recognise intact protein antigens in their native form. Instead, the protein must be broken down into component peptides by antigen-presenting cells for presentation to T lymphocytes in association with HLA molecules on the antigen-presenting cell surface (Fig. 4.7). This process is known as antigen processing and presentation, and it is the complex of peptide and HLA together that is recognised by individual T cells. The structure of HLA molecules varies widely between individuals. Since each HLA molecule has the capacity to present a subtly different peptide repertoire to T lymphocytes, this ensures enormous diversity in recognition of antigens by the T-cell population. All nucleated cells have the capacity to process and present antigens, but cells with specialised antigen-presenting functions include dendritic cells, macrophages and B lymphocytes. These cells express the stimulatory molecules CD80 and CD86, providing the necessary 'second signal' by binding to the co-stimulatory molecule CD28, which is expressed on T cells. Mechanisms also exist to inhibit activation of T cells.

4.3 Classes and properties of antibody

Antibody	Concentration in adult serum	Complement activation*	Opsonisation	Presence in external secretions	Other properties
IgG	6.0–16.0 g/L	IgG1 +++ IgG2 + IgG3 +++	IgG1 ++ IgG3 ++	++	Four subclasses: IgG1, IgG2, IgG3, IgG4 Distributed equally between blood and extracellular fluid, and transported across placenta IgG2 is particularly important in defence against polysaccharide antigens
IgA	1.5–4.0 g/L	–	–	++++	Two subclasses: IgA1, IgA2 Highly effective at neutralising toxins Particularly important at mucosal surfaces
IgM	0.5–2.0 g/L	++++	–	+	Highly effective at agglutinating pathogens
IgE	0.003–0.04 g/L	–	–	–	Majority of IgE is bound to mast cells, basophils and eosinophils Important in allergic disease and defence against parasite infection
IgD	Not detected	–	–	–	Function in B-cell development

Fig. 4.7 Antigen presentation. For T-cell activation, antigen must be processed via antigen-presenting cells (APCs). Pathogens, bearing pathogen-associated molecular patterns (PAMPs) on their surface, are recognised by pattern recognition receptors (PRRs) on the APC. Following endocytosis, the pathogen is broken down intracellularly. Antigenic peptides are then loaded onto human leucocyte antigens (HLAs), also known as major histocompatibility complexes (MHCs), and presented at the APC surface. The combination of peptide and HLA is then recognised by the T-cell receptor (TCR). For T-cell activation, a second, co-stimulatory signal is required through binding of CD80 or CD86 on the APC to CD28 on the T cell, and interleukin 2 (IL-2), which is produced in an autocrine manner by T cells that are undergoing activation. Other molecules are present that can inhibit T-cell activation. These include the cytotoxic T lymphocyte–associated protein 4 (CTLA4), which competes with CD28 for binding to CD80 and CD86. Once activated, T cells proliferate and, depending on their subtype, have various functions with distinct patterns of cytokine production, as indicated. Memory cells are also generated that can mount a rapid immune response on encountering the same antigen. (CD28 and CD80/86 = co-stimulatory molecules; IL = interleukin; IFN-γ = interferon-gamma; TCR = T-cell receptor; TGF-β = transforming growth factor beta; TNF-α = tumour necrosis factor alpha)

One example is CTLA4, which competes with CD28 for CD80/CD86 binding. Another is the programmed cell death protein 1 (PD-1), which is expressed on lymphocytes and inhibits lymphocyte activation when bound by its ligand, the programmed cell death ligand 1 (PDL-1). This is a molecule expressed on some tumour cells (see Fig. 4.7) as well as other cell types. Monoclonal antibodies, which inhibit this interaction, are important treatments for certain types of cancer (see tumour immunology later in this chapter).

T lymphocytes can be divided into two subgroups based on function and recognition of HLA molecules. These are designated $CD4^+$ and $CD8^+$ T cells, according to the 'cluster of differentiation' (CD) antigen number of key proteins expressed on their cell surface.

$CD8^+$ T lymphocytes

These cells recognise antigenic peptides in association with HLA class I molecules (HLA-A, HLA-B, HLA-C). They kill infected cells directly through the production of pore-forming molecules such as perforin and release of digesting enzymes triggering apoptosis of the target cell and are particularly important in defence against viral infection.

$CD4^+$ T lymphocytes

These cells recognise peptides presented on HLA class II molecules (HLA-DR, HLA-DP and HLA-DQ) and have mainly immunoregulatory functions. They produce cytokines and provide co-stimulatory signals that support the activation of $CD8^+$ T lymphocytes and assist the production of mature antibody by B cells. In addition, their close interaction with phagocytes determines cytokine production by both cell types. $CD4^+$ lymphocytes can be further subdivided into subsets based on the cytokines they produce:

- Th1 (T-helper) cells typically produce IL-2, IFN-γ and TNF-α, and support the development of delayed-type hypersensitivity responses. They are involved in defending against intracellular pathogens and have been implicated in the pathogenesis of several autoimmune diseases, including type 1 diabetes, multiple sclerosis, rheumatoid arthritis, and Crohn disease.
- Th2 cells typically produce IL-4, IL-5, IL-10 and IL-13. They are implicated in mounting immune response against extracellular parasites, bacteria and allergens and are thought to be involved in the pathogenesis of asthma and atopic dermatitis.
- T-regulatory cells (T-regs) are a further subset of specialised $CD4^+$ lymphocytes that are important in suppressing activation of other cells and preventing autoimmune disease. They produce cytokines such as TGF-β and IL-10.
- Th17 cells are pro-inflammatory cells defined by their production of IL-17. They are related to regulatory T cells. Th17 cells have a key role in defence against extracellular bacteria and fungi. They also have a role in the pathogenesis of seronegative spondyloarthropathies.

T-cell activation is regulated by a balance between co-stimulatory molecules, the second signal required for activation, and inhibitory molecules that down-regulate T-cell activity. One such inhibitory molecule, CTLA4, has been harnessed therapeutically in the form of abatacept, which is a fusion protein composed of the Fc fragment of immunoglobulin linked to CTLA4. This is used to inhibit T-cell activation in rheumatoid arthritis, psoriatic arthritis and solid organ transplantation. Conversely, ipilimumab is an antibody that blocks CTLA4 which is used to activate T cells in the treatment of certain cancers. Similarly, pembrolizumab, a monoclonal antibody that blocks PD-1, and atezolizumab, a monoclonal antibody that blocks PD-L1, are both used to activate T cells in the treatment of certain types of cancer.

The inflammatory response

Inflammation is the response of tissues to injury or infection and is necessary for normal repair and healing. This section focuses on the general principles of the inflammatory response and its multisystem manifestations. The role of inflammation in specific diseases is discussed in many other chapters of this book.

Acute inflammation

Acute inflammation is the result of rapid and complex interplay between the cells and soluble molecules of the innate immune system. The classical external signs include heat, redness, pain and swelling (Fig. 4.8). The inflammatory process is initiated by local tissue injury or infection. Damaged epithelial cells produce cytokines and antimicrobial peptides, causing early infiltration of phagocytic cells. Production of leukotrienes, prostaglandins, histamine, kinins, anaphylatoxins and inducible nitric oxide synthase also occurs within inflamed tissue. These mediators cause vasodilatation and increase vascular permeability, causing trafficking of fluid and cells into the affected tissue. In addition, pro-inflammatory cytokines, such as IL-1, TNF-α and IL-6 produced at the site of injury, are released systemically and act on the hypothalamus to cause fever, and on the liver to stimulate production of acute phase proteins.

The acute phase response

The acute phase response refers to the production of a variety of proteins by the liver in response to inflammatory stimuli. These proteins have a wide range of activities. Circulating levels of C-reactive protein and serum amyloid A may be increased 100- to 1000-fold, contributing to host defence and stimulating repair and regeneration. Fibrinogen plays an essential role in wound healing, and α1-antitrypsin and α1-antichymotrypsin control the pro-inflammatory cascade by neutralising the enzymes produced by activated neutrophils, preventing widespread tissue destruction. In addition, antioxidants such as haptoglobin and manganese superoxide dismutase scavenge for oxygen free radicals, while increased levels of iron-binding proteins such as ferritin and lactoferrin decrease the iron available for uptake by bacteria. Immunoglobulins are not acute phase proteins but are often increased in chronic inflammation.

Septic shock

Septic shock is the clinical manifestation of overwhelming inflammation. It is characterised by excessive production of pro-inflammatory cytokines by macrophages, causing hypotension, hypovolaemia and tissue oedema. In addition, uncontrolled neutrophil activation causes release of proteases and oxygen free radicals within blood vessels, damaging the vascular endothelium and further increasing capillary permeability. Direct activation of the coagulation pathway combines with endothelial cell disruption to form clots within the damaged vessels. The clinical consequences include cardiovascular collapse, acute respiratory distress syndrome, disseminated intravascular coagulation, multi-organ failure and often death. Septic shock most frequently results from infection with gram-negative bacteria, because lipopolysaccharide produced by these organisms is particularly effective at activating the inflammatory cascade. Early recognition and appropriate early intervention can improve patient outcome. More details on the diagnosis and management of septic shock are provided in Chapter 10.

Resolution of inflammation

Resolution of an inflammatory response is crucial for normal healing. This involves active down-modulation of inflammatory stimuli and repair of bystander damage to local tissues. Extravasated neutrophils undergo apoptosis and are phagocytosed by macrophages, along with the remains of microorganisms. Macrophages also synthesise collagenase and elastase, which break down local connective tissue and aid in the removal of debris. Normal tissue homeostasis is also associated with reversion of parenchymal cells to a non-inflammatory phenotype. Macrophage-derived cytokines, including transforming growth factor beta (TGF-β) and platelet-derived growth factor, stimulate fibroblasts and promote the synthesis of new collagen, while angiogenic factors stimulate new vessel formation.

Fig. 4.8 **Clinical features of acute inflammation.** In this example, a break in the skin has allowed cellulitis to develop close to the right knee, with multiple systemic sequelae as shown. (ACTH = adrenocorticotrophic hormone; CRP = C-reactive protein) *Clinical photo from Mosby's dictionary of medicine, nursing, and health professions. 11th ed. St. Louis: Mosby, Elsevier Inc; 2022.*

Hyperinflammation

Hyperinflammatory conditions are being increasingly recognised, with impaired cytotoxicity linked to excessive release of pro-inflammatory cytokines and subsequent macrophage activation. This can lead to haemophagocytic lymphohistiocytosis (HLH), which is a life-threatening hyperinflammatory condition, with inappropriate activation of macrophages, T cells and cytokine release, and extensive tissue damage. Primary, or familial, HLH usually presents in infancy and a number of inborn errors of immunity have been identified in this context. Secondary HLH is typically triggered by infection but can also be seen in malignancy and autoimmune disease. Emerging evidence suggests that genetic variants are also involved in secondary HLH. Prompt recognition and aggressive anti-inflammatory therapy is required. The diagnosis and management of HLH is discussed in Chapter 24.

Chronic inflammation

In most instances, the development of an active immune response results in clearance and control of the inflammatory stimulus and resolution of tissue damage. Failure of this process may result in chronic inflammation, with significant associated bystander damage, known as hypersensitivity responses. Persistence of microorganisms can result in ongoing accumulation of neutrophils, macrophages and activated T lymphocytes within the lesion. If this is associated with local deposition of fibrous tissue, a granuloma may form. Granulomas are characteristic of tuberculosis and leprosy (Hansen disease), in which the microorganism is protected by a robust cell wall that shields it from killing, despite phagocytosis.

Laboratory features of inflammation

Inflammation is associated with changes in many laboratory investigations. Leucocytosis is common and reflects the transit of activated neutrophils and monocytes to the site of infection. The platelet count may also be increased. The most widely used laboratory measure of acute inflammation is C-reactive protein (CRP). Circulating levels of many other acute phase reactants, including fibrinogen, ferritin and complement components, are also increased in response to acute inflammation, while albumin levels are reduced. Chronic inflammation is frequently associated with a normocytic normochromic anaemia.

C-reactive protein

C-reactive protein (CRP) is an acute phase reactant synthesised by the liver, which opsonises invading pathogens. Circulating concentrations of CRP increase within 6 hours of the start of an inflammatory stimulus. Serum concentrations of CRP provide a direct biomarker of acute inflammation and, because the serum half-life of CRP is 18 hours, levels fall promptly once the inflammatory stimulus is removed. Sequential measurements are useful in monitoring disease activity (Box 4.4). For reasons that remain unclear, some diseases are associated with only minor elevations of CRP despite unequivocal evidence of active inflammation. These include systemic lupus erythematosus (SLE), systemic sclerosis, ulcerative colitis and leukaemia. An important practical point is that if the CRP is raised in these conditions, it suggests intercurrent infection rather than disease activity. Since the CRP is a more sensitive early indicator of the acute phase response, it is generally used in preference to the erythrocyte sedimentation rate (ESR). If both ESR

4.4 Conditions commonly associated with abnormal C-reactive protein (CRP) and/or erythrocyte sedimentation rate (ESR)

Condition	Consequence	Effect on CRP[1]	Effect on ESR[2]
Acute bacterial, fungal or viral infection	Stimulates acute phase response	Increased (range 50–150 mg/L; in severe infections may be > 300 mg/L)	Increased
Necrotising bacterial infection	Stimulates profound acute inflammatory response	Greatly increased (may be > 300 mg/L)	Increased
Chronic bacterial or fungal infection **Localised abscess, bacterial endocarditis or tuberculosis**	Stimulates acute and chronic inflammatory response with polyclonal increase in immunoglobulins, as well as increased acute phase proteins	Increased (range 50–150 mg/L)	Increased disproportionately to CRP
Acute inflammatory diseases **Crohn disease, polymyalgia rheumatica, inflammatory arthritis, gout**	Stimulates acute phase response	Increased (range 50–150 mg/L)	Increased
Systemic lupus erythematosus, Sjögren syndrome	Chronic inflammatory response	Normal or slightly elevated	Increased
Multiple myeloma	Monoclonal increase in serum immunoglobulin without acute inflammation	Normal	Increased
Pregnancy, old age, end-stage renal disease	Increased fibrinogen	Normal	Moderately increased

[1] Reference range < 5 mg/L.
[2] Reference range: adult males < 10 mm/hr, adult females 3–15 mm/hr.

and CRP are used, any discrepancy should be resolved by assessing the individual determinants of the ESR, which are discussed below.

Erythrocyte sedimentation rate

The ESR is an indirect measure of inflammation. It measures how fast erythrocytes fall through plasma, which is determined by the composition of plasma proteins and the morphology of circulating erythrocytes. These factors govern the propensity of red cells to aggregate, the major determinant of the ESR. Erythrocytes are inherently negatively charged, which prevents them from clumping together in the blood stream. Since plasma proteins are positively charged, increased concentrations of these proteins neutralise the negative charge of erythrocytes, overcoming their inherent repulsive forces and causing them to aggregate, resulting in rouleaux formation. Rouleaux have a higher mass-to-surface area ratio than single red cells, and therefore sediment faster. The most common reason for an increased ESR is an acute phase response, which causes an increase in the concentration of acute phase proteins, including CRP. However, other conditions that do not affect acute phase proteins may alter the composition and concentration of other plasma proteins (see Box 4.4). For example, immunoglobulins comprise a significant proportion of plasma proteins but do not participate in the acute phase response. Thus, any condition that causes an increase in serum immunoglobulins will increase the ESR without a corresponding increase in CRP. In addition, abnormal red cell morphology can make rouleaux formation impossible. For these reasons, an inappropriately low ESR occurs in spherocytosis and sickle-cell disorder.

Plasma viscosity

Plasma viscosity is another surrogate measure of plasma protein concentration. Like the ESR, it is affected by the concentration of large plasma proteins, including fibrinogen and immunoglobulins. It is not affected by properties of erythrocytes and is generally considered to be more reliable than the ESR as a marker of inflammation.

Presenting problems in immune disorders

Recurrent infections

Infections can occur in otherwise healthy individuals, but recurrent infection raises suspicion of an immune deficiency. Depending on the component of the immune system affected, the infections may involve bacteria, viruses, fungi or protozoa, as summarised in Box 4.5. T-cell deficiencies can involve pathogens from all groups.

Aetiology

Infections secondary to immune deficiency occur because of defects in the number or function of phagocytes, B cells, T cells or complement, as described later in this chapter.

Clinical assessment

Clinical features that may indicate immune deficiency are listed in Box 4.6. Frequent or severe infections, or ones caused by unusual organisms or at unusual sites, are typical of immune deficiency.

Investigations

Initial investigations should include full blood count and white cell differential, CRP, renal and liver function tests, urine dipstick, serum immunoglobulins with protein electrophoresis and HIV testing. Additional microbiological tests, virology and imaging are required to identify the causal organism and localise the site of infection, as outlined in Box 4.7. If primary immune deficiency is suspected on the basis of initial investigations, more specialised tests should be considered, as summarised in Box 4.8.

Management

If an immune deficiency is suspected but has not yet been formally characterised, patients should not receive live vaccines because of the risk of vaccine-induced disease. Further management depends on the underlying cause and details are provided later.

Intermittent fever

Intermittent fever has a wide differential diagnosis, including recurrent infection, malignancy and certain rheumatic disorders, such as Still disease, vasculitis and SLE, but systemic autoinflammatory disorders are also a potential cause.

Aetiology

Systemic autoinflammatory disorders are genetic disorders caused by pathogenic variants in genes responsible for regulating the inflammatory response. The symptoms are caused by activation of intracellular signalling pathways involved in the regulation of inflammation, with over-production of pro-inflammatory cytokines such as IL-1.

4.5 Immune deficiencies and common patterns of infection

Phagocyte deficiency	Complement deficiency	Antibody deficiency	T-lymphocyte deficiency
Bacteria			
Staphylococcus aureus *Pseudomonas aeruginosa* *Serratia marcescens* *Burkholderia cenocepacia* *Nocardia* *Mycobacterium tuberculosis* Atypical mycobacteria	*Neisseria meningitidis* *Neisseria gonorrhoeae* *Haemophilus influenzae* *Streptococcus pneumoniae*	*Haemophilus influenzae* *Streptococcus pneumoniae* *Staphylococcus aureus*	*Mycobacterium tuberculosis* Atypical mycobacteria
Fungi			
Candida spp. *Aspergillus* spp.	–	–	*Candida* spp. *Aspergillus* spp. *Pneumocystis jirovecii*
Viruses	–	–	Cytomegalovirus (CMV) Enteroviruses Epstein–Barr virus (EBV) Herpes zoster virus Human papillomavirus Human herpesvirus 8
Protozoa	–	*Giardia lamblia*	*Toxoplasma gondii* *Cryptosporidia*

4.6 Warning signs of primary immune deficiency*

In children	In adults
≥4 new ear infections within 1 year	≥2 new ear infections within 1 year
≥2 serious sinus infections within 1 year	≥2 new sinus infections within 1 year, in the absence of allergy
≥2 months on antibiotics with little effect	Recurrent viral infections
≥2 pneumonias within 1 year	≥1 pneumonia per year for more than 1 year
Failure of an infant to gain weight or grow normally	Chronic diarrhoea with weight loss
Recurrent deep skin or organ abscesses	Recurrent deep skin or organ abscesses
Persistent thrush in mouth or elsewhere on skin after infancy	Persistent thrush or fungal infection on skin or elsewhere
Need for intravenous antibiotics to clear infections	Recurrent need for intravenous antibiotics to clear infections
≥2 deep-seated infections such as sepsis, meningitis or cellulitis	Infection with atypical mycobacteria
A family history of primary immune deficiency	A family history of primary immune deficiency

*The presence of two or more of the listed features may indicate the presence of an underlying primary immunodeficiency.

4.7 Initial investigations in suspected immune deficiency

Test	Value	Comment
Full blood count	Full white cell differential	May define pathway for further investigation
Acute phase reactants	Help determine presence of active infection	
Serum immunoglobulins	Detection of antibody deficiency	
Serum protein electrophoresis	Detection of paraprotein	May be the cause of immune paresis; paraprotein should be excluded prior to diagnosis of primary antibody deficiency
Serum free light chains/Bence Jones proteins	Detection of paraprotein	
Human immunodeficiency virus (HIV) test	To exclude HIV as cause of secondary immune deficiency	
Imaging according to history and examination findings	Detection of active infection/end-organ damage	To support treatment decisions

Clinical assessment

A full clinical history and physical examination should be performed, paying attention to the patient's ethnic background and any family history of a similar disorder. If this assessment shows no evidence of underlying infection, malignancy or a rheumatic disease and there is a positive family history with early age at onset, then the likelihood of a systemic autoinflammatory disorder is increased.

Investigations

Blood should be taken for a full blood count, measurement of ESR and CRP, and assessment of renal and liver function. Serum ferritin should be checked, as very high levels support the diagnosis of Still disease. Blood and urine cultures should also be performed, along with an autoimmune screen that includes measurement of antinuclear antibodies and consideration of antineutrophil cytoplasmic antibodies to check for evidence of SLE or vasculitis, respectively. Imaging may be required to exclude occult infection. If these investigations provide no evidence of infection or another cause, then genetic analysis should be considered to confirm the diagnosis of a systemic autoinflammatory disorder. Negative genetic testing does not, however, entirely exclude such a condition, as new pathogenic variants continue to be identified.

Management

Symptomatic management with non-steroidal anti-inflammatory drugs (NSAIDs) should be initiated, pending the results of investigations. If the response to NSAIDs is inadequate, glucocorticoids can be tried, provided that infection has been excluded. If a systemic autoinflammatory disorder is confirmed, then definitive therapy should be initiated, depending on the underlying diagnosis, as discussed later in this chapter (p. 74).

4.8 Specialist investigations in suspected immune deficiency

Test	Value	Comment
Complement (C3/C4/CH50/AP50)	Investigation of recurrent pyogenic bacterial infection	Inherited complement deficiency likely to give low/absent results on functional assays
Test vaccination	Determination of functional humoral immune response	Helpful in patients with borderline low or normal immunoglobulins but confirmed recurrent infection
Neutrophil function	Investigation of recurrent invasive bacterial and fungal infection, especially with catalase-positive organisms	Respiratory burst low/absent in chronic granulomatous disease
	Investigation of leucocyte adhesion deficiency	Leucocytosis with absent CD11a, b, c expression
Lymphocyte immunophenotyping (by flow cytometry)	Determination of specific lymphocyte subsets, T cell, B cell, NK cell	May define specific primary immune deficiency, such as absent B cells in X-linked agammaglobulinaemia
Lymphocyte proliferation	Determination of lymphocyte proliferation in response to mitogenic stimulation	Poor responses seen in certain T-cell immune deficiencies
Cytokine production	To determine T-cell immune function in response to antigen stimulation; limited availability, not routine	Can be helpful, for example, in investigation of atypical mycobacterial infection
Genetic testing, now being increasingly used to identify inborn error of immunity	Under specialist supervision when specific primary immune deficiency suspected	May confirm genetic cause, with implications for family members and future antenatal testing

(NK = natural killer)

Immune deficiency

The consequences of immune deficiency include recurrent infection, autoimmunity as a result of immune dysregulation, and increased susceptibility to malignancy, especially malignancy driven by viral infections such as Epstein–Barr virus. Immune deficiency may arise through intrinsic defects in immune function, but is much more commonly due to secondary causes, including infection, drug therapy, malignancy and ageing. This section gives an overview of primary immune deficiencies. More than 550 inborn errors of immunity (IEI) have now been described. Some of these are summarised in Box 4.9 and Figure 4.9. They are caused by pathogenic variants in single genes, and present clinically with increased susceptibility to infection, autoimmunity, autoinflammatory diseases, allergy, bone marrow failure and malignancy. The manifestation of immune deficiency depends on the component of the immune system that is defective (see Box 4.5). Many of these conditions present in childhood or adolescence. The majority are autosomal recessive, but X-linked and autosomal dominant patterns of inheritance also occur. Some examples of primary immune deficiency affecting innate and adaptive immunity are set out below, with disease manifestations explained by the underlying genetic defect.

Primary phagocyte deficiencies

Primary phagocyte deficiencies typically present with recurrent bacterial and fungal infections, which may involve unusual sites. Affected patients require aggressive management of infections, including intravenous antibiotics and surgical drainage of abscesses, and long-term prophylaxis with antibacterial and antifungal agents. Important examples are illustrated in Figure 4.10 and discussed below.

Chronic granulomatous disease

This is caused by pathogenic variants in one of the six genes that encode NADPH oxidase enzymes, which results in failure of oxidative killing. The most common type is caused by loss-of-function variants in *CYBB*. The defects cause increased susceptibility to infection with catalase-positive organisms such as *Staphylococcus aureus*, *Burkholderia cenocepacia* and *Aspergillus*. Intracellular killing of mycobacteria in macrophages is also impaired. Infections most commonly involve the lungs, lymph nodes, soft tissues, bone and skin, with deep abscess formation. The condition is complicated by granulomatous inflammation. Most cases are X-linked, and males are predominantly affected.

Leucocyte adhesion deficiencies

These very rare disorders of phagocyte migration occur because of failure to express adhesion molecules on the surface of leucocytes, resulting in their inability to exit the blood stream. One example is leucocyte adhesion deficiency type 1, caused by loss-of-function variants in the *ITGB2* gene which encodes the beta-2 integrin which is essential for adhesion of leucocytes to the endothelium (see Fig. 4.10). They are characterised by recurrent bacterial infections, but sites of infection lack evidence of neutrophil infiltration, such as pus formation. Peripheral blood neutrophil counts may be very high during acute infection because of the failure of mobilised neutrophils to exit blood vessels. Specialised tests show reduced or absent expression of adhesion molecules on neutrophils.

Defects in cytokines and cytokine receptors

Pathogenic variants in the genes encoding cytokines such as IFN-γ, IL-12, IL-23 or their receptors result in failure of intracellular killing by macrophages, and affected individuals are particularly susceptible to mycobacterial infections (see Fig. 4.10).

Complement pathway deficiencies

Loss-of-function pathogenic variants have been identified in almost all the complement pathway proteins (see Fig. 4.4). While most complement deficiencies are rare, mannose-binding lectin deficiency is common and affects about 5% of the northern European population, many of whom are asymptomatic (see below).

Clinical features

Patients with deficiency in complement proteins can present in different ways. In some cases, the presenting feature is recurrent infection with encapsulated bacteria, particularly *Neisseria* spp., reflecting the importance of the membrane attack complex in defence against these organisms. However, genetic deficiencies of the classical complement pathway (C1, C2 and C4) also present with an increased risk of autoimmune disease, particularly SLE. Individuals with mannose-binding lectin deficiency have an increased incidence of bacterial infections if subjected to an additional cause of immune compromise, such as premature birth or chemotherapy. The significance of this condition has been debated, however, since population studies have shown no overall increase in infectious disease or mortality in patients with this disorder. Deficiency of the regulatory protein Cl inhibitor is not associated with recurrent infection but causes recurrent angioedema as discussed below.

4.9 Genetic causes of immunodeficiency

Category	Mechanism	Genes	Inheritance
Severe combined immunodeficiency			
Absent T cells, B cells present, SCID	Loss of function of common gamma chain (important for downstream signalling of a number of immune receptors) Deficiency in the Jak3 signalling molecule	*IL2RG* *JAK3*	XLR AR
Absent T cells, absent B cells, SCID	Deficiency of the recombination activating proteins which initiate the V(D)J recombination process	*RAG1/RAG2*	AR
Bare lymphocyte syndrome	Absent or diminished HLA expression on CD4 and CD8 lymphocytes	*RFX-B* and other genes	AR
Combined immunodeficiency with other features			
Immunodeficiency with congenital thrombocytopenia with small platelets (Wiskott–Aldrich syndrome)	Deficiency of WASP, which is necessary for signalling in haemopoetic cells	*WAS*	XLR
DiGeorge syndrome (thymic defects with additional congenital anomalies)	Decreased T-cell production and function due to an absent or poorly developed thymus	22q11.2 deletion	AD
Predominantly antibody deficiencies			
X-linked agammaglobulinemia Severe reduction in all Ig isotypes and decreased/absent B cells	Deficiency of Bruton kinase necessary for B-cell development	*BTK*	XLR
Common variable immune deficiency	Mechanism unknown. Low IgG and IgA. Low IgM in some cases	Unknown	Variable
Immune dysregulation			
Familial haemophagocytic lymphohistiocytosis	Activation and proliferation of T lymphocytes and macrophages	*PRF1* *STX11, STXBP2, UNC13D*	AR AD AR/AD AR
Immune dysregulation, polyendocrinopathy, enteropathy (IPEX)	Deficiency of FOXP3, which regulates production of regulatory T cells	*FOXP3*	XLR
Autoimmune lymphoproliferative syndrome	Deficiency of Fas or Fas ligand results in defective apoptosis of lymphocytes causing immune activation	*TNFRSF6* *TNFSF6*	AD or AR AR
Defects in phagocyte number or function			
X-linked chronic granulomatous disease	Defect of phagocyte NADPH oxidase	*CYBB*	XLR
Defects in intrinsic and innate immunity			
Mendelian susceptibility to mycobacterial disease	Susceptibility to mycobacteria and *Salmonella* due to defects in Th1 cytokines/cytokine receptors	*IL-12RB1* *IL-12B* *IL-12RB2*	AR AR AR
Predisposition to herpes simplex encephalitis	Pathogenic variants in components of the Toll-like receptor 3 pathway	*TLR3* and others	AR and AD forms
Predisposition to mucocutaneous candidiasis	Pathogenic variants in components of the IL-17 signalling pathway	*STAT1, IL17R,* *IL17F*	AD AR AD

(AD = autosomal dominant; AR = autosomal recessive; HLA = human leucocyte antigen; Ig = immunoglobulin; NADPH = nicotinamide adenine dinucleotide phosphate; SCID = severe combined immune deficiency; WASP = Wiskott–Aldrich syndrome protein; XLR = X-linked recessive)

Investigations

Whilst measurement of complement components C3 and C4 is widely available, these tests may not identify patients with functional complement deficiency. Assessment should include specialised functional tests of complement-mediated haemolysis. These are known as the CH50 (classical haemolytic pathway 50) and AP50 (alternative pathway 50) tests. If abnormal, haemolytic tests are followed by measurement of individual complement components.

Management

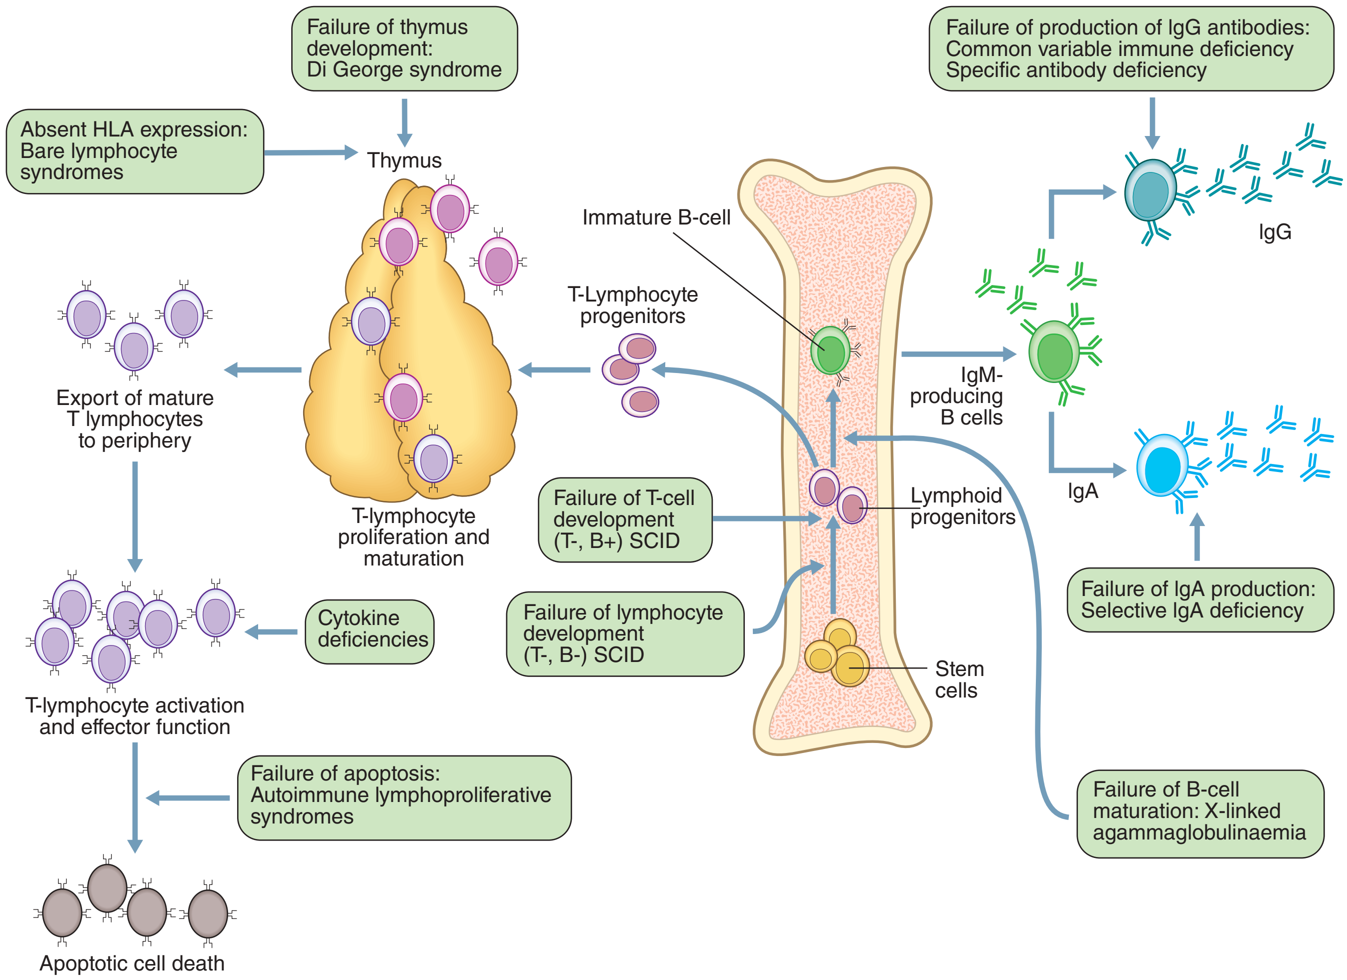
Patients with complement deficiencies should be vaccinated with meningococcal, pneumococcal and *H. influenzae* B vaccines to boost their adaptive immune responses. Lifelong prophylactic penicillin to prevent meningococcal infection is recommended, as is early access to acute medical assessment in the event of infection. Patients should also carry a MedicAlert or similar. At-risk family members should be screened for complement deficiencies with functional complement assays.

Primary antibody deficiencies

Primary antibody deficiencies occur as the result of abnormalities in B-cell function, as summarised in Figure 4.9 and Box 4.9. They are characterised by recurrent bacterial infections, particularly of the respiratory and gastrointestinal tract. The most common causative organisms are encapsulated bacteria such as *Streptococcus pneumoniae* and *H. influenzae*. These disorders usually present in infancy, when the protective benefit of transplacentally derived maternal immunoglobulin has waned. The most important causes are discussed in more detail below.

X-linked agammaglobulinaemia

This rare X-linked recessive disorder is caused by pathogenic variants in the Bruton tyrosine kinase (*BTK)* gene, which is a signalling protein required for B-cell development. Affected males present with severe bacterial infections during infancy. There is a marked reduction in B-cell numbers



Failure of thymus development: Di George syndrome
Failure of production of IgG antibodies: Common variable immune deficiency Specific antibody deficiency
Absent HLA expression: Bare lymphocyte syndromes
Thymus
Immature B-cell
IgG
T-Lymphocyte progenitors
Export of mature T lymphocytes to periphery
IgM-producing B cells
T-lymphocyte proliferation and maturation
Failure of T-cell development (T-, B+) SCID
Lymphoid progenitors
IgA
Failure of IgA production: Selective IgA deficiency
Cytokine deficiencies
Failure of lymphocyte development (T-, B-) SCID
Stem cells
T-lymphocyte activation and effector function
Failure of apoptosis: Autoimmune lymphoproliferative syndromes
Failure of B-cell maturation: X-linked agammaglobulinaemia
Apoptotic cell death

Fig. 4.9 **Immunodeficiency syndromes.** Immunodeficiency may result from defects in differentiation and function of T cells, B cells or both cell types. Pathogenic variants in the pathways that regulate differentiation of lymphocyte precursors cause severe combined immune deficiency with absent T cells and B cells (T−, B− SCID). Defects at a later stage cause failure of T-cell development, whereas B cells are present (T−, B+ SCID). Although B cells are present, they don't function normally, as T cells are required for activation. In DiGeorge syndrome there is impaired lymphocyte development due to failure of thymus development. Other causes of T-cell defects include absent HLA expression and cytokine deficiencies whereas defects in apoptosis cause autoimmune lymphoproliferative syndromes. Pure B-cell deficiency occurs in X-linked hypogammaglobulinaemia due to BTK variants. Defects in IgG production and IgA production cause common variable immune deficiency and selective IgA deficiency, respectively. See text and Box 4.9 for more details. (HLA = human leucocyte antigen; Ig = immunoglobulin)

and immunoglobulin levels are low or undetectable. Management is with immunoglobulin replacement therapy and antibiotics to treat infections.

Selective IgA deficiency

This is the most common primary antibody deficiency, affecting 1:600 northern Europeans. Although IgA deficiency is usually asymptomatic with no clinical sequelae, about 30% of individuals experience recurrent mild respiratory and gastrointestinal infections. The diagnosis can be confirmed by measurement of IgA levels, which are low or undetectable (<0.05 g/L). IgG and IgM are normal, although in some patients there is a compensatory increase in serum IgG levels. Specific treatment is generally not required.

Common variable immune deficiency

Common variable immune deficiency (CVID) is characterised by low serum IgG and IgA levels, with or without low IgM, and failure to make antibody responses to exogenous pathogens. B-cell numbers may be normal or low but not absent. It is a heterogeneous adult-onset primary immune deficiency; the underlying cause is unknown in most cases, although pathogenic variants have been identified in a minority of patients, who are then classified accordingly. The presentation is with recurrent infections, and bronchiectasis is a recognised complication. Paradoxically, antibody-mediated autoimmune diseases, such as idiopathic thrombocytopenic purpura and autoimmune haemolytic anaemia, are common in CVID. It is also associated with an increased risk of malignancy, particularly lymphoproliferative disease.

Specific antibody deficiency

This is a poorly characterised condition resulting in defective antibody responses to polysaccharide antigens. Some patients are also deficient in the antibody subclasses IgG2 and IgG4, and this condition was previously called IgG subclass deficiency. There is overlap between specific antibody deficiency, IgA deficiency and CVID, and some patients may progress to a more global antibody deficiency over time.

Investigations

Serum immunoglobulins should be measured in conjunction with protein and urine electrophoresis to exclude secondary causes of hypogammaglobulinaemia (Box 4.10) and B- and T-lymphocyte subsets should also be measured. Specific antibody responses to known pathogens should be assessed by measuring IgG antibodies against tetanus, *H. influenzae* and *Streptococcus pneumoniae* (most patients will have been exposed to these antigens through infection or immunisation). If specific antibody levels are low, immunisation with the appropriate killed vaccine should be followed by repeat antibody measurement 6–8 weeks later; failure to mount a response indicates a significant defect in antibody production. These functional tests have generally superseded IgG subclass quantitation.

Phagocytes cannot be activated due to defects in cytokines or their receptors
Chronic granulomatous disease
Microorganisms cannot be destroyed in lysosomes due to NADPH oxidase deficiency

Fig. 4.10 Normal phagocyte function and mechanisms of primary phagocyte deficiency. Under normal circumstances, neutrophils traverse the endothelium to enter tissues by the cell surface molecule lymphocyte function-associated antigen 1 (LFA1), which binds to intercellular adhesion molecule 1 (ICAM1) on endothelium. In order for macrophages to engulf and kill microorganisms, they need to be activated by cytokines and also require nicotinamide adenine dinucleotide phosphate (NADPH) oxidase to generate free radicals. Primary phagocyte deficiencies can occur as the result of leucocytes being unable to traverse endothelium due to defects in LFA1, because of pathogenic variants in cytokines or their receptors, or because of defects in NADPH oxidase. (IFN-γ = interferon-gamma; IL = interleukin)

4.10 Investigation of primary antibody deficiencies

	Serum immunoglobulin (Ig) concentrations				Circulating lymphocyte numbers		Test immunisation
	IgM	IgG	IgA	IgE	B cells	T cells	
Selective IgA deficiency	Normal	Often elevated	Absent	Normal	Normal	Normal	Not applicable*
Common variable immune deficiency	Normal or low	Low	Low or absent	Low or absent	Variable	Variable	No antibody response
Specific antibody deficiency	Normal	Normal	Normal	Normal	Normal	Normal	No antibody response to polysaccharide antigens

*Test immunisation is not usually performed in IgA deficiency but some patients may have impaired responses.

Management

The mainstay of treatment in most patients with antibody deficiency is immunoglobulin replacement therapy. Human normal immunoglobulin (Box 4.11) is derived from plasma from hundreds of donors and contains IgG antibodies to a wide variety of common organisms. Replacement immunoglobulin may be administered either intravenously or subcutaneously, with the aim of maintaining trough IgG levels (the IgG level just prior to an infusion) within the normal range. This has been shown to minimise progression of end-organ damage and improve clinical outcome. Patients with antibody deficiencies also require aggressive treatment of infections when they occur; prophylactic antibiotics may be indicated. Treatment may be self-administered and is life-long. Benefits of immunisation are limited because of the defect in IgG antibody production, but patients may derive some T-cell benefit from vaccination. As with all primary immune deficiencies, live vaccines should be avoided.

Primary T-lymphocyte deficiencies

These are a group of diseases characterised by recurrent viral, protozoal and fungal infections (see Box 4.5, Box 4.9 and Fig. 4.9). Many T-cell deficiencies are also associated with defective antibody production because of the importance of T cells in providing help for B cells. These disorders generally present in childhood, but primary T-cell immunodeficiency can also present in adults. Individual conditions are discussed in more detail below.

DiGeorge syndrome

This results from failure of development of the third and fourth pharyngeal pouches and is usually caused by a deletion of chromosome 22q11. The immune deficiency is accounted for by failure of thymic development; however, the immune deficiency can be very heterogeneous. Affected

4.11 Types of immunoglobulin preparation for therapeutic use

Normal human immunoglobulin

Derived from multiple plasma donors and provides passive immunity to those unable to produce immunoglobulin, be that as a result of primary or secondary antibody deficiency. Immunoglobulin replacement therapy provides short-term protection, lasting for the duration of the passively transferred antibodies, IgG having a half-life of approximately 21 days. Treatment is therefore required on an ongoing basis.

Hyperimmune globulin

Concentrated antibody products, initially derived from animal sources (diphtheria and tetanus anti-toxins), but more recently of human origin, developed for the prevention of a number of infectious diseases, including rabies as post-exposure treatment, hepatitis B and varicella zoster virus as post-exposure prophylaxis, and cytomegalovirus as prophylaxis in patients on immune suppressive therapy, particularly transplant recipients.

Convalescent plasma

Convalescent plasma derived from individual donors with high antibody levels against certain pathogens following recovery from natural infection, recently under investigation for the treatment of epidemic/pandemic infection, such as Ebola virus infection and more recently COVID-19, where clinical trials of ABO-compatible convalescent plasma for severe COVID-19 pneumonia proved disappointing, possibly as a result of the intervention being given too late in the course of infection.

patients can have very low numbers of circulating T cells despite normal development in the bone marrow. It is associated with multiple developmental anomalies, including congenital heart disease, hypoparathyroidism, tracheo-oesophageal fistulae, cleft lip and palate.

Bare lymphocyte syndromes

These very rare disorders are caused by pathogenic variants in a variety of genes that regulate expression of HLA molecules or their transport to the cell surface. If HLA class I molecules are affected, CD8$^+$ lymphocytes fail to develop normally, while absent expression of HLA class II molecules affects CD4$^+$ lymphocyte maturation. In addition to recurrent infections, failure to express HLA class I is associated with systemic vasculitis caused by uncontrolled activation of NK cells.

Severe combined immune deficiency

Severe combined immune deficiency (SCID) results from pathogenic variants in a number of genes that regulate lymphocyte development, with failure of T-cell maturation, with or without accompanying B- and NK-cell maturation. The most common cause is X-linked SCID, resulting from loss-of-function pathogenic variants in the interleukin-2 receptor gamma (*IL2RG*) gene. The gene product is a component of several interleukin receptors, including those for IL-2, IL-7 and IL-15, which are absolutely required for T- and NK-cell development. This results in T cell–negative, NK cell–negative, B cell–positive SCID. Another cause is deficiency of the enzyme adenosine deaminase (ADA), which causes lymphocyte death due to accumulation of toxic purine metabolites intracellularly, resulting in T cell–negative, B cell–negative and NK cell–negative SCID.

The absence of an effective adaptive immune response causes recurrent bacterial, fungal and viral infections soon after birth. Stem cell transplantation (SCT) is the treatment option of first choice. Gene replacement therapy has been approved for treatment of ADA deficiency when there is no suitable donor for SCT, has been used successfully in X-linked SCID and is under investigation for a number of other causes of SCID.

Investigations

The principal tests for T-lymphocyte deficiencies are a total lymphocyte count with interpretation based on age-related reference ranges, and quantitation of individual lymphocyte subpopulations. Serum immunoglobulins should also be measured. Second-line, functional tests of T-cell activation and proliferation may be indicated. Patients in whom T-lymphocyte deficiencies are suspected should be tested for HIV infection. Genetic testing to identify the underlying cause is usually undertaken following specialist referral.

Management

A diagnosis of SCID requires urgent action. Patients with T-cell deficiencies should be considered for anti-*Pneumocystis* and antifungal prophylaxis and require aggressive management of infections when they occur. Immunoglobulin replacement is indicated for associated defective antibody production. Stem cell transplantation or gene therapy may be appropriate in some disorders. Where a family history is known and antenatal testing confirms a specific defect, stem cell therapy prior to recurrent invasive infection can improve outcome.

Autoimmune lymphoproliferative syndrome

This rare disorder is caused by failure of normal lymphocyte apoptosis, predominantly due to mutations in *TNFSF6* which encodes Fas ligand or *TNFRSF6* which encodes the *Fas* receptor gene, although additional genetic defects have also been identified. Both proteins are involved in regulating programmed cell death in lymphocytes. This results in massive accumulation of autoreactive T cells, which cause autoimmune-mediated anaemia, thrombocytopenia and neutropenia. Other features include lymphadenopathy, splenomegaly and a variety of other autoimmune diseases. Susceptibility to infection is increased because of the neutropenia.

Secondary immune deficiencies

Secondary immune deficiencies are much more common than primary immune deficiencies and occur when the immune system is compromised by external factors (Box 4.12). Common causes include infections, such as HIV and measles, and cytotoxic and immunosuppressive drugs, particularly those used in the management of transplantation, autoimmunity and cancer. Physiological immune deficiency occurs at the extremes of life; the decline of the immune response in the elderly is known as immune senescence (Box 4.13). Management of secondary immune deficiency is described in the relevant chapters on infectious diseases (Ch. 14), haematological disorders (Ch. 24) and oncology (Ch. 8).

Systemic autoinflammatory disorders

These rare disorders are characterised by recurrent episodes of fever and organ inflammation, associated with an elevated acute phase response.

Familial Mediterranean fever

Familial Mediterranean fever (FMF) is the most common of the systemic autoinflammatory disorders, predominantly affecting people of Mediterranean origin. It results from mutations of the *MEFV* gene, which encodes a protein called pyrin that normally regulates neutrophil-mediated inflammation by indirectly suppressing the production of IL-1. FMF is characterised by recurrent painful attacks of fever, associated with peritonitis, pleuritis and arthritis, which last for a few hours to 4 days, and are associated with markedly increased CRP levels. Symptoms resolve completely between episodes. Most individuals have their first attack before the age of 20. The major complication of FMF is AA amyloidosis (see below). Colchicine significantly reduces the number of febrile episodes in 90% of patients but is ineffective during acute attacks. Anti-cytokine therapy blocking IL-1 with anakinra or canakinumab can be effective for patients with symptoms refractory to colchicine.

Mevalonate kinase deficiency

Mevalonate kinase deficiency, previously known as hyper-IgD syndrome, is an autosomal recessive disorder that causes recurrent attacks of fever, abdominal pain, diarrhoea, lymphadenopathy, arthralgia, skin lesions and aphthous ulceration. Most patients are from Western Europe, particularly the Netherlands and northern France. It is caused by loss-of-function mutations in the gene encoding mevalonate kinase, which is involved

4.12 Causes of secondary immune deficiency

Physiological

- Ageing
- Prematurity
- Pregnancy

Infection

- HIV infection
- Measles
- Mycobacterial infection

Iatrogenic

- Immunosuppressive therapy
- Antineoplastic agents
- Glucocorticoids
- Stem cell transplantation
- Radiation injury
- Antiepileptic agents

Malignancy

- B-cell malignancies including leukaemia, lymphoma and myeloma
- Solid tumours
- Thymoma

Biochemical and nutritional disorders

- Malnutrition
- Renal insufficiency/dialysis
- Diabetes mellitus
- Specific mineral deficiencies (iron, zinc)

Other conditions

- Burns
- Asplenia/hyposplenism

4.13 Immune senescence

- **T-cell responses**: decline, with reduced delayed-type hypersensitivity responses.
- **Antibody production**: decreased for many exogenous antigens. Although autoantibodies are frequently detected, autoimmune disease is less common.
- **Response to vaccination**: reduced; 30% of healthy older people may not develop protective immunity after influenza vaccination.
- **Allergic disorders and transplant rejection**: less common.
- **Susceptibility to infection**: increased; community-acquired pneumonia by threefold and urinary tract infection by 20-fold. Latent infections, including tuberculosis and herpes zoster, may be reactivated.
- **Manifestations of inflammation**: may be absent, with lack of pyrexia or leucocytosis.
- **Secondary immune deficiency**: common.

in the metabolism of cholesterol. It remains unclear why this causes a systemic autoinflammatory disorder. Serum IgD and IgA levels may be persistently elevated, and CRP levels are increased during acute attacks. Standard anti-inflammatory drugs, including colchicine and glucocorticoids, are ineffective in suppressing the attacks but IL-1 inhibitors, such as anakinra, and TNF inhibitors, such as etanercept, may improve symptoms and can induce complete remission in some patients.

TNF receptor–associated periodic syndrome

The TNF receptor–associated periodic syndrome (TRAPS), also known as Hibernian fever, is an autosomal dominant syndrome caused by heterozygote pathogenic variants in the *TNFRSF1A* gene, which encodes the TNFR1 receptor. The variants cause TNFR1 to be misfolded and internalised causing activation of pro-inflammatory gene expression. The presentation is with recurrent attacks of fever, arthralgia, myalgia, serositis and rashes. Attacks may be prolonged for 1 week or more. During a typical attack, laboratory findings include neutrophilia, increased CRP and elevated IgA levels. The diagnosis can be confirmed by low serum levels of the soluble type 1 TNF receptor and by sequencing of the *TNFRSF1A* gene. As in FMF, the major complication is amyloidosis, and regular screening for proteinuria is advised. Acute episodes respond to systemic glucocorticoids. Therapy with IL-1 inhibitors, such as anakinra and canakinumab, can be effective in preventing and treating attacks.

Cryopyrin-associated periodic syndrome (CAPS)

This disorder includes three phenotypes: familial cold autoinflammatory syndrome, Muckle–Wells syndrome and neonatal-onset multisystem inflammatory disease. CAPS results from gain-of-function pathogenic variants of the *NLRP3* gene coding cryopyrin, which forms part of the inflammasome. Defects lead to overproduction of IL-1, resulting in the inflammatory manifestations. Treatments are now targeted at the IL-1 pathway, using anakinra or canakinumab.

The number of pathogenic variants associated with systemic autoinflammatory syndromes is increasing, but not all patients have a confirmed molecular diagnosis.

Amyloidosis

Amyloidosis is the name given to a group of acquired and hereditary disorders characterised by the extracellular deposition of insoluble proteins.

Pathophysiology

Amyloidosis is caused by deposits consisting of fibrils of the specific protein involved, linked to glycosaminoglycans, proteoglycans and serum amyloid P. Protein accumulation may be localised or systemic, and the clinical manifestations depend on the organ(s) affected. Amyloid diseases are classified by the aetiology and type of protein deposited (Box 4.14).

Clinical features

The clinical presentation may be with nephrotic syndrome, cardiomyopathy or peripheral neuropathy. Amyloidosis should always be considered as a potential diagnosis in patients with these disorders when the cause is unclear.

Investigations

The diagnosis is established by biopsy, which may be of an affected organ, rectum or subcutaneous fat. The pathognomonic histological feature is apple-green birefringence of amyloid deposits when stained with Congo red dye and viewed under polarised light. Immunohistochemical staining can identify the type of amyloid fibril present. Quantitative scintigraphy with radiolabeled serum amyloid P is a valuable tool in determining the overall load and distribution of amyloid deposits.

Management

The aims of treatment are to support the function of affected organs and, in acquired amyloidosis, to prevent further amyloid deposition through treatment of the primary cause. When the latter is possible, regression of existing amyloid deposits may occur.

Autoimmune disease

Autoimmunity can be defined as the presence of immune responses against self-tissue. This may be a harmless phenomenon, identified only by the presence of low-titre autoantibodies or autoreactive T cells. However, if these responses cause significant organ damage, autoimmune diseases occur. These are a major cause of chronic morbidity and disability, affecting up to 1 in 30 adults at some point during life.

Pathophysiology

Autoimmune diseases result from the failure of immune tolerance, the process by which the immune system recognises and accepts self-tissue. Central immune tolerance occurs during lymphocyte development, when T and B lymphocytes that recognise self-antigens are eliminated before they develop into fully immunocompetent cells. This process is most active in fetal life but continues throughout life as immature lymphocytes are generated. Some autoreactive cells inevitably evade deletion and escape into the circulation, however, and are controlled through peripheral tolerance mechanisms. Peripheral immune tolerance mechanisms include the suppression of autoreactive cells by regulatory T cells; the generation of functional

4.14 Causes of amyloidosis

Disorder	Pathological basis	Predisposing conditions	Other features
Acquired systemic amyloidosis			
Reactive (AA) amyloidosis	Increased production of serum amyloid A as part of prolonged or recurrent acute inflammatory response	Chronic infection (tuberculosis, bronchiectasis, chronic abscess, osteomyelitis) Chronic inflammatory diseases (untreated rheumatoid arthritis, familial Mediterranean fever)	90% of patients present with non-selective proteinuria or nephrotic syndrome
Light chain amyloidosis (AL)	Increased production of monoclonal light chain	Monoclonal gammopathies, including myeloma, benign gammopathies and plasmacytoma	Restrictive cardiomyopathy, peripheral and autonomic neuropathy, carpal tunnel syndrome, proteinuria, spontaneous purpura, amyloid nodules and plaques Macroglossia occurs rarely but is pathognomonic Prognosis is poor
Dialysis-associated (Aβ_2M) amyloidosis	Accumulation of circulating β_2-microglobulin due to failure of renal catabolism in kidney failure	Renal dialysis	Carpal tunnel syndrome, chronic arthropathy and pathological fractures secondary to amyloid bone cyst formation Manifestations occur 5–10 years after the start of dialysis
Senile systemic amyloidosis	Normal transthyretin protein deposited in tissues	Age > 70 years	Feature of normal ageing (affects > 90% of 90-year-olds) Usually asymptomatic
Hereditary systemic amyloidosis			
> 20 forms of hereditary systemic amyloidosis	Production of protein with an abnormal structure that predisposes to amyloid fibril formation. Most commonly due to pathogenic variants in *transthyretin* gene	Autosomal dominant inheritance	Peripheral and autonomic neuropathy, cardiomyopathy Renal involvement unusual 10% of gene carriers are asymptomatic throughout life

hyporesponsiveness (anergy) in lymphocytes that encounter antigen in the absence of the co-stimulatory signals that accompany inflammation; and cell death by apoptosis. Autoimmune diseases develop when self-reactive lymphocytes escape from these tolerance mechanisms.

Multiple genetic and environmental factors contribute to the development of autoimmune disease. Autoimmune diseases are much more common in women than in men, for reasons that remain unclear. Many are associated with genetic variations in the HLA loci, reflecting the importance of HLA genes in shaping lymphocyte responses. Other important susceptibility genes include those determining cytokine activity, co-stimulation (the expression of second signals required for full T-cell activation; see Fig. 4.7) and cell death. Many of the same genetic variants underlie multiple autoimmune disorders, reflecting their common pathogenesis (Box 4.15). Even though some of these associations are the strongest that have been identified in complex genetic diseases, they have very limited predictive value and are generally not useful in determining management of individual patients. Several environmental factors may be associated with autoimmunity in genetically predisposed individuals, including infection, cigarette smoking and hormone levels. The most widely studied of these is infection, as occurs in acute rheumatic fever following streptococcal infection, or reactive arthritis following bacterial infection. Several mechanisms have been invoked to explain the autoimmunity that occurs after an infectious trigger. These include cross-reactivity between proteins expressed by the pathogen and the host (molecular mimicry), such as Guillain–Barré syndrome and *Campylobacter* infection; release of sequestered antigens from tissues that are damaged during infections that are not usually visible to the immune system; and production of inflammatory cytokines that overwhelm the normal control mechanisms that prevent bystander damage. Occasionally, autoimmune disease may be an adverse effect of drug treatment. For example, metabolic products of the anaesthetic agent halothane can bind to liver enzymes, resulting in a structurally novel protein that is recognised as a foreign antigen by the immune system. This can provoke the development of autoantibodies and activated T cells, which can cause hepatic necrosis. Autoimmune complications of immune checkpoint inhibitor therapy are increasingly recognised, see below.

Clinical features

The clinical presentation of autoimmune disease is highly variable. Autoimmune diseases can be classified by organ involvement or by the predominant mechanism responsible for tissue damage. The Gell and Coombs classification of hypersensitivity is the most widely used and distinguishes four types of immune response that result in tissue damage (Box 4.16).

4.15 Association between common gene variants and autoimmune diseases

Gene	Function	Diseases
HLA complex	Key determinants of antigen presentation to T cells	Most autoimmune diseases
PTPN22	Regulation of T- and B-cell receptor signalling	Rheumatoid arthritis, type 1 diabetes, systemic lupus erythematosus
CTLA4	Important co-stimulatory molecule that transmits inhibitory signals to T cells	Rheumatoid arthritis, type 1 diabetes
IL23R	Cytokine-mediated control of T cells	Inflammatory bowel disease, psoriasis, ankylosing spondylitis
TNFRSF1A	Control of tumour necrosis factor network	Multiple sclerosis
ATG5	Autophagy	Systemic lupus erythematosus

- *Type I hypersensitivity* is relevant in allergy but is not associated with autoimmune disease. This type of hypersensitivity will be covered in more detail below.
- *Type II hypersensitivity* causes injury to a single tissue or organ and is mediated by specific autoantibodies. An example of this type of hypersensitivity is myasthenia gravis, whereby IgG antibodies are directed at the acetylcholine receptor, compromising neuromuscular transmission (Ch. 27).
- *Type III hypersensitivity* results from deposition of immune complexes, which initiates activation of the classical complement cascade, as well as recruitment and activation of phagocytes and CD4$^+$ lymphocytes. The site of immune complex deposition is determined by the relative amount of antibody, size of the immune complexes, nature of the antigen and local haemodynamics. Generalised deposition of immune complexes gives rise to systemic diseases such as SLE.
- *Type IV hypersensitivity* is mediated by activated T cells and macrophages, which together cause tissue damage. Delayed drug hypersensitivity and contact dermatitis are good examples of type IV hypersensitivity.

Investigations

Autoantibodies

Many autoantibodies have been identified and are used in the diagnosis and monitoring of autoimmune diseases, as discussed elsewhere in this book. Antibodies can be quantified by titre (the maximum dilution of the serum at which the antibody can be detected) or by concentration in standardised units using techniques such as enzyme-linked immunosorbent assays (ELISA), in which the antigen is used to coat microtitre plates to which the patient's serum is added (Fig. 4.11A). In routine clinical practice, ELISA assays are widely used for the detection and quantitation of a number of autoantibodies such as anti-CCP antibodies, anti-double stranded DNA antibodies, intrinsic factor antibodies and anti-myeloperoxidase antibodies. Immunoblotting using appropriately diluted patient serum (Fig. 4.11B) is usually performed when several autoantibodies require to be tested in a single patient sample. Common scenarios are in patients suspected to have connective tissue disease, myositis or autoimmune liver disease. These are typically reported in a semiquantitative manner from weak (+) to strong (+++). The results should be interpreted in the context of the clinical history and associated immunofluorescent patterns. All strips contain an internal positive control (marked as Ko or Co). The black bars on the strip separate the antigens being tested. In the example shown, the patient sample is positive for multiple autoantibodies in the ANA profile, the myositis profile, the systemic sclerosis panel (SSc) and the liver profile. Indirect immunofluorescence (Fig. 4.11C), a qualitative assay, is used for detection of anti-nuclear antibodies, anti-neutrophil cytoplasmic antibodies, anti-neuronal antibodies and various other autoantibodies, depending on the tissue substrate used. The pattern of staining is reported in addition to the dilution of patient serum at which staining is observed. Staining with a 1 in 80 dilution is considered as low positive with steps of 1 in 160, and 1 in 320 to values of >1 in 640, which are considered strongly positive. The initial dilution applied will be determined by the autoantibody being tested. In general terms, detection of autoantibodies at high levels of serum dilution are considered more clinically relevant than staining with low levels of serum dilution, but these tests are not diagnostic in themselves, and the patterns observed should be interpreted based on the clinical picture. Figure 4.11C shows an anti-nucleolar antibody, which may be seen in SSc; a homogeneous ANA, which may be seen in SLE; a speckled ANA, which may be seen in Sjogren's syndrome and a positive P-ANCA pattern, which can be seen in systemic vasculitis. Luminex technology (not shown) can also be used for autoantibody testing but is more widely used in tissue typing. Reference ranges for commonly tested autoantibodies are provided in Chapter 35.

i 4.16 Gell and Coombs classification of hypersensitivity diseases

Type	Mechanism	Example of disease in response to exogenous agent	Example of autoimmune disease
Type I Immediate hypersensitivity	IgE-mediated mast cell degranulation	Allergic disease	None described
Type II Antibody-mediated	Binding of cytotoxic IgG or IgM antibodies to antigens on cell surface causes cell killing	ABO blood transfusion reaction Hyperacute transplant rejection	Autoimmune haemolytic anaemia Idiopathic thrombocytopenic purpura Goodpasture disease Myasthenia gravis
Type III Immune complex-mediated	IgG or IgM antibodies bind soluble antigen to form immune complexes that trigger classical complement pathway activation	Serum sickness Farmer's lung	Systemic lupus erythematosus Cryoglobulinaemia
Type IV Delayed type	Activated T cells and phagocytes	Acute cellular transplant rejection Nickel hypersensitivity	Type 1 diabetes Hashimoto thyroiditis

Complement

Measurement of complement components can be useful in the evaluation of immune complex-mediated diseases. Classical complement pathway activation leads to a decrease in circulating C4 levels and is often also associated with decreased C3 levels. Serial measurement of C3 and C4 can be helpful as a surrogate measure of disease activity in conditions such as SLE.

Cryoglobulins

Cryoglobulins are antibodies that can be directed against other immunoglobulins, which form immune complexes that precipitate in the cold. They can lead to type III hypersensitivity reactions, with typical clinical manifestations including purpuric rash, often of the lower extremities, arthralgia and peripheral neuropathy. Cryoglobulins are classified into three types, depending on the properties of the immunoglobulin involved (Box 4.17). Testing for cryoglobulins requires the transport of a serum specimen to the laboratory at 37°C. Cryoglobulins should not be confused with cold agglutinins; the latter are autoantibodies specifically directed against the I/i antigen on the surface of red cells, which can cause intravascular haemolysis in the cold (p. 979).

Management

The management of autoimmune disease depends on the organ system involved; further details are provided elsewhere in this book. In general, treatment of autoimmune diseases involves glucocorticoids and immunosuppressive agents, which are increasingly used in combination with biologic agents targeting disease-specific cytokines and their receptors. Not all conditions require immune suppression, however. For example, the management of coeliac disease involves dietary gluten withdrawal, while autoimmune hypothyroidism requires appropriate thyroxine supplementation.

Allergy

In this section the focus will be on IgE-mediated hypersensitivity. See Box 4.16 and associated text for other types of hypersensitivity reactions.

Allergic diseases are a common and increasing cause of illness, affecting between 15% and 20% of the population at some time. They comprise a range of disorders from mild to life-threatening and affect many organs. Atopy is the tendency to produce an exaggerated IgE immune response to otherwise harmless environmental substances, while an allergic disease can be defined as the clinical manifestation of this inappropriate IgE immune response.

Fig. 4.11 Autoantibody testing. **A** Measurement of autoantibody levels by enzyme-linked immunosorbent assay (ELISA). The antigen of interest is used to coat microtitre plates to which patient serum is added. If autoantibodies are present, these bind to the target antigen on the microtitre plate. The amount of bound antibody is quantitated by adding a secondary antibody linked to an enzyme that converts a colourless substrate to a coloured one, which can be detected by a plate reader. **B** Detection of autoantibodies by immunoblotting. Test strips are coated with purified antigens in parallel lines. The strips are incubated with patient serum or plasma and controls. After washing to remove unbound antibody, strips are incubated with enzyme-conjugated alkaline phosphatase-labelled anti-human IgG. After washing and addition of a chromogenic substrate, an enzyme-mediated colour reaction develops. After a final wash, the strips are dried, and any observed banding pattern is scanned for band intensity against an electronic template. The black bars on the strip separate the antigens being tested. Positive results are seen as vertical grey lines below the test antigen and the intensity of staining corresponds to the concentration of antibody in the patient's serum. The strength of staining is expressed both as a number and as a grade from + (weak) to +++ (strong). Note that all strips contain an internal quality control (marked as Ko or Co), to ensure the assay has worked. In the example shown, the patient sample was positive for multiple autoantibodies in the ANA profile, the Myositis profile, the Systemic sclerosis (SSc) profile and the Liver profile. **C** Qualitative analysis of autoantibodies by patterns of indirect immunofluorescence staining. In this assay, patient serum is added to cell substrate and a secondary antibody is added with a fluorescent label to detect any bound antibody. If antibodies are present, they are detected as bright green staining using a fluorescence microscope. Different antinuclear antibody patterns may be seen in different types of connective tissue disease using a HEp2 or HEp2000 (human epithelial cell line) as substrate (see Ch. 25). Immunofluorescence can be undertaken using different substrates, according to the autoantibody under investigation. An antinucleolar ANA can be seen in systemic sclerosis, a homogeneous ANA can be seen in SLE, and a speckled ANA can be seen in SLE or Sjögren syndrome. In the context of small vessel vasculitis, the tissue substrate is ethanol-fixed neutrophils. Two main staining patterns of antineutrophil cytoplasmic antibodies (ANCA) are clinically relevant, cytoplasmic and perinuclear, seen in granulomatosis with polyangiitis and microscopic polyangiitis (Ch. 25), the autoantibodies recognising proteinase 3 and myeloperoxidase, respectively. *(B and C, Nucleolar and Homogeneous) Courtesy of Juliet Dunphy, Biomedical Scientist, Royal United Hospital Bath, UK; (C, Speckled and P-ANCA) Courtesy of Mr Richard Brown, Clinical Scientist in Immunology, Southwest Pathology Services, UK.*

Pathophysiology

The immune system does not normally respond to the many environmental substances to which it is exposed on a daily basis. In allergic individuals, however, an initial exposure to a normally harmless exogenous substance (known as an allergen) triggers the production of specific IgE antibodies by activated B cells. These IgE antibodies bind to high-affinity IgE receptors on the surface of mast cells, a step that is not itself associated with clinical sequelae. However, re-exposure to the allergen leads to binding to and cross-links of membrane-bound IgE, which in turn leads to mast cell activation, with release of a variety of vasoactive mediators (the early phase response; Fig. 4.12). This type I hypersensitivity reaction forms the basis of an allergic response, which can range from sneezing and rhinorrhea to anaphylaxis (Box 4.18). In some individuals, the early phase response is followed by persistent activation of mast cells, manifest by ongoing swelling and local inflammation. This is known as the late phase reaction and is mediated by mast cell metabolites, basophils, eosinophils and macrophages. Long-standing or recurrent allergic inflammation may give rise to a chronic inflammatory response characterised by a complex infiltrate of macrophages, eosinophils and T lymphocytes, in addition to mast cells and basophils. Once this has been established, inhibition of mast cell mediators with antihistamines is clinically ineffective in isolation.

4.17 Classification of cryoglobulins

	Type I	Type II	Type III
Immunoglobulin (Ig) isotype and specificity	Isolated monoclonal IgM paraprotein with no particular specificity	Immune complexes formed by monoclonal IgM paraprotein directed towards constant region of IgG	Immune complexes formed by polyclonal IgM or IgG directed towards constant region of IgG
Prevalence	25%	25%	50%
Disease association	Lymphoproliferative disease, especially Waldenström macroglobulinaemia	Infection, particularly hepatitis C; lymphoproliferative disease	Infection, particularly hepatitis C; autoimmune disease, including rheumatoid arthritis and systemic lupus erythematosus
Symptoms	*Hyperviscosity:* Raynaud phenomenon Acrocyanosis Retinal vessel occlusion Arterial and venous thrombosis	*Small-vessel vasculitis:* Purpuric rash Arthralgia Neuropathy Cutaneous ulceration, hepatosplenomegaly, glomerulonephritis, Raynaud phenomenon	*Small-vessel vasculitis:* Purpuric rash, arthralgia Cutaneous ulceration hepatosplenomegaly, glomerulonephritis Raynaud phenomenon

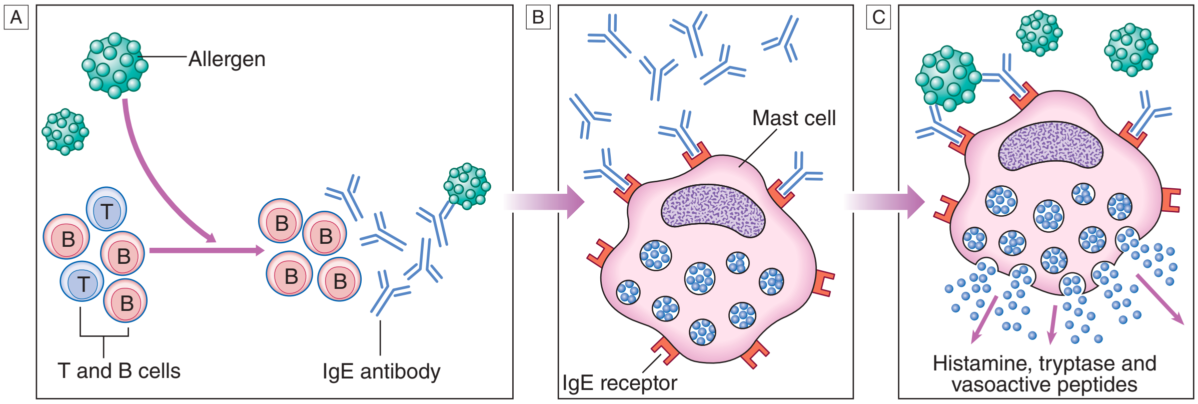

Fig. 4.12 Type I (immediate) hypersensitivity response. **A** After an encounter with allergen, B cells produce immunoglobulin E (IgE) antibody against the allergen. **B** Specific IgE antibodies bind to circulating mast cells via high-affinity IgE cell surface receptors. **C** On re-encounter with allergen, the allergen binds to the IgE antibody-coated mast cells. This cross-linking of the IgE triggers mast cell activation with release of vasoactive mediators.

4.18 Clinical manifestations of allergy

Dermatological

- Urticaria
- Atopic eczema if chronic
- Allergic contact eczema
- Angioedema

Respiratory

- Asthma
- Atopic rhinitis

Ophthalmological

- Allergic conjunctivitis

Gastrointestinal

- Food allergy

Other

- Anaphylaxis
- Drug allergy
- Allergy to insect venom

The increasing incidence of allergic diseases is largely unexplained but one widely held theory is the 'hygiene hypothesis'. This proposes that infections in early life are critically important in maturation of the immune response and bias the immune system against the development of allergies; the high prevalence of allergic disease is the penalty for the decreased exposure to infection that has resulted from improvements in sanitation and health care. Genetic factors also contribute strongly to the development of allergic diseases. A positive family history is common in patients with allergy, and genetic association studies have identified a wide variety of predisposing variants in genes controlling innate immune responses, cytokine production, IgE levels and the ability of the epithelial barrier to protect against environmental agents. The expression of a genetic predisposition is complex, and is governed by environmental factors, such as pollutants and cigarette smoke, and the incidence of bacterial and viral infection.

Mast cell activation may also be non-specifically triggered through other signals, such as neuropeptides, anaphylatoxins and bacterial peptides. The Mas-related G protein–coupled receptor X2 (MRGPRX2) is expressed on mast cells that mediates non-IgE-dependent degranulation. It has been implicated as a cause of multiple mast cell–mediated disorders, including chronic urticaria, atopic dermatitis, and chronic pain. The receptor can be triggered by a number of drugs, including certain antibiotics and neuromuscular blocking agents used in anaesthesia, leading to clinical feature that may be indistinguishable from IgE-mediated allergy. Some drugs can activate mast cells through activating both IgE expression and MRGPRX2.

Clinical features

Common presentations of allergic disease are shown in Box 4.18. Those that affect the respiratory system and skin are discussed in more detail in Chapter 17 and Chapter 26, respectively. Here we focus on general principles of the approach to the allergic patient and some specific examples of allergic disease.

Anaphylaxis

The most severe form of IgE-mediated allergy is anaphylaxis, which is a medical emergency. Anaphylaxis is a potentially life-threatening, systemic reaction to an allergen, characterised by circulatory collapse, bronchospasm, laryngeal stridor, often associated with angioedema, and urticaria. The risk of death is increased in patients with pre-existing asthma, particularly if this is poorly controlled, and in situations where treatment with adrenaline (epinephrine) is delayed. Further details are provided in the 'Presenting problems in acute medicine' section in Chapter 10.

Insect venom allergy

Local non-IgE-mediated reactions to insect stings are common and may cause extensive swelling around the sting site, lasting up to 7 days. These usually do not require specific treatment. Toxic reactions to venom after multiple simultaneous stings may mimic anaphylaxis. In addition, exposure to large amounts of insect venom frequently stimulates the production of IgE antibodies, and thus may be followed by allergic reactions to single stings. Allergic IgE-mediated reactions vary from mild to life-threatening. Antigen-specific immunotherapy (desensitisation; see below) with bee or wasp venom can reduce the incidence of recurrent anaphylaxis from 50%–60% to approximately 10% but requires 3–5 years of treatment or more.

Peanut allergy

Peanut allergy is the most common food-related allergy. More than 50% of patients present before the age of 3 years and some individuals react to their first known exposure to peanuts, thought to result from sensitisation to arachis oil in topical creams. Peanuts are ubiquitous in the Western diet, and every year up to 25% of peanut-allergic individuals experience a reaction because of inadvertent exposure.

Birch oral allergy syndrome

This syndrome is characterised by the combination of birch pollen hay fever and local oral symptoms, including itch and angioedema, after contact with certain raw fruits, raw vegetables and some nuts. Cooked fruits and vegetables are tolerated without difficulty. The condition is due to shared or cross-reactive allergens that are destroyed by cooking or digestion, hence cooked foods being tolerated. It can be confirmed by skin-prick testing using fresh fruit. Severe allergic reactions are unusual.

Lipid transfer protein allergy

Reactions to plant foods in patients sensitised to lipid transfer proteins tend to be more severe than those of oral allergy syndrome. Lipid transfer proteins (LTPs) are abundant in the peel of plants and are found, for example, in stone fruits. The proteins are highly cross-reactive and the allergens in this condition are heat stable. Systemic reactions can occur, and co-factors such as concomitant infection, alcohol or non-steroidal anti-inflammatory ingestion are known to be important modifiers in the clinical manifestations.

Other common food allergens include egg, dairy products (both especially in paediatric practice), tree nuts, fish, shellfish, soy and wheat.

Diagnosis

When assessing a patient with possible allergy, it is important to identify what the patient means by the term, as up to 20% of the UK population describe themselves as having a food allergy; in fact, less than 1% have true allergy, as defined by an IgE-mediated hypersensitivity reaction confirmed on double-blind challenge. The nature of the symptoms should be established, and specific triggers identified, along with the predictability of a reaction, and the time lag between exposure to a potential allergen and onset of symptoms. An allergic reaction usually occurs within minutes of exposure and provokes predictable, reproducible symptoms such as angioedema, urticaria and wheezing. Specific enquiry should be made about other allergic symptoms, past and present, and about a family history of allergic disease. Potential allergens in the home and workplace should be identified. A detailed drug history should always be taken, including details of adherence to medication, possible adverse effects and the use of over-the-counter or complementary therapies.

Investigations

Skin-prick/intradermal tests

Skin-prick testing is a key investigation in the assessment of patients suspected of having allergy. A droplet of diluted, standardised allergen is placed on the forearm and the skin is superficially punctured through the droplet with a sterile lancet. Positive and negative control material must be included in the assessment. After 15 minutes, a positive response is indicated by a local weal response 3 mm or more larger than the negative control. A major advantage of skin-prick testing is that the patient can clearly see the results, which may be useful in gaining adherence to avoidance measures. Disadvantages include the remote risk of a severe allergic reaction, so resuscitation facilities should be available. Results are unreliable in patients with extensive skin disease. Antihistamines inhibit the magnitude of the response and should be discontinued for at least 3 days before testing; low-dose glucocorticoids do not influence test results. A number of other prescribed medicines can also lead to false-negative results, including amitriptyline and risperidone. These should be avoided or appropriately substituted for up to 14 days in advance of testing. In some situations, direct prick-to-prick testing can be used, if there is no standardised allergen extract available or if standard extract/specific IgE testing is negative but the clinical suspicion is high. In the context of drug allergy, intradermal testing may be helpful.

Specific IgE tests

An alternative to skin-prick testing is the quantitation of IgE directed against the suspected allergen. The sensitivity and specificity of specific IgE tests (previously known as radioallergosorbent tests, RAST) are lower than those of skin-prick tests. However, IgE tests may be useful if skin testing is inappropriate, such as in patients taking antihistamines or those with severe skin disease or dermatographism. They can also be used to test for cross-reactivity – for example, with multiple insect venoms, where component-resolved diagnostics, using recombinant allergens, is now increasingly used rather than crude allergen extract.

False negative and false positive specific IgE results can be seen, especially for certain foods and drugs. A negative result does not exclude the presence of allergy, and a positive result reflects sensitisation but does not confirm the presence of clinical allergy. The clinical history is key to allergy diagnosis, highlighting the importance of pre-test probability when undertaking testing.

Serum total IgE

Serum total IgE measurements are not routinely indicated in the investigation of allergic disease, other than to aid in the interpretation of specific IgE results, as false-positive specific IgEs are common in patients with atopy, who often have a high total IgE level. Although atopy is the most common cause of an elevated total IgE in developed countries, there are many other causes, including parasitic and helminth infections, lymphoma, drug reactions and eosinophilic granulomatosis with polyangiitis (EGPA). Normal total IgE levels do not exclude allergic disease.

Eosinophilia

Peripheral blood eosinophilia is common in atopic individuals but lacks specificity. Eosinophilia of more than 20% or an absolute eosinophil count over 1.5×10^9/L should initiate a search for a non-atopic cause, such as eosinophilic granulomatosis with polyangiitis, parasitic infection or an underlying hypereosinophilic syndrome.

Mast cell tryptase

Measurement of serum mast cell tryptase is extremely useful in investigating a possible anaphylactic event. Ideally, measurements should be made at the time of the reaction following appropriate resuscitation, with further samples 3 hours and 24 hours later. The basis of the test is that circulating levels of mast cell degranulation products rise dramatically to a peak 1–2 hours after a systemic allergic reaction. Tryptase is the most stable of these and is easily measured in serum. Serial measurement may confirm a mast cell activating event, particularly if a dynamic rise is seen (defined as baseline mast cell tryptase $\times$ 1.2 + 2 μg/L).

Supervised exposure to allergen

Tests involving supervised exposure to an allergen (allergen challenge) are usually performed in specialist centres on carefully selected patients, and include bronchial provocation testing, nasal challenge, and food or drug challenge. These may be particularly useful in the investigation of occupational asthma or food allergy. Patients can be considered for challenge testing when skin tests and/or IgE tests are negative, as they can be helpful in ruling out allergic disease.

Management

Several approaches can be deployed in the management of allergic individuals, as discussed below.

Avoidance of the allergen

This is indicated in all cases and should be rigorously attempted, with the advice of specialist dietitians and occupational physicians as necessary.

Antihistamines

Antihistamines are useful in the management of allergy as they inhibit the effects of histamine on tissue H_1 receptors. Long-acting, non-sedating preparations are particularly useful for prophylaxis.

Glucocorticoids

These are highly effective in allergic disease, and if used topically, adverse effects can be minimised.

Sodium cromoglicate

Sodium cromoglicate stabilises the mast cell membrane, inhibiting release of vasoactive mediators. It is effective as a prophylactic agent in asthma and allergic rhinitis but has no role in management of acute attacks. It is poorly absorbed and therefore generally ineffective in the management of food allergies.

Antigen-specific immunotherapy

This involves the sequential administration of increasing doses of allergen extract over a prolonged period. The mechanism of action is not fully understood but it is highly effective in the prevention of insect venom anaphylaxis and of allergic rhinitis secondary to grass pollen allergy. The traditional route of administration is by subcutaneous injection, which carries a risk of anaphylaxis and should be performed only in specialist centres. Sublingual immunotherapy is also increasingly used. Oral immunotherapy with peanut extract, marketed as Palforzia, has been approved in several countries for children with peanut allergy. The aim of treatment is to raise the threshold of allergen exposure at which the individual reacts. It can, however, be associated with allergic reactions. Early childhood exposure to peanut has more recently been shown to reduce the risk of developing peanut allergy and tolerance to peanut can persist over at least 12 months in the absence of peanut consumption.

Omalizumab

Omalizumab is a monoclonal antibody directed against IgE; it inhibits the binding of IgE to mast cells and basophils. It is licensed for treatment of refractory chronic spontaneous urticaria and for severe persistent allergic asthma that has failed to respond to standard therapy. For urticaria, the recommended dose is 300 mg 4-weekly. In asthma the dose depends on baseline IgE level and body weight (see Ch. 17 for further details). It is under investigation for allergic rhinitis but not yet approved for this indication. Anti-cytokine treatment for management of atopic eczema is covered in Chapter 26.

Adrenaline (epinephrine)

Adrenaline given by injection in the form of a pre-loaded self-injectable device can be life-saving in the acute management of anaphylaxis (Ch. 10). Adrenaline is first-line treatment in this context.

Patients with confirmed allergy should be issued with an allergy action plan and advised to carry information relating to their allergy.

Angioedema

Angioedema is an episodic, localised, non-pitting swelling of submucous or subcutaneous tissues.

Pathophysiology

The causes of angioedema are summarised in Box 4.19. It may be a manifestation of allergy or non-allergic degranulation of mast cells in response to drugs and toxins. In these conditions the main cause is mast cell degranulation with release of histamine and other vasoactive mediators. In hereditary angioedema, the cause is C1 inhibitor deficiency, which leads to increased local release of bradykinin. Angiotensin-converting enzyme (ACE) inhibitor–induced angioedema also occurs as the result of increased bradykinin levels due to inhibition of its breakdown.

Clinical features

Angioedema is characterised by soft-tissue swelling that most frequently affects the face (Fig. 4.13) but can also affect the extremities and genitalia. Involvement of the larynx or tongue may cause life-threatening respiratory tract obstruction, and oedema of the intestinal mucosa may cause acute abdominal pain.

Investigations

Differentiating the mechanism of angioedema is important in determining the most appropriate treatment. A clinical history of allergy or drug exposure can give clues to the underlying diagnosis. If no obvious trigger can be identified, measurement of complement C4 is useful in differentiating hereditary and acquired angioedema from other causes. If C4 levels are low at the time of an acute attack, further investigations should be initiated to look for evidence of C1 inhibitor deficiency.

Management

Management depends on the underlying cause. Angioedema associated with allergen exposure generally responds to antihistamines and glucocorticoids. Following acute management of angioedema secondary to drug therapy, drug withdrawal should prevent further attacks, although ACE inhibitor–induced angioedema can continue for a limited period post drug withdrawal. Angioedema can also be seen with angiotensin II receptor blockers, although less frequently than with the ACE inhibitors. The rate of angioedema cross-reactivity between these drug classes is low. Management of angioedema associated with C1 inhibitor deficiency is discussed below.

Hereditary angioedema

Hereditary angioedema (HAE), also known as inherited C1 inhibitor deficiency, is an autosomal dominant disorder caused by decreased production or activity of C1 inhibitor protein. This complement regulatory protein inhibits spontaneous activation of the classical complement pathway (see Fig. 4.4). It also acts as an inhibitor of the kinin cascade, activation of which increases local bradykinin levels, giving rise to local pain and swelling.

Clinical features

The angioedema in HAE may be spontaneous or triggered by local trauma or infection. Multiple parts of the body may be involved, especially the face, extremities, upper airway and gastrointestinal tract. Oedema of the intestinal wall causes severe abdominal pain and many patients with undiagnosed HAE undergo exploratory laparotomy. The most important complication is laryngeal obstruction, often associated with minor dental procedures, which can be fatal. Episodes of angioedema are self-limiting and usually resolve within 48 hours. Patients with HAE generally present in adolescence but may go undiagnosed for many years. A family history can be identified in 80% of cases. HAE is not associated with allergic diseases and is specifically not associated with urticaria.

4.19 Types of angioedema

	Allergic reaction to specific trigger	Idiopathic angioedema	Hereditary angioedema	ACE inhibitor–associated angioedema
Pathogenesis	IgE-mediated degradation of mast cells	Non-IgE-mediated degranulation of mast cells	C1 inhibitor deficiency, with resulting increased local bradykinin concentration	Inhibition of breakdown of bradykinin
Key mediator	Histamine	Histamine	Bradykinin	Bradykinin
Prevalence	Common	Common	Rare autosomal dominant disorder	0.1%–0.2% of patients treated with ACE inhibitors
Clinical features	Usually associated with urticaria History of other allergies common Follows exposure to specific allergen, in food, animal dander or insect venom	Usually associated with urticaria May be triggered by physical stimuli such as heat, pressure or exercise Dermatographism common Occasionally associated with underlying infection or thyroid disease	Not associated with urticaria or other features of allergy Does not cause anaphylaxis May cause life-threatening respiratory tract obstruction Can cause severe abdominal pain	Not associated with urticaria Does not cause anaphylaxis Usually affects the head and neck, and may cause life-threatening respiratory tract obstruction Can occur years after the start of treatment
Investigations	Specific IgE tests or skin-prick tests	Specific IgE tests and skin-prick tests often negative Hypothyroidism should be excluded	Complement C4 (invariably low in acute attacks) C1 inhibitor level and function	No specific investigations
Treatment	Allergen avoidance Antihistamines	Antihistamines are mainstay of treatment and prophylaxis	Unresponsive to antihistamines Anabolic steroids C1 inhibitor concentrate or icatibant for acute attacks	ACE inhibitor should be discontinued ARBs should be avoided if possible unless there is a strong indication
Associated drug reactions	Specific drug allergies	NSAIDs Opioids, radiocontrast media		ACE inhibitors, ARBs

(ACE = angiotensin-converting enzyme; ARBs = angiotensin II receptor blockers; IgE = immunoglobulin E; NSAIDs = non-steroidal anti-inflammatory drugs)

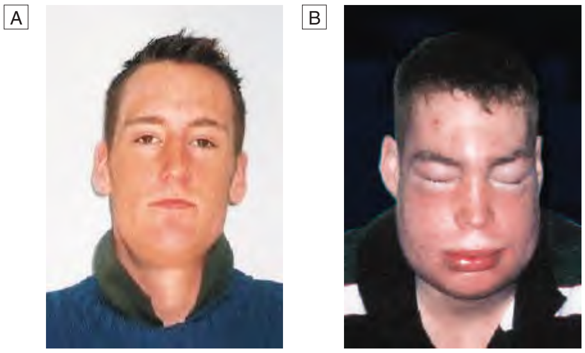

Fig. 4.13 Angioedema. This young man has hereditary angioedema. **A** Normal appearance. **B** During an acute attack. *From Helbert M. Flesh and bones of immunology. Edinburgh: Churchill Livingstone, Elsevier Ltd; 2006.*

Investigations

Acute episodes are accompanied by low C4 levels; a low C4 during an episode of angioedema should therefore trigger further investigation. The diagnosis can be confirmed by measurement of C1 inhibitor levels and function.

Management

Severe acute attacks should be treated with plasma-derived or recombinant C1 inhibitor or the bradykinin receptor antagonist icatibant 30 mg by subcutaneous injection. Patients should be issued with supplies of both and have a written action plan for management of acute attacks and prophylaxis for dental or surgical intervention. They should also be advised to carry information documenting their condition.

Anabolic steroids, such as danazol, can be used to prevent attacks and act by increasing endogenous production of complement proteins, but are limited by treatment toxicity. Tranexamic acid can be helpful as prophylaxis in some patients. Both, however, are being superseded by more targeted therapies.

As kallikrein has a critical role in the generation of bradykinin, inhibition of kallikrein has been shown to be an effective way of treating and preventing HAE attacks. Preventive therapies have been developed, targeting kallikrein at the protein level. These include lanadelumab, a monoclonal antibody to kallikrein (300 mg subcutaneously every 2–4 weeks), and the orally administered kallikrein inhibitor berotralstat (150 mg daily). New options that are being researched but which have not yet been introduced in clinical practice include the antisense oligonucleotide donidalorsen and gene-editing therapy.

Acquired C1 inhibitor deficiency

This rare disorder is clinically indistinguishable from HAE but presents in late adulthood. It is associated with autoimmune and lymphoproliferative diseases. Most cases are due to the development of autoantibodies to C1 inhibitor, but the condition can also be caused by autoantibodies that activate C1. Treatment of the underlying disorder may induce remission of angioedema. As with HAE, a low C4 is seen during acute episodes.

Pregnancy and the immune system

Major adaptations occur in the immune system during pregnancy so that the mother does not mount an immune response to the developing fetus. These adaptations can influence the risk and severity of certain infectious diseases such as varicella pneumonia (see p. 1307) as well as the activity of some autoimmune diseases. Some considerations for the development and management of immunological diseases during pregnancy and breastfeeding are summarised in Box 4.20.

Transplantation and graft rejection

Transplantation provides the opportunity for definitive treatment of end-stage organ disease. The major complications are graft rejection, drug toxicity and infection consequent to immunosuppression. Transplant survival continues to improve, as a result of the introduction of less toxic immunosuppressive agents and increased understanding of the processes of transplant rejection. Stem cell transplantation and its complications are discussed in more detail in Chapter 24.

Transplant rejection

Solid organ transplantation inevitably stimulates an aggressive immune response by the recipient, unless the transplant is between monozygotic twins. The type and severity of the rejection response is determined by the genetic disparity between the donor and recipient, the immune status of the host and the nature of the tissue transplanted (Box 4.21). The most important genetic determinant is the difference between donor and recipient HLA proteins. The extensive polymorphism of these proteins means that donor HLA antigens are almost invariably recognised as foreign by the recipient immune system, unless an active attempt has been made to minimise incompatibility.

- *Hyperacute rejection* results in rapid and irreversible destruction of the graft (see Box 4.21). It is mediated by pre-existing recipient antibodies against donor HLA antigens, which arise as a result of previous exposure through transplantation, blood transfusion or pregnancy. It is very rarely seen in clinical practice, as the use of screening for anti-HLA antibodies and pre-transplant cross-matching ensures the prior identification of such recipient–donor incompatibility.
- *Acute cellular rejection* is the most common form of graft rejection. It is mediated by activated T lymphocytes and results in deterioration in graft function. If allowed to progress, it may cause fever, pain and tenderness over the graft. It is usually amenable to increased immunosuppressive therapy.
- *Acute vascular rejection* is mediated by antibody formed de novo after transplantation. It is more curtailed than the hyperacute response because of the use of intercurrent immunosuppression but it is also associated with reduced graft survival. Aggressive immunosuppressive therapy is indicated and physical removal of antibody through plasmapheresis may be indicated in severe cases. Not all post-transplant anti-donor antibodies cause graft damage; their consequences are determined by specificity and ability to trigger other immune components, such as the complement cascade.
- *Chronic allograft failure*, also known as chronic rejection, is a major cause of graft loss. It is associated with proliferation of transplant vascular smooth muscle, interstitial fibrosis and scarring. The pathogenesis is poorly understood but contributing factors include immunological damage caused by subacute rejection, hypertension, hyperlipidaemia and chronic drug toxicity.

4.20 Immunological diseases in pregnancy

Allergic disease

- **Maternal dietary restrictions during pregnancy or lactation**: current evidence does not support these for prevention of allergic disease.
- **Breastfeeding for at least 4 months**: prevents or delays the occurrence of atopic dermatitis, cow's milk allergy and wheezing in early childhood, as compared with feeding formula milk containing intact cow's milk protein.

Autoimmune disease

- **Suppressed T cell–mediated immune responses in pregnancy**: some autoimmune diseases may improve during pregnancy but can flare immediately after delivery. Systemic lupus erythematosus (SLE) is an exception, however, as it is prone to exacerbation in pregnancy or the puerperium.
- **Passive transfer of maternal antibodies**: can mediate autoimmune disease in the fetus and newborn, including Graves disease, myasthenia gravis, congenital heart block and neonatal SLE.
- **Antiphospholipid syndrome** (p. 1012): an important cause of fetal loss, intrauterine growth restriction and pre-eclampsia.
- **HIV in pregnancy**: see p. 334.

Investigations

Pre-transplantation testing

HLA typing determines an individual's HLA polymorphisms and facilitates donor–recipient matching. Potential transplant recipients are also screened for the presence of anti-HLA antibodies. The recipient is excluded from receiving a transplant that carries these alleles.

Donor–recipient cross-matching is a functional assay that directly tests whether serum from a recipient (which potentially contains anti-donor antibodies) is able to bind and/or kill donor lymphocytes. It is specific to a prospective donor–recipient pair and is done immediately prior to transplantation. A positive cross-match is a contraindication to transplantation because of the risk of hyperacute rejection.

Post-transplant biopsy: C4d staining

C4d is a fragment of the complement protein C4 (see Fig. 4.4). Deposition of C4d in graft capillaries indicates local activation of the classical complement pathway and provides evidence of antibody-mediated damage. This is useful in the early diagnosis of vascular rejection.

Complications of transplant immunosuppression

Transplant recipients require indefinite treatment with immunosuppressive agents. In general, two or more immunosuppressive drugs are used in synergistic combination in order to minimise adverse effects. These include glucocorticoids, antiproliferative agents such as azathioprine and mycophenolate mofetil, and the calcineurin inhibitors ciclosporin and tacrolimus, which inhibit T-cell signalling and prevent lymphocyte activation. Other more targeted immunosuppressives include anti-thymocyte globulin (ATG), which is a cocktail of polyclonal antibodies directed against antigens on the T-cell surface; basiliximab, which is a monoclonal antibody directed against CD25 (IL-2Rα chain), expressed on activated T cells; and belatacept, which selectively inhibits T-cell activation through blockade of CD80/CD86. More details are provided in Chapter 18.

The major complications of long-term immunosuppression are infection and malignancy. The risk of some opportunistic infections may be minimised through the use of prophylactic medication, such as ganciclovir for cytomegalovirus prophylaxis and trimethoprim–sulfamethoxazole for *Pneumocystis* prophylaxis. Immunisation with killed vaccines is appropriate, although the immune response may be attenuated. Live vaccines should not be given.

4.21 Classification of transplant rejection

Type	Time	Pathological findings	Mechanism	Treatment
Hyperacute rejection	Minutes to hours	Thrombosis, necrosis	Pre-formed antibody to donor antigens results in complement activation (type II hypersensitivity)	None – irreversible graft loss
Acute cellular rejection	5–30 days	Cellular infiltration	CD4$^+$ and CD8$^+$ T cells (type IV hypersensitivity)	Increase immunosuppression
Acute vascular rejection	5–30 days	Vasculitis	Antibody and complement activation	Increase immunosuppression
Chronic allograft failure	> 30 days	Fibrosis, scarring	Immune and non-immune mechanisms	Minimise drug toxicity, control hypertension and hyperlipidaemia

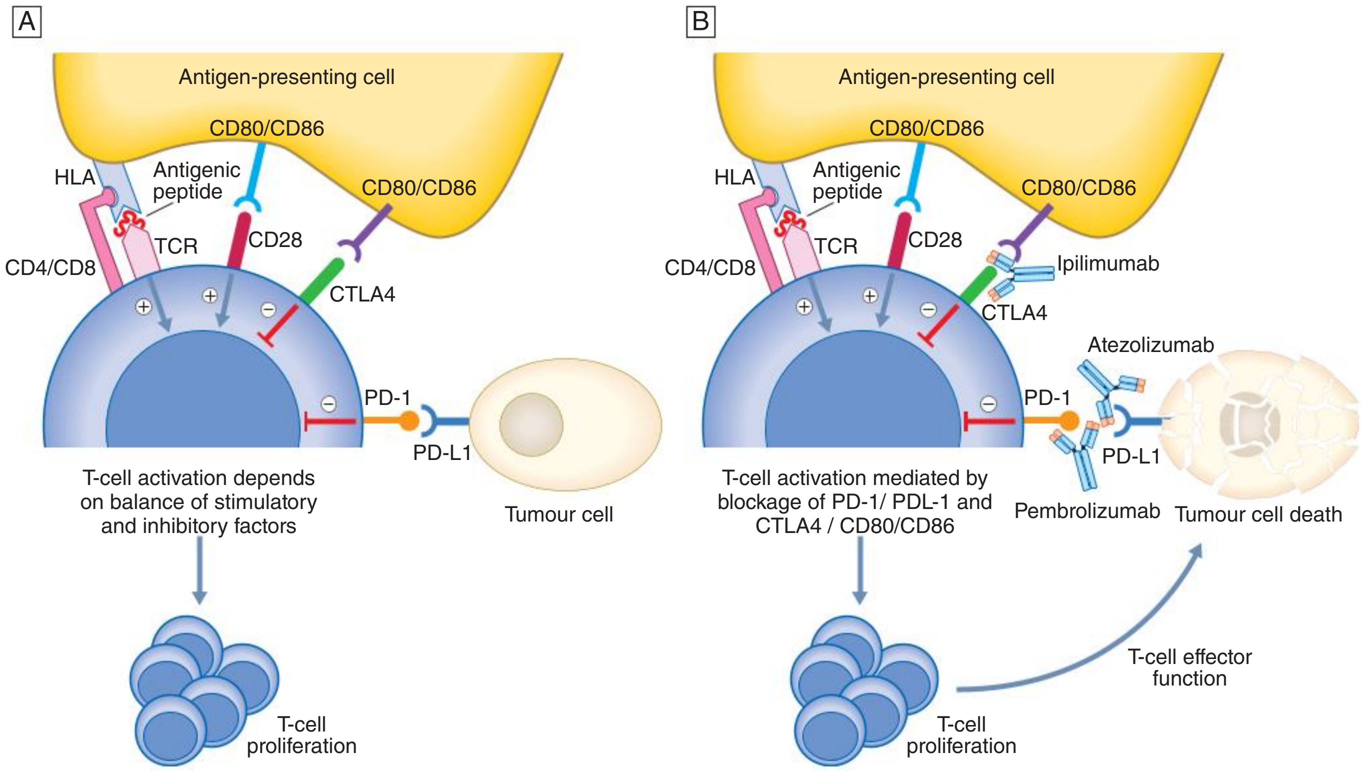

Fig. 4.14 **Immune checkpoint inhibition in cancer.** **A** The stimulatory and inhibitory pathways associated with T-cell activation in the context of malignancy are shown (see also Fig. 4.7). **B** How the immune checkpoint pathways CTLA4, PD-1 and PD-L1 can be inhibited by monoclonal antibodies directed at the immune checkpoint proteins, thus promoting T-cell activity against the target antigen. Immune checkpoint inhibition can be very effective treatment for certain types of malignancy. (CTLA4 = cytotoxic T-lymphocyte-associated protein 4; HLA = human leucocyte antigen; PD-1= programmed cell death protein 1; PD-L1 = programmed death ligand 1; TCR = T-cell receptor)

The increased risk of malignancy arises because T-cell suppression results in failure to control viral infections associated with malignant transformation. Virus-associated tumours include lymphoma (associated with Epstein–Barr virus), Kaposi sarcoma (associated with human herpesvirus 8) and skin tumours (associated with human papillomavirus). Immunosuppression is also linked with a small increase in the incidence of common cancers not associated with viral infection (such as lung, breast and colon cancer), reflecting the importance of T cells in anticancer surveillance.

Organ donation

The major problem in transplantation is the shortage of organ donors. Cadaveric organ donors are usually previously healthy individuals who experience brainstem death, frequently because of road traffic accidents or cerebrovascular events. Even if organs were obtained from all potential cadaveric donors, their numbers would be insufficient to meet current demands. An alternative is the use of living donors. Altruistic living donation, usually from close relatives, is widely used in renal transplantation. Living organ donation is inevitably associated with some risk to the donor and is highly regulated to ensure appropriate appreciation of the risks involved. Because of concerns about coercion and exploitation, non-altruistic organ donation (the sale of organs) is illegal in most countries.

Tumour immunology

Surveillance by the immune system is critically important in monitoring and removing damaged and mutated cells as they arise. The ability of the immune system to kill cancer cells effectively is influenced by tumour immunogenicity and specificity. Many cancer antigens are poorly expressed and specific antigens can mutate, either spontaneously or in response to treatment, which can result in evasion of immune responses. In addition, the inhibitory pathways that are used to maintain self-tolerance and limit collateral tissue damage during antimicrobial immune responses can be co-opted by cancerous cells to evade immune destruction. Recognition and understanding of these immune checkpoint pathways has led to the development of a number of new treatments for cancers that are otherwise refractory to treatment. Immune checkpoint blockade enhances anti-tumour immunity by blocking down-regulators of immune activation (Fig. 4.14). The immune checkpoint inhibitor ipilimumab inhibits CTLA4, which is an inhibitor of T-cell activation. Binding of PD-L1 to PD-1 inhibits T-cell activation and this interaction is blocked by pembrolizumab, which targets PD-1, and atezolizumab, which blocks PD-L1. These medicines and other PD-1–PD-L1 blockers have shown benefit in a number of tumour types, including melanoma, non-small cell lung cancer, urothelial cancers, colorectal malignancy and Hodgkin lymphoma. These agents can, however, have serious inflammatory side effects, with immune-related adverse events most commonly involving the skin, liver, endocrine and gastrointestinal tracts, which may be treatment limiting. The effects of the different agents vary, with lung and thyroid involvement being more common with anti-PD-1 therapy, and colitis and hypophysitis being more common with anti-CTLA4 therapy, with anti-CTLA4 therapy–related events often being more severe. However, patients who have had a favourable response to immune checkpoint blockade but discontinue as a result of immune-related adverse events may maintain their anti-tumour response. Glucocorticoids are considered first-line therapy for these side effects, with additional immune suppression if required. The development of autoimmunity reflects the importance of these pathways in the control of self-tolerance.

Another recent advance is CAR-T cell therapy, in which genetically engineered, chimeric antigen receptor (CAR) T cells are specifically developed for the treatment of an individual patient. This involves reprogramming the patient's own immune cells, to attack a specific target cell. The CAR-T cells are manufactured by first harvesting the patient's own T cells by apheresis. The gene encoding the CAR-T construct is transduced into these T cells in vitro. The resulting CAR-T cells are then expanded in tissue culture before being reinfused into the patient. The CAR structure usually consists of 4 domains: the antigen recognition domain, the hinge region (or ectodomain), the transmembrane domain, and the intracellular signalling domain (or endodomain). The CD3 zeta domain of the T-cell

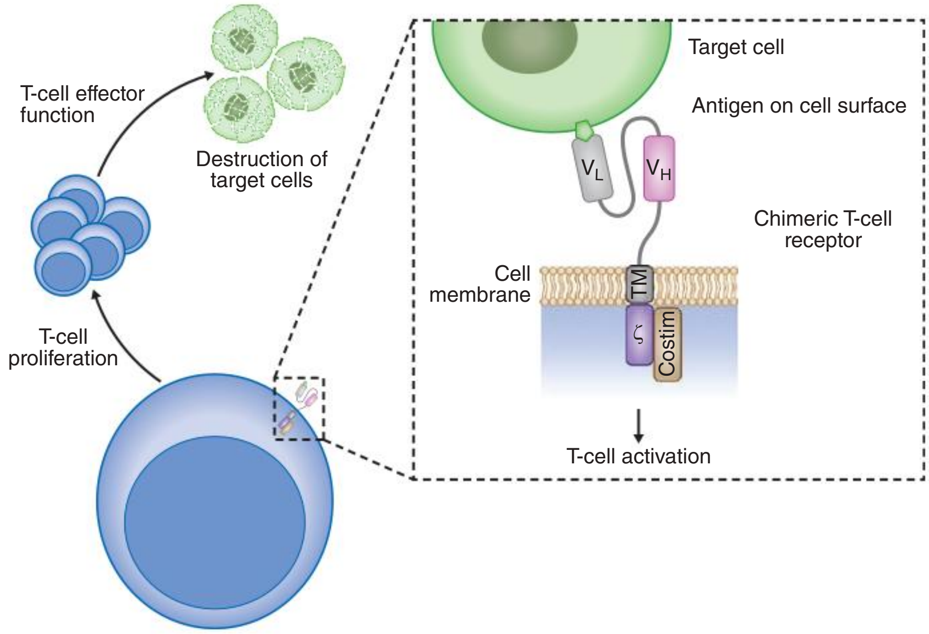

Fig. 4.15 **Chimeric antigen receptor T cells.** The chimeric antigen receptor (CAR) is genetically engineered by combining the extracellular antigen receptor binding domain from a monoclonal antibody (V_H and V_L are the heavy and light chain variable regions) with the intracellular activation domain from a T-cell receptor (ζ) and co-stimulatory subunits (Costim) linked by a transmembrane (TM) component. During the process, the extracellular domain of the T-cell receptor is cleaved and removed (∝–e). The new CAR uses the monoclonal antibody binding domain to bind to the target and this can now activate the T-cell effector killing mechanisms without the need for co-stimulatory signals allowing the CAR-T cell to kill the target cell.

receptor is used as the main signal, but as for other T cells, a co-stimulatory signal or domain is required, which is incorporated into the CAR as shown in Figure 4.15. The antigen recognition domain interacts with the target antigen and is derived from the variable region of monoclonal antibodies directed against the antigen in question. It consists of linked variable fragments of heavy and light chains. Once antigen is bound, the CARs cluster together, activating intracellular signalling pathways that lead to T-cell activation and destruction of the target cells.

This technology has mainly been applied to treatment-refractory haematological malignancies (Ch. 24), but more recently has been used in patients with severe, progressive, treatment-refractory autoimmune disease, including SLE, idiopathic inflammatory myositis and systemic sclerosis, with positive results (Ch. 25). In this situation, the aim of treatment is to reset the aberrant autoimmune response through extensive B-cell depletion. Further trials are required to determine the place of CAR-T cell therapy in this context.

Therapy with CAR-T cells can induce prolonged remission in patients with certain B-cell malignancies, often with minimal long-term toxicity, and are probably curative for a subset of patients. However, it is a very costly treatment and one which is associated with serious adverse effects including cytokine storm and antibody deficiency when the CAR-T cell is directed at B-cell antigens. These issues can require specific management in their own right.

Multiple Choice Questions

4.1. In the investigation of allergy, which of the following statements are correct?

A. Mast cell tryptase is labile in serum and therefore not a useful biomarker of mast cell activation
B. Measurement of total IgE is not useful
C. Component resolved diagnostics can have a role in assessing allergen cross reactivity
D. Skin testing is not affected by antihistamine medication
E. Some antidepressant medications can lead to false-negative skin test results

Answer: C and E.

Mast cell tryptase is stable in serum, making it a particularly convenient biomarker of mast cell activation. A total IgE can be helpful in atopic patients as a high total level can be associated with false-positive specific IgEs. Component resolved diagnostics (CRD) uses purified native or recombinant allergens to detect specific IgE directed against individual allergenic molecules. CRD can discriminate genuine sensitisation from sensitisation due to cross-reactivity and in some cases can be used in risk stratification, having predictive value, such as in peanut and some nut allergies. A number of medications, including certain antidepressant classes, can have antihistamine properties and thereby interfere with skin testing. Patients should be advised to discontinue interacting medications in advance of testing.

4.2. Which of the following are required for naïve T-cell activation?

A. Antigen processing by antigen-presenting cells
B. Antigenic peptide presentation by pattern recognition receptors
C. HLA class 1 for CD4 T cells
D. Co-stimulatory molecules
E. Intracellular T-cell signalling

Answer: A, D and E.

Unlike B cells, which recognise native antigen, T cells require antigen processing through professional antigen-presenting cells (APCs), with presentation of antigenic peptide by self-HLA molecules expressed at the APC surface. The Ag–HLA complex then interacts with the T-cell receptor. Pattern recognition receptors are expressed by phagocytic cells and recognise pathogen-associated molecular patterns on invading microorganisms. They do not present antigen to T cells. CD4 T cells recognise antigenic peptide presented by HLA class II molecules; CD8 T cells recognise antigenic peptide presented by HLA class I molecules. A second signal, known as co-stimulation, is required for naïve T-cell activation. Downstream intracellular T-cell signalling then drives T-cell proliferation.

4.3. Which of the following statements are correct regarding T-cell populations?

A. CD4 T cells kill virally infected cells through production of pore-forming molecules such as perforin and release of enzymes triggering apoptosis of the target cell
B. CD8 T cells are important in defence against viral infection
C. Th1 (T-helper) cells typically produce IL-2, IFN-γ and TNF-α
D. T-regs are regulatory CD4 T cells that promote activation of other cells and augment autoimmune disease
E. Th17 cells are pro-inflammatory cells that produce IL-17 and have a key role in defence against extracellular bacteria and fungi

Answer: B, C and E.

CD8 T cells, not CD4 T cells, kill infected cells directly through the production of pore-forming molecules, such as perforin, and release of enzymes triggering apoptosis of the target cell. CD8 T cells are particularly important in defence against viral infection. Th1 (T-helper) cells typically produce IL-2, IFN-γ and TNF-α, and support the development of delayed-type hypersensitivity responses. T-regulatory cells (T-regs) are a subset of specialised $CD4^+$ lymphocytes important in actively suppressing activation of other cells and preventing autoimmune disease. They produce cytokines such as TGF-β and IL-10. Th17 cells are pro-inflammatory cells defined by their production of IL-17. They have a key role in defence against extracellular bacteria and fungi. They also have a role in the development of autoimmune disease.

4.4. In tumour immunology, which of the following statements are correct?

A. NK cells have an important role in immune surveillance
B. Tumour cells reliably express HLA molecules to allow immune recognition by T cells
C. Immune checkpoint blockade includes anti-CTLA and anti-PD-1 pathways
D. Autoimmune disease is a recognised complication of immune checkpoint blockade in tumour therapy
E. Tumour progression occurs rapidly if immune checkpoint blockade is withdrawn

Answer: A, C and D.

NK cells have an important role in tumour surveillance especially as tumour cells lose their HLA expression, thereby allowing NK cell activation. Loss of HLA expression is one of the mechanisms by which tumours can evade T-cell immunity. Immune checkpoint blockade includes antibodies directed at the normally down-regulatory pathways, thereby allowing immune cells to be active against the tumour. Some patients maintain the anti-tumour effect of immune checkpoint blockade despite treatment withdrawal in the event of drug toxicity.

4.5. In the context of organ transplantation, which of the following statements are correct?

A. The major complications are graft rejection, drug toxicity and infection
B. HLA incompatibility does not have a bearing on transplant outcome
C. Acute cellular rejection is predominantly mediated by activated B cells
D. Post-transplantation, failure to control viral infections associated with malignant transformation leads to an increased risk of malignancy
E. Co-stimulatory blockade has no role in post-transplant immune suppression

Answer: A and D.

The major complications of transplantation are graft rejection, drug toxicity and infection consequent to immunosuppression. Solid organ transplantation stimulates an aggressive immune response by the recipient, unless the transplant is between monozygotic twins. The most important genetic determinant is the difference between donor and recipient HLA proteins. The polymorphism of these proteins means that donor HLA antigens are almost invariably recognised as foreign by the recipient immune system, unless an active attempt has been made to minimise incompatibility. Acute cellular rejection is mediated by activated T lymphocytes and results in deterioration in graft function. The risk of post-transplant malignancy arises because T-cell suppression results in failure to control viral infections associated with malignant transformation, e.g. lymphoma associated with Epstein–Barr virus, Kaposi sarcoma associated with human herpesvirus 8 and skin tumours associated with human papillomavirus. Co-stimulatory blockade, using the CTLA-4 fusion protein belatacept, with high affinity for CD80/86 on T cells, selectively inhibits T-cell activation and has a role in post-transplant immune suppression.

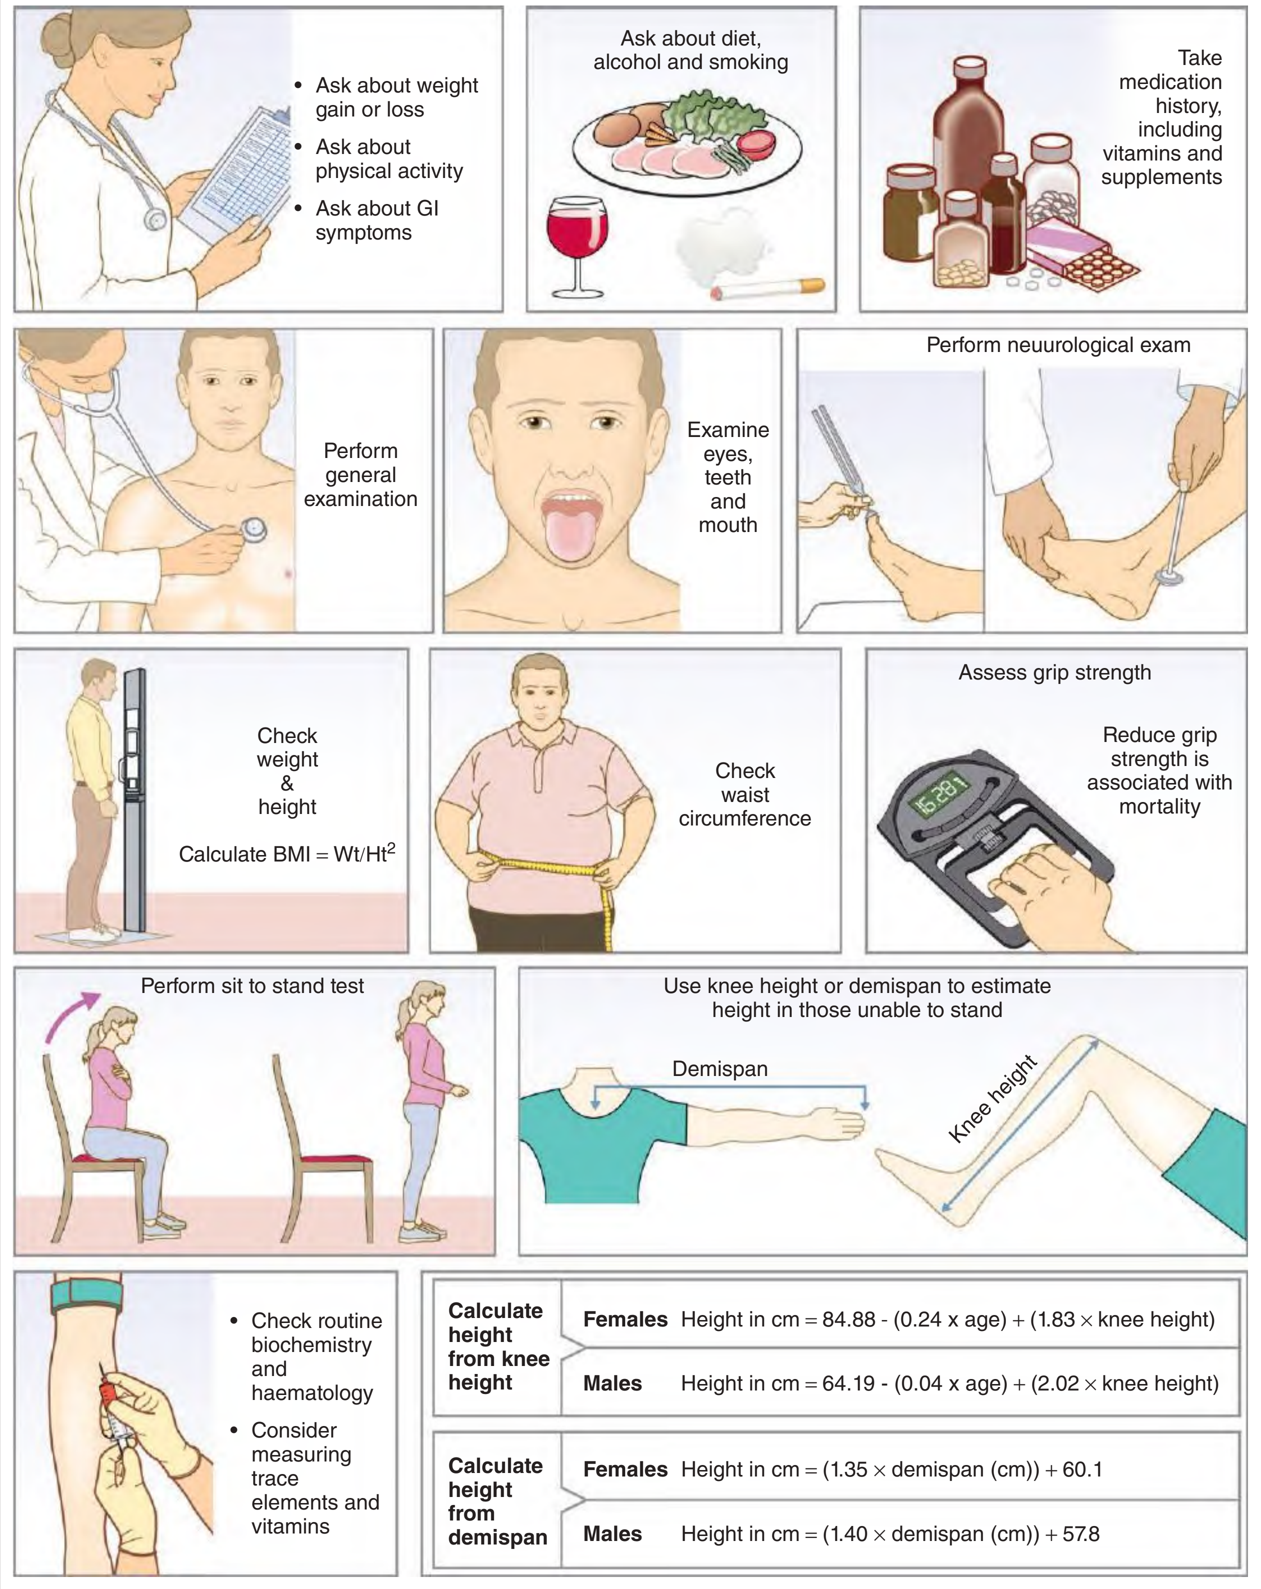
Clinical assessment and investigation of nutritional status

Clinical evaluation of nutritional status



Ask about weight gain or loss
Ask about physical activity
Ask about GI symptoms
Ask about diet, alcohol and smoking
Take medication history, including vitamins and supplements
Perform general examination
Examine eyes, teeth and mouth
Perform neuurological exam
Check weight & height
Calculate BMI = Wt/Ht²
Check waist circumference
Assess grip strength
Reduce grip strength is associated with mortality
Perform sit to stand test
Use knee height or demispan to estimate height in those unable to stand
Demispan
Knee height
Check routine biochemistry and haematology
Consider measuring trace elements and vitamins

Calculate height from knee height	**Females**	Height in cm = 84.88 - (0.24 x age) + (1.83 × knee height)
	Males	Height in cm = 64.19 - (0.04 x age) + (2.02 × knee height)
Calculate height from demispan	**Females**	Height in cm = (1.35 × demispan (cm)) + 60.1
	Males	Height in cm = (1.40 × demispan (cm)) + 57.8

Nutritional factors and disease

Nutritional status is a conceptual term that comprises three interrelated components (Box 5.1). All are needed to perform the functions required in health and to respond to stresses. Grasping the complexity of nutritional status is important for understanding any disease and to optimise management. It is not sufficient to consider just one or two of the three components in isolation. While certain elements within each of the three components can be measured, and they may point towards a nutritional problem, it is not possible to measure nutritional status with a single test. Its assessment requires clinical skills and experience. Nutritional assessment should include information on past medical and surgical history (particularly intestinal surgery), drug history and dietary history to enquire about eating habits and food preferences (ideally by a trained dietitian). All doctors must be alert to the three roles of nutrition. In every case, consider if nutrition (1) might contribute to the cause of disease, and be a means of prevention; (2) might be impaired because of disease; and (3) might contribute to recovery. A clear understanding of nutrition is essential to deal with the needs of individual patients and inform public policy.

Obtaining adequate nutrition is a fundamental requirement for optimal growth, function and health of every cell and organ, determining the health, and ultimately survival, of every individual. Nutritional adequacy can be threatened by natural supply, by competition, and by ignorance or trickery. The politics of human food provision constitute a prominent factor in wars, natural disasters and the profit-driven global economy. In recent decades, stable plentiful nutrition unknown to previous generations has led to a pandemic of obesity and its health consequences in post-industrial countries. However, famine and under-nutrition still dominate ill-health in lower-income countries until they transition, often suddenly, into Westernised over-nutrition. Quality, or nutritional balance, of food consumption, and thus the food supply, also influences health. Over recent years, several countries have introduced nutritional surveillance programs to monitor the nutritional health of their populations. Examples include the National Health and Nutrition Examination Survey (NHANES) in the USA, the National Diet and Nutrition Survey (NDNS) in the UK and the National Family Health Survey (NHFS) in India. The aims of these surveys are to evaluate the nutritional status of target populations and identify malnutrition and over-nutrition, in order to inform evidence based nutritional policies to improve public health.

Physiology of nutrition

The main nutritional components of food are carbohydrates, proteins, fats, vitamins, minerals, and water. Carbohydrates, proteins, and fats are referred to as macronutrients and are a source of energy. Other nutrients including vitamins, essential amino acids and essential fatty acids must be consumed in the diet to maintain health (Box 5.2). Nutrients come from foods of different types which are consumed intermittently and sometimes only occasionally. The key food groups that are recommended for a healthy diet are shown in Figure. 5.1. The physiology and language of

5.1 The inter-related components that define nutritional status

What we eat – **diet composition**

- Self-reported intake (retrospective)
- Objectively observed food consumption
- Estimated or measured nutrient consumption

What we are – **body composition**

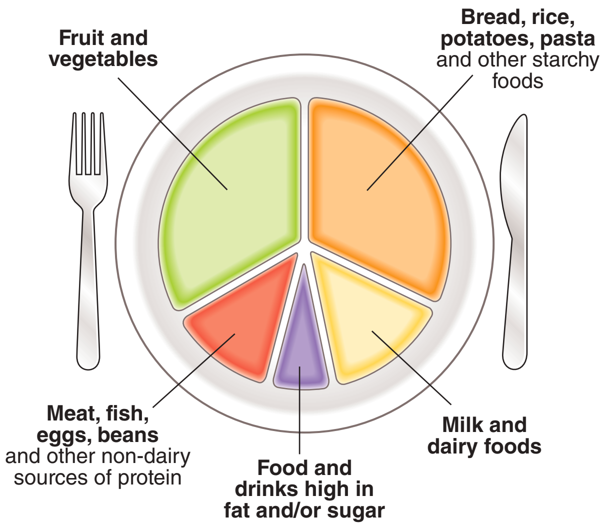
- Water content, chemical composition
- Two-compartment (fat/lean tissue), imaging
- Bone mass/specific tissue composition

What we (can) do – **functions**

- Metabolic, cellular
- Organ/whole-body function
- Physical, mental and social activities

5.2 Classification of nutrients

Nutrient	Examples	Comment
Macronutrients	Carbohydrate Protein Fat	Consumed in relatively large amounts Source of energy and provide building blocks to maintain bodily systems and structures
Fat-soluble vitamins	A, D, E, K	Needed for vision, skeletal health, blood clotting and the immune system
Water-soluble vitamins	B_1, B_2, B_6, B_{12}, folate, C	Needed for energy metabolism, neuronal health, blood formation
Minerals	Calcium, chloride, magnesium, phosphorus, potassium, sodium	Needed for cellular function and fluid homeostasis, neuronal health, muscle function and skeletal health
Trace minerals	Cobalt, copper, fluoride, iodine, iron, manganese, selenium, sulphur, zinc	Serve as co-factors for a variety of enzymes and structural proteins
Essential fatty acids	Linoleic acid Alpha-linoleic acid	Components of cell membranes Precursors of bioactive lipid mediators Sources of energy
Essential amino acids	Tryptophan Histidine Methionine Threonine Isoleucine Valine Phenylalanine Lysine Leucine	Components of proteins and peptides Cannot be synthesised de novo within the body



Fruit and vegetables
Bread, rice, potatoes, pasta and other starchy foods
Meat, fish, eggs, beans and other non-dairy sources of protein
Food and drinks high in fat and/or sugar
Milk and dairy foods

nutrition is therefore similar to economics, involving intermittent supply, losses at different rates, storage, obligatory costs, impacts on function, and mitigation of impacts by alterations in the internal economy.

Energy balance

The laws of thermodynamics dictate that *energy intake = energy expenditure ± changes in energy storage*. Therefore, if energy intake is greater than expenditure, then energy storage must increase in the form of weight gain. Conversely if energy intake is less than expenditure, weight loss occurs. Energy expenditure comprises three components. The largest is basal metabolic rate (BMR), which is the obligatory energy expenditure required to maintain metabolic functions of tissues at rest. It is closely predicted by body weight, and lower in females and older or inactive people (Fig. 5.2A). Extra energy is needed for growth, pregnancy and lactation and for physical activity, which varies considerably with occupation and lifestyle (Fig. 5.2B). The energy required to digest food (generating heat as diet-induced thermogenesis) accounts for approximately 10% of total energy expenditure, protein requiring more energy than other macronutrients (Fig. 5.2C).

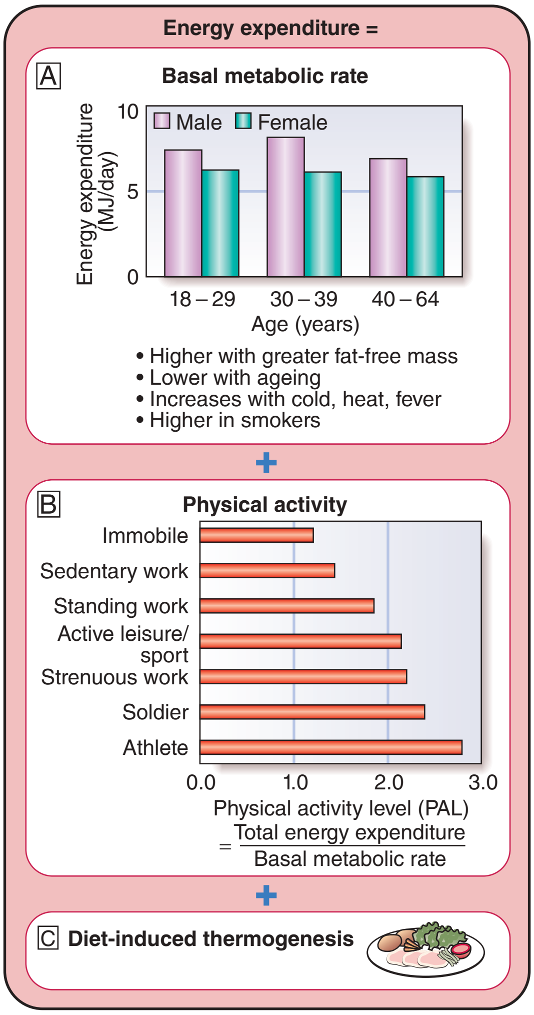

Fig. 5.2 Determinants of energy expenditure. **A** Basal metabolic rate (BMR) in men and women according to age. The BMR declines from middle age and is lower in women, even after adjustment for body size because of differences in fat-free mass. **B** Effect of physical activity on BMR. As energy is required for movement and activity, physical activity increases BMR. The physical activity level (PAL) is the multiple of BMR by which total energy expenditure is increased by activity. Leisure or sport activity increases PAL by about 0.3 for each 30–60 minutes of moderate exercise performed 4–5 times per week. The UK population median for PAL is 1.6, with estimates of 1.5 for the less active and 1.8 for the more active. **C** Energy is consumed in order to digest food. This is referred to as diet-induced thermogenesis and accounts for about 10% of energy expenditure.

Energy intake is determined by the macronutrients carbohydrate, fat and protein. These, along with alcohol, if present in the diet, provide fuel for mitochondria to generate energy (as adenosine triphosphate (ATP)). The energy provided and the amounts that can be stored in the body differ with different nutrients, as shown below:

- fat – 37 kJ/g (9 kcal/g): stored as body fat, usually sufficient for ≥ 40 days
- alcohol – 29 kJ/g (7 kcal/g): not stored: toxic, must be metabolised immediately
- protein – 17 kJ/g (4 kcal/g): not stored, but can be oxidised in extreme starvation
- carbohydrate – 16 kJ/g (3.75 kcal/g): stored as glycogen in liver and muscle, sufficient for 12–24 hours

Figure 5.3 illustrates the differences in energy intake based on national averages in the UK and rural and urban communities in India derived from fat, carbohydrate and protein. The UK figure assumes that on average, 5% of energy intake is from alcohol. It can be appreciated that the relative amounts of fat and protein in rural India are much less than in the UK, but that in the urban Indian population the amount of fat and protein are midway between rural India and the UK. It should be noted that these values obscure substantial individual and regional variations in both countries.

Regulation of energy balance

Energy intake and expenditure are tightly regulated. Energy balance is coordinated in the hypothalamus, which receives afferent signals that indicate nutritional status in the short term (Fig. 5.4). The hormone

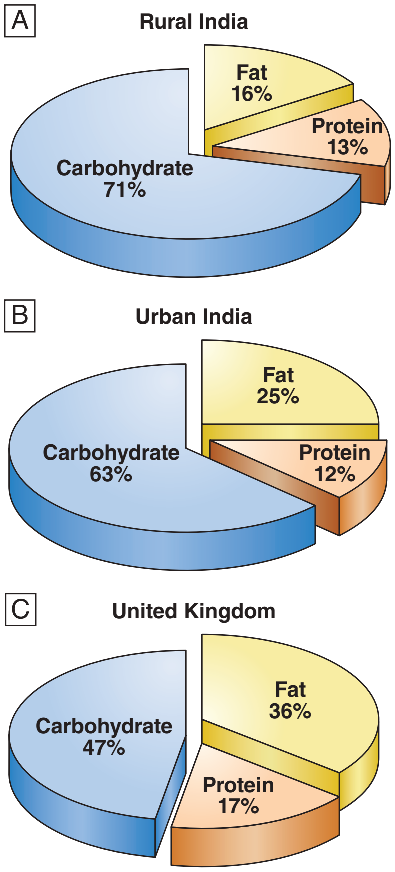

Fig. 5.3 Sources of energy intake in the UK, rural India and urban India. Note that in rural India the amounts of fat and protein are less than in the UK, but in urban India the proportions are midway between rural India and the UK. *Sources: UK Department of Health, What India Eats: ICMR, National Institute of Nutrition, Hyderabad, India.*

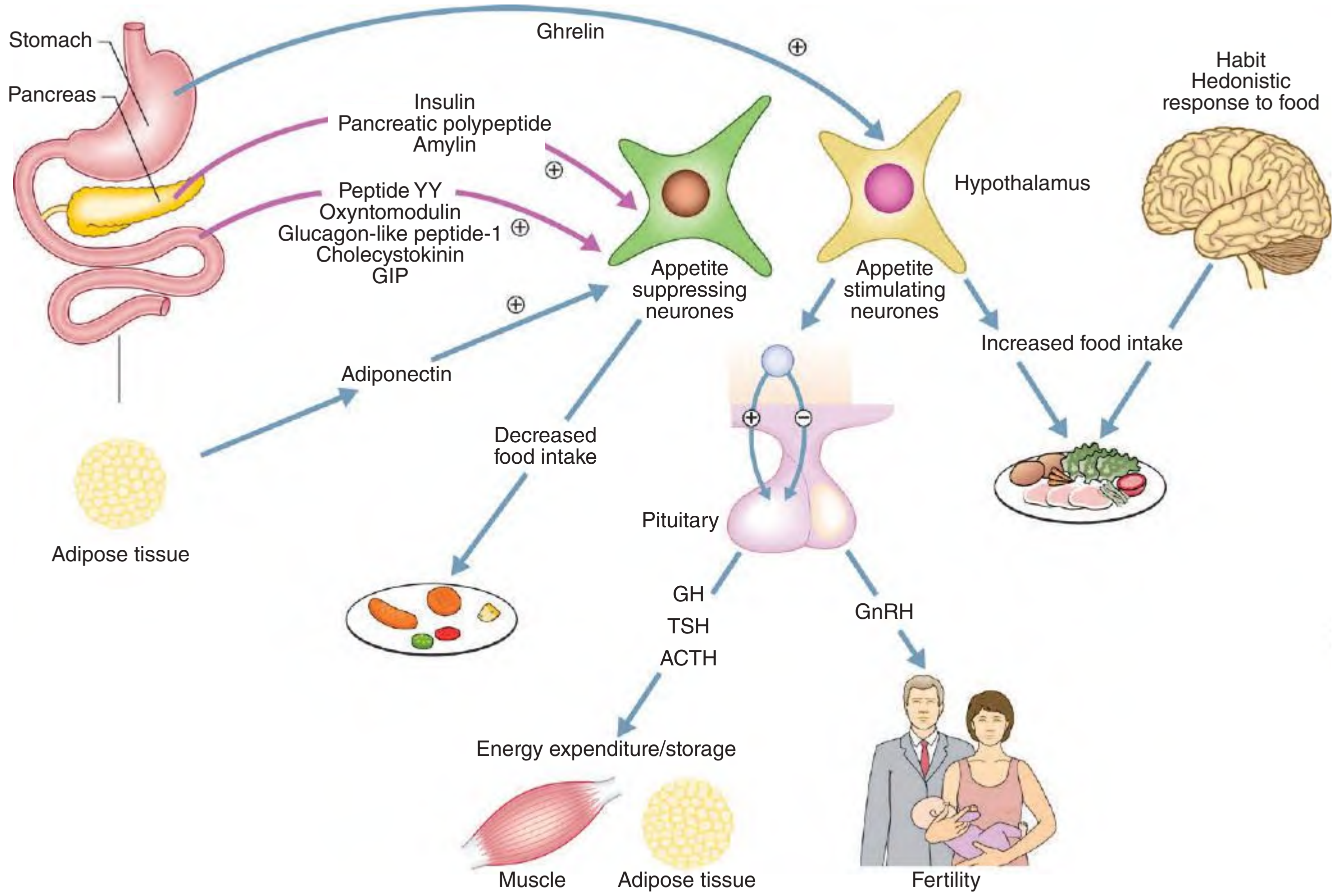

Fig. 5.4 **Factors influencing energy balance.** This figure reflects appetite regulation in response to food consumption, but a wider range of hormones also affect appetite, including neuropeptide Y (NPY), thyroid hormones, cortisol, oestrogen, progesterone and testosterone. The effects of these hormones on appetite are not simple and uni-directional: they have a more integratory role. The hypothalamus plays a key role in regulating energy balance by integrating hormonal signals that come from the gut on eating and from adipose tissue. The hypothalamus responds with release of neurotransmitters and hormones which influence energy expenditure and storage and reproduction. ⊕ indicates factors that induce satiety. ⊖ indicates factors that inhibit satiety. (ACTH = adrenocorticotrophic hormone; GH = growth hormone; GIP = glucose-dependent insulinotropic polypeptide; GnRH = gonadotropin-releasing hormone; TSH = thyroid-stimulating hormone)

ghrelin, which is derived from the stomach, falls immediately after eating and rises gradually thereafter, to suppress satiety and signal that it is time for the next meal. Conversely, insulin, peptide YY, oxyntomodulin, glucagon-like peptide 1, pancreatic polypeptide, cholecystokinin and glucose dependent insulinotropic polypeptide and amylin induce satiety and suppress food intake.

The hormones leptin and adiponectin, derived from adipose tissue, increase with growing fat mass and induce a sensation of satiety. The hypothalamus responds with changes in many local neurotransmitters that alter activity in pathways that influence energy balance (see Fig. 5.4), including hormones acting on the pituitary gland and neural control circuits that connect with the cerebral cortex and autonomic nervous system.

In general, appetite matches requirement very closely: even when body weight is doubled by obesity, the mismatch between intake and expenditure is usually under 1%. Food shortage, with loss of weight, is the main threat to survival faced by any organism, and negative energy balance immediately signals a range of physiological messages. Energy is conserved by dropping core temperature, and by reducing BMR and physical activity. Chronic food shortage, or micronutrient deficiency, prevents growth and blocks reproductive function, delaying maturation and halting ovulation. Pregnancy is most likely to occur during times of nutritional plenty, when both mother and baby have a better chance of survival. Anorexia nervosa and excessive exercise, as well as weight loss through illness, can cause amenorrhoea. Improved nutrition is thought to be the reason for the increasingly early onset of puberty in many societies. At the other extreme, obesity is also a common cause of amenorrhoea and infertility.

Responses to under- and over-nutrition

These complex regulatory pathways allow adaptation to variations in nutrition. In response to starvation, reproductive function is suppressed, BMR is reduced, and there are profound psychological effects, including energy conservation through lethargy. These adjustments can maintain body weight within certain limits. In the low-insulin state of starvation, fuels are liberated from stores, initially from glycogen (in muscle and liver), then from triglyceride (lipolysis in adipose tissue, with excess free fatty acid supply to the liver leading to ketosis) and finally in protein (proteolysis in muscle). In neonates and in women who are pregnant or breastfeeding, with high glucose requirements, starvation can result in ketosis with normal or low blood glucose.

In response to over-nutrition, BMR rises, and extra energy is required to carry increased body weight, so the original body weight is maintained within certain limits. In the high-insulin state of over-nutrition, excess energy is stored principally as fat in adipose tissue, but in individuals predisposed to the metabolic syndrome and type 2 diabetes it may also accumulate in and damage organ function in liver (non-alcoholic fatty liver disease), pancreas and skeletal muscle. If hypothalamic function is abnormal (such as in people with craniopharyngioma) or if there are pathogenic variants in pathways that regulate appetite (such as in people with pathogenic variants in the leptin or melanocortin-4 receptors), there is a loss of response to satiety signals, which, together with loss of adaptive changes in energy expenditure, results in relentless eating and weight gain. People living with obesity commonly have appetites driven by the same powerful physiology, which cannot be overcome by attempts at voluntary food restriction.

Macronutrients

Carbohydrates

Types of carbohydrate and their dietary sources are listed in Box 5.3. Longer chain carbohydrates (starches and sugars) are broken down to monosaccharides for absorption from the gut and supply just under half the energy in a well-balanced diet in the UK and about 70% in rural India (see Fig. 5.3). Carbohydrates can be synthesised de novo only in very small amounts from glycerol or protein. If the available carbohydrate intake is less than 100 g per day, increased lipolysis and fat oxidation occurs leading to dietary ketosis.

There is much public and media confusion arising from equating carbohydrates with sugars, and a belief that sugars are hazardous. Dietary guidelines correctly restrict the intake of added sugars (sucrose, maltose, fructose), which promote dental caries when there is fluoride insufficiency, and may lead to greater energy consumption by children. However, sugars in fruits and milk, or generated by starch hydrolysis in the gut, present no hazard in their natural whole-food matrix. Starches in cereal foods, root foods and legumes provide the largest proportion of energy in most diets around the world, and a high carbohydrate intake in traditional diets is associated with freedom from non-communicable diseases. Starches are polymers of glucose, linked by 1–4 glycosidic linkages. Some starches are digested promptly by salivary and then pancreatic amylase, producing rapid delivery of glucose to the blood. Other starches are digested more slowly, either because they are protected in the structure of the food, or because the molecule is unbranched (amylose). The area under the curve of blood glucose concentration over 2 hours after eating 50 g carbohydrate in a food, expressed as a percentage of the response to 50 g carbohydrate as glucose or white bread, is termed the *glycaemic index* of that food. High consumption of high-glycaemic-index foods is weakly associated with type 2 diabetes, but it should be noted that table sugar (sucrose) has a relatively low glycaemic index, being only 50% glucose. Sugar alcohols, such as those which are used as sweeteners, are not absorbed from the gut, causing diarrhoea if eaten in large amounts. The main sugar in milk is lactose, a vital energy source for infants. It is hydrolysed by intestinal lactase into glucose and galactose before it can be absorbed. Some people lose lactase activity as they age (usually after the age of 6). Those predominantly affected include East and South-east Asians, African Americans, Native Americans and some Africans. These individuals must limit intake of unfermented milk products. Temporary lactose intolerance is common after any gastroenteritis, but lactase production can be restored by cautious lactose reintroduction.

i **5.3 Types and dietary sources of carbohydrate**

Class	Examples	Source
Monosaccharides	Glucose, fructose, galactose, sucrose, lactose, maltose	Intrinsic: fruits, milks, vegetables Extrinsic (extracted, refined): beet or cane sucrose, high-fructose corn syrup
Short-chain carbohydrates	Maltodextrins, fructo-oligosaccharides	Fruits and vegetables
Starch polysaccharides	Amylose (linear form) Amylopectin (branched form)	Cereals (wheat, rice), root vegetables (potato), legumes (lentils, beans, peas)
Resistant starch*	Amylose (linear form) Amylopectin (branched form)	Cooked and cooled potato, pasta, rice
Non-starch polysaccharides (dietary fibre)	Cellulose Hemicellulose Pectins Gums	Many plant foods Pulses
Sugar alcohols	Sorbitol, xylitol	Sorbitol: stone fruits (apples, peaches, prunes) Xylitol: maize, berry fruits Both used as low-calorie sugar alternatives

*In resistant starch, the polysaccharide content is largely not accessible to digestive enzymes. Cooking modifies some resistant starches to become digestible, and cooling can create new resistant forms of polysaccharides.

Dietary fibre

Dietary fibre is carbohydrate that is not digested and absorbed in the small intestine. It passes into the large bowel as the main nutrient for the gut microbiota. Most dietary fibre consists of non-starch polysaccharides (NSP) (see Box 5.3), plus some 'resistant' dietary starch, altered by cooking to escape hydrolysis in the small intestine. The many bacterial species which make up the colonic microbiota digest fibre to produce short-chain fatty acids (SCFA), which are absorbed as fuel for the colonic epithelium and contribute to bowel health. These SCFA are also bioactive, stimulating production of hormones like glucagon-like peptide (GLP-1) from L cells in the colon. In infancy, some lactose in milk is not absorbed, and serves the same function.

Some types of NSP, notably the hemicellulose of wheat or psyllium, increase the water-holding capacity of the colonic contents and the bulk of faeces. They relieve simple constipation, appear to prevent diverticulosis and may reduce the risk of colon cancer. Viscous dietary fibres, like pectin and guar gum, delay glucose absorption and reduce glycaemic index, and reduce bile salt absorption and blood cholesterol concentration.

Fats

Fat is the highest-energy density macronutrient and incurs minimal energy costs for absorption and storage. Highly prized in ancient times, it is now cheap and is present in high amounts in some manufactured foods. Even small increases in fat consumption can cause of obesity.

The absorption of fat is described in Chapter 22 (see Fig. 22.5). Free fatty acids are absorbed, reassembled in chylomicrons to enter the circulation via mesenteric lymphatics into the systemic circulation. Fatty acid structures are shown in Figure 5.5. The principal polyunsaturated fatty acids (PUFA) in plant seed oils, linoleic acid (18:2 ω6) and α-linolenic acid (18:3 ω3) are the 'essential' fatty acids, which humans cannot synthesise de novo. They undergo further desaturation and elongation to produce, for example, γ-linolenic acid (18:3 ω6) and arachidonic acid (20:4 ω6).

Fig. 5.5 Schematic representation of fatty acids. Examples of a saturated fatty acid (myristic acid), a monounsaturated fatty acid (oleic acid) and a polyunsaturated fatty acid (linoleic acid) are shown. Standard nomenclature specifies the number of carbon atoms and indicates the number and position of the double bond(s) relative to the methyl ($-CH_3$, ω) end of the molecule after a colon.

These are precursors of prostaglandins and eicosanoids, and form part of the structure of lipid membranes in all cells. Oil-rich fish (sardines, salmon, herring) and fish oils are rich in ω3 PUFA (eicosapentaenoic (20:5 ω3) and docosahexaenoic (22:6 ω3) acids), which promote the anti-inflammatory cascade of prostaglandin production and occur in the lipids of the human brain and retina. They also reduce blood pressure, improve glucose tolerance and inhibit thrombosis by competitively antagonising thromboxane A_2 formation. Saturated fats have high melting points, mostly coming from warm-blooded animal sources: those with shorter chain lengths, from dairy foods, appear relatively safe, but those with long chain lengths, found particularly in animal fat and manufactured meat products, elevate LDL cholesterol and promote cardiovascular disease. Replacing them with PUFAs may help prevent coronary heart disease, provided the PUFAs are protected by their natural antioxidants. High intakes of *trans* fatty acids (TFAs), which are isomers of the natural *cis* fatty acids, reflect the use of oils that have been partially hydrogenated in the food industry to raise their melting point for use in manufactured foods. They behave like the long-chain saturated fats to promote cardiovascular disease, so it is recommended that TFAs are limited to <2% of dietary fat intake. Changes in industrial practice in the UK and United States have brought most people's TFA intakes below 1%, with the residual amount coming from ruminant digestion in milk. Cholesterol is also absorbed from food in chylomicrons and is an important substrate for steroid and sterol synthesis, but not an important source of energy, nor a major contributor to plasma cholesterol concentration as it is also synthesised in the liver.

Proteins

Proteins are made up of some 20 different amino acids. Nine are essential (see Box 5.2), which means that they cannot be synthesised endogenously by healthy humans, but are required for synthesis of important proteins, so must always be provided by the diet. While amino acids are well preserved by recycling, there are no stores, so a regular supply is needed to replace losses. Five other amino acids (cysteine, tyrosine, arginine, proline and glycine) are conditionally essential. This means that they can usually be synthesised from other amino acids, but that at times of stress (poor diet, pregnancy, growth, illness) this may be insufficient, demanding a greater dietary supply. The remaining necessary amino acids can be synthesised in the body by transamination, provided there is a sufficient supply of amino groups from proteins in the diet.

Dietary proteins of animal origin contain a mix of amino acids well matched to human needs and have greater nutritional value than proteins of vegetable origin, which are low in one or more of the essential amino acids. However, when different vegetable proteins are eaten together, classically a cereal and a legume, their amino acid contents are complementary and produce an adequate mix, a key feature of most surviving traditional diets, and an important principle for vegan diets. There is a persistent myth, amplified by opportunistic misleading marketing, that eating more protein will increase muscle mass or function. The reality is that muscle growth requires stimulation from physical training and does not require high protein consumption. When protein intake exceeds about 1.2 g/kg/day, it is simply (and expensively if supplements are purchased) oxidised as a macronutrient fuel.

Dietary recommendations for macronutrients

Recommendations for energy intake (Box 5.4) and proportions of macronutrients (Box 5.5) in the general population have been developed from detailed analyses, and quality assessment, of the totality of the scientific evidence and have changed little over the last 50 years. Recommended ranges or limits aim to provide sufficient essential nutrients for the great majority of healthy people at different life-stages, and to minimise the risks of chronic non-communicable diseases (obesity, type 2 diabetes, coronary heart disease, diverticulosis, cancers). The requirements during and after illness may be different, and pre-term infants have particular needs.

5.4 Daily adult energy requirements in health

Circumstances	Females	Males
At rest (basal metabolic rate)	5.4 MJ (1300 kcal)	6.7 MJ (1600 kcal)
Less active	8.0 MJ (1900 kcal)	9.9 MJ (2400 kcal)
Population median	8.8 MJ (2100 kcal)	10.8 MJ (2600 kcal)
More active	9.6 MJ (2300 kcal)	11.8 MJ (2800 kcal)

These values assume a BMI of 22.5 kg/m^2. For a female, height is 162 cm and weight 59.0 kg; for a male, height is 175 cm and weight 68.8 kg.

5.5 Macronutrient goals recommended by WHO

	Lower limit	Upper limit
Protein	10	N/A
Total fat	15	30
Saturated fatty acids	0	10
Polyunsaturated fatty acids	6	10
Trans fatty acids	0	1
Dietary cholesterol (mg/day)	0	300
Total carbohydrate	55	75
Free (added) sugars	0	10
Complex carbohydrate	50	70
Dietary fibre (g/day)		
As non-starch polysaccharides	> 20	N/A
As total dietary fibre	> 25	N/A
Total fruit and vegetables	> 400	N/A

Values are expressed as percentage of total energy intake, except dietary fibre and fruit and vegetables, which are g/day and cholesterol which is mg/day.

Investigation of nutritional status

Clinical history, dietary history and drug history usually provide sufficient information for the diagnosis and management of many conditions where there are disturbances in nutritional status. However, investigations can be helpful in assessing disturbances and disorders of energy balance.

Haematology

Abnormalities in the full blood count (FBC) may occur in people with malnutrition, as well as those undergoing bariatric surgery due to vitamin B_{12}, folate and iron deficiency.

Biochemistry

Measurements of glucose, HbA_{1c} and a serum lipid profile, and liver function tests (LFTs) are of value as part of the general workup in patients with obesity to detect impaired glucose tolerance, evidence of fatty liver disease and hyperlipidaemia. Thyroid function tests and screening for Cushing syndrome may be required in people with a sudden gain in weight during adulthood. Measurements of serum phosphate, potassium, magnesium and serum electrolytes are essential as part of the monitoring process during refeeding of patients with malnutrition. Measurements of urea and electrolytes, calcium and phosphate, LFTs, C-reactive protein (CRP), blood glucose, cholesterol and triglycerides are recommended for patients receiving parenteral nutrition. Measurement of micronutrients and vitamins can be of value in the assessment of patients with malabsorption and chronic malnutrition. However, circulating levels of many of these analytes are significantly influenced by inflammation (Box 5.6).

Imaging

Imaging is not generally helpful in the diagnosis of malnutrition or over-nutrition except in the investigations of underlying infection or complications like fatty liver. Dual-energy X-ray absorptiometry can be used to assess body composition but is mainly used as a research technique and is of limited value in routine clinical practice.

i 5.6 Effects of inflammation on circulating micronutrient concentrations

Analyte	Reference range	Raised CRP (100–200 mg/mL)
Iron	14–32 μmol/L (male) 10–28 μmol/L (female)	Decreased by 60%–90%
Zinc	10–18 μmol/L	Decreased by 40%–60%
Selenium	0.8–2.0 μmol/L	Decreased by 40%–60%
Copper	10–22 μmol/L	Increased by 30%
Vitamin A	1.0–2.8 μmol/L	Decreased by 30%
Vitamin E	15–40 μmol/L	Decreased by 20%–30%
Vitamin C	10–115 μmol/L	Minimal change to decreased by > 75%
Vitamin B_1	280–540 μgTDP/gHb	No change
Vitamin B_2	< 70% activation	No change
Vitamin B_6	18–135 nmol/L	Decreased by 40%–50%
Vitamin B_{12}	>210 ng/L	No change
Folate	2.8–20 μg/L	No change
Lycopene	100–300 μg/L	Decreased by > 90%
Beta-carotene	92–312 μg/L	Decreased by > 90%
Alpha-carotene	14–60 μg/L	Decreased by > 90%
Lutein	82–202 μg/L	Decreased by 70%

(CRP = C-reactive protein)

Disorders of altered energy balance

Obesity

Obesity is regarded as a global pandemic (syndemic) as it entails disastrous consequences for human health. In 2020, almost 30% of adults in the UK were obese, defined as a BMI ≥ 30 kg/m^2, compared with 16% in 1995 and 7% in 1980. Moreover, almost 66% of the total UK adult population is overweight (BMI ≥ 25 kg/m^2). The proportion with a normal weight (BMI 18.5–25 kg/m^2) falls to only about 11% by age 65, presenting a problem for interpreting disease associations, because those 11% at age 65 include very fit people, but also a relatively high proportion who have remained or become thinner through illness. In low- and middle-income countries, average obesity rates are lower, but these figures may disguise high rates of obesity and non-communicable diseases emerging in urban communities.

Complications

Obesity affects both morbidity and mortality (Figs. 5.6 and 5.7). Differences in mortality associated with differences in weight are difficult to interpret due to the confounding effects of lower body weight in cigarette smokers and those with other illnesses (such as cancer). The lowest mortality rates in Europeans are still in the BMI range 18.5–25 kg/m^2 (and at lower BMI in South-east Asians), but there is only a minor rise until BMI is above 30 kg/m^2. A BMI above 35 kg/m^2 at age 40 years reduces life expectancy by up to 7 years for non-smokers and by 13 years for smokers, and if type 2 diabetes develops, almost always with moderate overweight, life expectancy is reduced by about 7 years at any BMI. Cardiovascular disease (see Fig. 5.7A) is the major cause of death, but cancer rates are also increased in the overweight, especially colorectal cancer in males and cancer of the gallbladder, biliary tract, breast, endometrium and cervix in females. The risk of diabetes is also increased (see Fig. 5.7B). The severely obese (BMI > 35 kg/m^2) often spend much of their life disabled, physically, mentally and socially. Although an increased body weight results in greater bone density through increased mechanical stress, this does not translate into a lower incidence of fractures since lower extremity fractures are more common in the obese. Obesity may also have profound psychological consequences, compounded by stigmatisation and victim blaming, rather than offering sympathetic support for effective treatment.

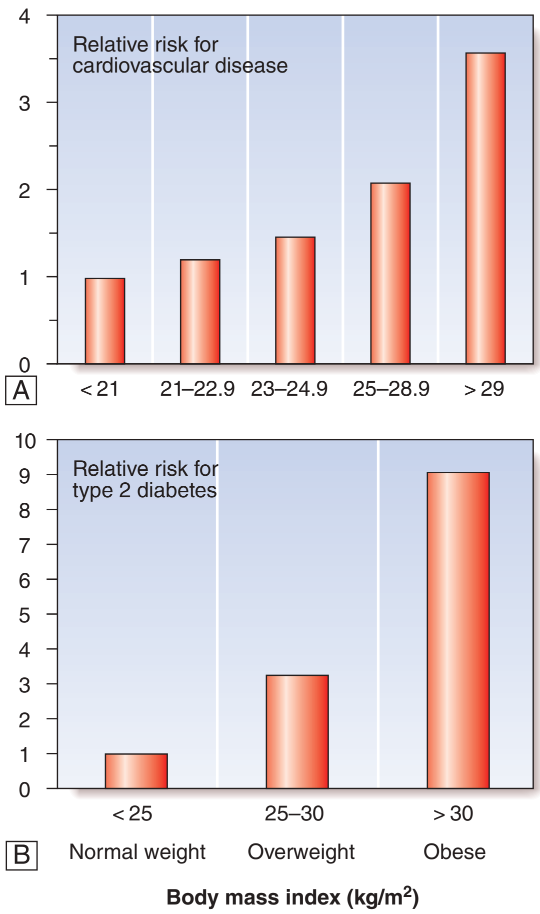

Fig. 5.7 Risks of cardiovascular disease and diabetes in women. Data are from the Nurses' Health Study in the United States and mostly relate to women of predominantly European descent. **A** Relative risk of cardiovascular disease. **B** Relative risk of diabetes in relation to body mass index.

Body fat distribution

For some complications of obesity, the distribution rather than the absolute amount of excess adipose tissue appears to be important. Increased intra-abdominal fat causes an 'apple-shaped' body contrasting with subcutaneous fat accumulation, which causes a pear-shaped body with larger hips and thighs. The former, more common in men, causes fat accumulation in the liver, pancreas, skeletal and cardiac muscle, promoting type 2 diabetes, metabolic syndrome and cardiovascular disease (see Figs. 5.6 and 5.7). Many bioactive factors are released from adipose tissue, including free fatty acids; and cytokines (adipokines). They include tumour necrosis factor alpha (TNF-α), adiponectin and resistin. These substances act on the liver and muscle, inducing insulin resistance and promoting type 2 diabetes. The key to remission of type 2 diabetes, with restoration of the first-phase insulin response to glucose, appears to be loss of ectopic fat in liver and pancreas.

Aetiology

Accumulation of fat results from a discrepancy between energy consumption and energy expenditure that is too large to be offset by hypothalamic regulation of BMR. A continued small daily positive energy balance of only 0.1 MJ (50 kcal; ~2% of intake) would lead to weight gain of ~25 kg over 10 years. With habituation to a subtle energy excess, body fat content shows tracking with age within obesogenic environments, such that children of obese families usually become obese adults. If physical activity decreases with age, which is now common, but food consumption is stable or increases, weight tends to increase throughout adult life.

i 5.7 Environmental reasons for the increasing prevalence of obesity

Increased energy intake

- ↑ Portion sizes
- ↑ Snacking, grazing and loss of regular meals
- ↑ Energy-dense 'added-value' food (fat and sugars)
- ↑ Affluence
- Effective marketing of foods

Decreased energy expenditure

- ↑ Car ownership
- ↓ Walking to school/work
- ↑ Automation and use of domestic labour-saving devices
- ↓ Manual labour in occupations
- ↓ Sports in schools
- ↑ Time spent on computer games and watching TV
- ↑ Central heating, washing machines

The obesity pandemic reflects dramatic changes over the last 40–50 years in both energy intake and expenditure (Box 5.7), although both are difficult to measure reliably. The estimated average global daily supply of food energy per person increased from approximately 9.8 MJ (2350 kcal) in the 1960s to approximately 11.7 MJ (2800 kcal) in the 1990s, but its delivery is unequal. For example, in India it is estimated that 5% of the population receives 40% of the available food energy, leading to obesity in the urban population in parallel with under-nutrition in some rural communities. In affluent societies, a significant proportion of this food supply is discarded. In the United States, men's average daily energy intake reportedly rose from 10.2 MJ (2450 kcal) in 1971 to 11.0 MJ (2618 kcal) in 2000. Portion sizes, particularly of energy-dense foods such as drinks with a high sugar content and salty snacks, have increased, and the 'food disappearance' rate (production and sales) has increased for all food groups, with greater consumption of catered meals and less food waste. Obesity is correlated positively with the number of hours spent watching screens, inversely with sleep time, and inversely with levels of physical activity. Labour-saving devices play a part and minor activities such as fidgeting, termed non-exercise activity thermogenesis (NEAT), may contribute to energy expenditure and protect against obesity.

Susceptibility to obesity

Susceptibility to obesity varies between individuals. Obese subjects do not have a slow metabolism: their BMR is higher than that of lean subjects in absolute terms, although it may be below average on a per kg basis. Twin and adoption studies confirm a familial influence on obesity, but both environmental and genetic factors contribute. The pattern of inheritance suggests a polygenic disorder, which accounts for about 25%–70% of the variation in weight. Genome-wide association studies have identified a handful of important genes, some of which encode proteins known to be involved in the control of appetite or metabolism function. However, these account for less than 5% of variation in body weight. Sophisticated modelling now suggests that variations in body fat and obesity are probably determined by the interactions of a vast number of genes which affect appetite and metabolism, each with a small influence, plus epigenetic modification of gene expression. Genes also influence fat distribution and therefore risk of metabolic consequences of obesity.

Rarely single-gene disorders may lead to severe obesity. These include pathogenic variants in the melanocortin-4 receptor *(MC4R)*, which are found in approximately 5% of people with severe early-onset obesity; loss-of-function variants in proopiomelanocortin *(POMC)* the precursor for adrenocorticotrophic hormone (ACTH); and loss-of-function variants in the leptin receptor and the leptin genes (see Fig. 5.4). The latter can be treated by leptin injections. Additional genetic conditions in which obesity is a feature include Prader–Willi and Lawrence–Moon–Biedl syndromes.

Clinical features and investigations

In assessing an individual presenting with obesity, the aims are fourfold:

1. to exclude an underlying cause
2. to identify complications
3. to quantify the current and potential problems
4. to agree upon a management plan with the individual, based on evidence, proportionate to the problem and optimally supported.

Measuring waist circumference is useful with BMI under 35 kg/m^2: above this level, it is unnecessary and becomes unreliable as the waist descends under gravity. Risks of metabolic and cardiovascular complications are worse with a high waist circumference; lower cut-offs of BMI and waist circumference indicate higher risk in South Asians (Box 5.8).

A general history of dietary patterns and preferences may be helpful in guiding dietary advice but substantial under-reporting of food consumption is almost universal among overweight people. Pathological eating behaviour such as binge eating, nocturnal eating or bulimia demand specific management. Alcohol is rarely a major source of energy intake but should be considered as a possible obstacle to effective treatment. Many commonly prescribed drugs cause weight gain and impede weight loss (Box 5.9). If possible, these should be withdrawn or doses reduced.

In a small minority of patients presenting with a short history of marked change in adult weight gain trajectory, specific causal factors such as hypothyroidism or Cushing syndrome can be identified and treated (see Box 5.9). All obese patients should have thyroid function tests performed, and an overnight dexamethasone suppression test or 24-hour urine free cortisol if Cushing syndrome is suspected clinically. Monogenic causes of obesity are relevant only in children presenting with severe obesity, but obesity commonly accompanies conditions with learning and behavioural difficulties, such as Down syndrome, where the goodwill of carers may contribute.

5.8 Risk of type 2 diabetes and cardiovascular disease in relation to BMI and waist circumference in men and women

BMI	Classification	Waist circumference*		
		Men < 94 cm Women < 80 cm	Men 94–102 cm Women 80–88 cm	Men > 102 Women > 88
18.5–24.9	Normal	Low	Increased	Severe
25.0–29.0	Overweight	Low	Moderate	Very severe
30.0–34.9	Obese class I	Moderate	Severe	Very severe
35.0–39.9	Obese class II	N/A	Very severe	Very severe
≥ 40	Obese class III	N/A	Very severe	Very severe

The risks shown do not apply to people of South Asian ancestry. Among this ethnic group, the Western Pacific Region Office of WHO recommends that BMI > 23.0 is overweight and > 25.0 is obese. Lower cut-offs for waist circumference have been proposed for South Asians but have not been validated.

*When BMI is > 35 kg/m^2, waist circumference is difficult to measure because the waist descends under gravity, so does not add to the increased risk. N/A = not applicable as it is impossible to be in obese class II and III with a low waist circumference.

5.9 Medical and drug-induced causes of weight gain

Endocrine diseases

- Hypothyroidism
- Cushing syndrome
- Insulinoma
- Hypothalamic tumours or injury

Medications*

- Atypical antipsychotics (olanzapine)
- Antidepressants (amitriptyline, mirtazapine)
- Antineuropathic drugs (gabapentin, pregabalin)
- Antidiabetic drugs (sulphonylureas, thiazolidinediones, insulin)
- Pizotifen
- Glucocorticoids
- Sodium valproate
- Beta-adrenoceptor antagonists (β-blockers)

*Medications that promote weight gain are worse in combination.

Assessment of the multiple complications and impacts on life and work of obesity (see Fig. 5.6) requires a full history, and careful examination and screening investigations. Blood pressure should be measured with a large cuff, if required. Associated type 2 diabetes and dyslipidaemia are detected by measurement of HbA$_{1c}$ and a serum lipid profile, respectively, ideally in a fasting morning sample. Elevated serum transaminases occur in patients with non-alcoholic fatty liver disease.

Management

The health risks of obesity are often preventable or reversible if obesity is identified and treated early. Modest weight loss (5–10 kg) ameliorates all cardiometabolic risk factors and reduces the incidence of type 2 diabetes, but multiple risks remain. More substantial weight loss (10–15 kg or more) is needed to gain remission of established type diabetes, or of sleep apnoea. Sustaining substantial weight loss is notoriously hard, so strategies to prevent and reverse obesity should be high on public health priority agendas. However, no country has yet demonstrated an effective approach which checks the emergence of obesity. Many initiatives have evidence for limited success while the initiative is in place, including promoting ‘healthy eating’ in schools, enhancing walking and cycling options for commuters, and liaising with the food industry to reduce energy, sugar and fat content and to label foods appropriately. Unfortunately, these measures tend most to benefit those better educated who already suffer less from overweight and obesity. Taxes on high-sugar drinks have been introduced in some countries, with some evidence for short-term changes in consumption but not on average body weight, probably because artificially sweetened alternatives still stimulate an appetite for more energy-dense foods. Unfortunately, many heavily promoted low-fat foods are often still energy dense.

Most patients seeking assistance with obesity appear motivated to lose weight and have often done so previously, without long-term success. These patients may hold inaccurate perceptions of their energy intake and expenditure, and an unrealistic view of the target weight that they would regard as a success. An empathetic explanation of energy balance, which recognises that some individuals are more susceptible to obesity than others and find it more difficult to lose body weight and sustain this loss, is important. Reassurance that there is no underlying endocrine or metabolic problem can be helpful, especially for family members or carers. Appropriate goals for weight loss should be agreed, recognising that a given amount of weight loss achieves greater risk reduction at higher levels of BMI, but accommodating the perceptions of the patient. An initial reasonable goal for most patients with BMI up to 30 kg/m^2 is to lose 5%–10% of body weight using conventional diet and lifestyle modifications. With BMI above 30 kg/m^2, or if type 2 diabetes or other serious complications are present, greater weight loss of over 10–15 kg is recommended, and more intensive intervention is indicated, with separate strategies for inducing and for maintaining weight loss of this order (Fig. 5.8). Modern adjunctive drug treatments such as GLP-1 agonists can be very effective to initiate and sustain major weight losses for those who alter their diet substantially.

Lifestyle advice

Behavioural modification to avoid or mitigate some effects of the obesogenic environment (see Box 5.7) is the cornerstone of long-term control of weight. Adopting more disciplined eating patterns, and preplanned meals, is advised. Advising modest extra activity to increase physical activity level (PAL) ratios (see Fig. 5.2) may be successful for younger people, but this must be sustainable and regular as a daily routine such as walking rather than driving to work. Older patients, and those with arthritis or type 2 diabetes find increasing physical activity very hard. Regular support, and positive strategic encouragement when problems arise, from a dietitian or weight loss group, is very valuable.

Weight loss diets

The general lifestyle advice above, with medical encouragement, may gradually induce weight loss and a grateful patient. However, weight regain is a huge problem, as people tend to slip back to their normal diets and lifestyles, especially when life-events step in. Contrary to much previous teaching, the evidence is now consistent that more rapid and greater early weight loss tends to result in better quality of life, and in better long-term maintenance. More rapid weight loss may also be required to prepare for surgery.

Very-low-energy diets (VLEDs, under 800 kcal/day) or low-energy diets of 800–1000 kcal/day are similarly effective for rapid weight loss of 1.5–2.5 kg/week, compared to 0.5 kg/week on conventional regimens. Both are safe if provided as a nutritionally complete formula diet, and most successful with encouragement from an experienced and supportive physician or nutritionist. A minimum content of 40–50 g protein daily minimises muscle degradation, over 20 g of fat helps to avoid gallstone formation, with sufficient magnesium to avoid constipation, and fluid intake of at least 2.5 L/day to avoid dehydration, which can cause orthostatic hypotension, headache, constipation and nausea. Medical supervision is needed for patients whose glucose-lowering and antihypertensive medications need withdrawal or reduction with rapid weight loss.

Fig. 5.8 Therapeutic options for obesity. Relevant comorbidities include type 2 diabetes, hypertension, cardiovascular disease, sleep apnoea, and waist circumference of > 102 cm in men or 88 cm in women. This is an approximate consensus of the numerous national guidelines, which vary slightly in their recommendations and are revised every few years. (BMI = body mass index)

Medications

The obesity pandemic has stimulated huge investment by the pharmaceutical industry in finding drugs for obesity. The focus on these medicines has been to promote weight loss although the greater problem for patients is long-term maintenance of a lower weight. Drug therapy should only be used as an adjunct to lifestyle advice and support, which should be continued throughout and following treatment. The medicines currently licensed for the treatment of obesity are outlined in Box 5.10 and discussed in detail below.

Orlistat This medicine inhibits pancreatic and gastric lipases. The standard dose of 120 mg taken with each of the three main meals reduces dietary fat absorption by about 30%. It is not absorbed, and adverse effects relate to fat malabsorption if the diet still contains too much fat: loose oily stools, faecal urgency, flatus and malabsorption of fat-soluble vitamins. Its efficacy is partly explained because patients taking orlistat adhere better to low-fat diets to avoid unpleasant gastrointestinal side-effects, but it is favoured by few patients.

Centrally acting appetite suppressants The combination of phentermine 7.5 mg and topiramate 46 mg daily in a slow release formulation, marketed as Qsymia, reduces appetite and is more effective than placebo at inducing weight loss. It is approved in the United States but concerns over teratogenicity of topiramate and cardiovascular effects of both phentermine and topiramate (albeit at higher doses) have blocked its approval in Europe. The combination of the opioid antagonist naltrexone and the noradrenaline (norepinephrine) and dopamine re-uptake inhibitor bupropion, marketed as Mysimba, is approved in both the United States and Europe but has numerous adverse effects.

Glucagon-like peptide 1 agonists The glucagon-like peptide (GLP-1) agonists are one of the most effective medications for the treatment of obesity and are also used to treat type 2 diabetes (Ch. 21). These drugs are remarkably safe and quite well tolerated. The main side-effects are gastrointestinal upset. This can be minimised if the dose is kept very low to start, and then slowly increased. Liraglutide is approved for the

5.10 Medicines used as adjuncts to diet and lifestyle support for the treatment of obesity

Medicine	Maximum licenced dose	Mechanism of action	Weight loss versus placebo	Main adverse effects
Orlistat	120 mg three times daily by mouth	Inhibits lipases Reduces fat absorption	5%	GI upset Deficiency of fat-soluble vitamins
Phentermine/topiramate	25 mg/46 mg daily by mouth	Suppresses appetite by inhibiting noradrenaline (norepinephrine) in the hypothalamus	10%	Cardiovascular disease Depression
Naltrexone/bupropion	8 mg/90 mg orally up to four times daily	Suppresses appetite by mechanisms that are unclear	5%	GI upset, tremor, fatigue, vertigo, tinnitus
Liraglutide	3 mg daily SC	Suppresses appetite by activating GLP-1 receptor	5%	Nausea Diarrhoea
Semaglutide	2.4 mg weekly SC 14 mg daily orally	Suppresses appetite by activating GLP-1 receptor	12%	Nausea Diarrhoea
Tirzepatide	10–15 mg daily orally	Suppresses appetite by activating GLP-1 and GIP receptors	25%	Nausea, vomiting Diarrhoea

Note that these medicines are effective only when used in combination with lifestyle measures such as a calorie-controlled diet and increased physical activity.
(GIP = glucose-dependent insulinotropic polypeptide; GLP-1 = glucagon-like peptide; SC = subcutaneous)

Fig. 5.9 **Bariatric surgical procedures.** **A** Laparoscopic banding (due to increasing complications, such as band erosion, this is less used) with the option of a reservoir band and subcutaneous access to restrict the stomach further after compensatory expansion has occurred. **B** Sleeve gastrectomy. **C** Roux-en-Y gastric bypass (the most commonly used form of bariatric surgery in the UK).

treatment of obesity in Europe and the United States, at a daily subcutaneous dose of up to 3 mg. It is recommended to stop liraglutide if 3 mg/day for 3 months fails to generate >5% weight loss (usually indicating poor dietary compliance). Another GLP-1 agonist, semaglutide, is also licensed for obesity at a dose up to 2.4 mg/week subcutaneously. It generates even greater weight losses than liraglutide, with similar safety, and an oral form, in a dose up to 50 mg/day, is also available and has shown similar efficacy.

Dual receptor agonists Tirzepatide is an agonist at both the GLP-1 receptor and the glucose-dependent insulinotropic polypeptide (GIP) receptor. It is licensed for obesity treatment after demonstrating an almost 25% greater weight loss than placebo in randomised trials. This rivals the effects of bariatric surgery, with very substantial cardiometabolic benefits.

Drug therapy is usually reserved for patients with high risk of complications from obesity (see Fig. 5.6). All the clinical consequences of obesity are improved, some dramatically. For example, semaglutide provides the only effective treatment, extending survival, for the large numbers of people with obesity and heart failure with preserved ejection fraction. All licensed drugs reduce the cardiovascular and diabetes risks and weight loss of >10% is associated with reduced cardiac events. However, approvals are currently for weight loss, which often is not maintained after treatment is stopped and so the duration of drug treatment is controversial. Although life-long therapy has been advocated this is not yet widely accepted for the treatment of obesity. Weight gain despite continued drug treatment generally reflects reduction in professional support and relaxation of dietary control, for which reinforcement and new lifestyle measures are needed. Patients who demonstrate early weight loss (>5% after 12 weeks on the optimum dose) achieve greater and longer-term weight loss. Treatment can be stopped in non-responders at this point and alternative strategies considered.

Surgery

Bariatric surgery is the most effective treatment for obesity, in terms of amount and duration of weight loss (see Fig. 5.8 and Box 5.10 and is associated with improvements in all obesity-related risk factors and reduced mortality. Bariatric surgery should be contemplated in motivated patients who have very high risks of complications of obesity, when optimal dietary and drug therapy has been insufficiently effective. It is usually reserved for those with severe obesity (BMI >40 kg/m^2), or those with a BMI >35 kg/m^2 and significant complications, such as type 2 diabetes or obstructive sleep apnoea, although some evidence-based guidelines now suggest surgery can be considered at a lower weight with recent-onset diabetes and a BMI >30 kg/m^2. Only experienced specialist surgeons should undertake these procedures, in collaboration with a multidisciplinary team and plans for life-long follow-up. Several approaches are used, as illustrated in Figure 5.9, and all can be performed laparoscopically. The mechanism of weight loss, and its maintenance, after bariatric surgery is controversial. It may not simply relate to limiting the stomach size, or absorptive capacity, but also in disrupting release of ghrelin from the stomach or promoting release of other peptides from the small bowel, thereby enhancing satiety signalling in the hypothalamus. Diabetes usually improves rapidly after surgery, particularly after gastric bypass, but this is mainly attributable to severe energy restriction in the perioperative period. Increased release of incretin hormones such as GLP-1 may contribute to improved glucose control.

i **5.11 Effectiveness and adverse effects of bariatric surgery**

Procedure	Operative mortality*	Expected 2-year weight loss (kg)	Adverse effects
Gastric banding	<0.2%	19–25	Band slippage, erosion, stricture, port site infection
Sleeve gastrectomy	<0.2	20–30	Iron deficiency Vitamin B_{12} deficiency
Roux-en-Y gastric bypass	0.5	20–40	Internal hernia Stomal ulcer Early dumping syndrome (hypovolaemic) Late dumping syndrome (hypoglycaemic) Iron deficiency Vitamin B_{12} deficiency Vitamin D deficiency

Note that weight regain is a common problem within 5 years of all types of surgery, particularly with gastric banding and sleeve gastrectomy.

*Operative mortality refers to death related to surgery and includes death during the same hospital admission or within 30 days from surgery.

Bariatric surgery has taught us a lot about the pathogenesis of obesity and the health improvements possible with substantial weight loss, but it is not a one-stop solution. Complications of one kind or another, often multiple and some serious, affect almost all patients after bariatric surgery, depending on the approach (Box 5.11). Perioperative mortality is now under 1% in experienced centres, but post-operative respiratory problems, wound infection and dehiscence, staple leaks, stomal stenosis, marginal ulcers and venous thrombosis may occur. Additional problems may arise at a later stage, such as pouch and distal oesophageal dilatation with loss of effectiveness, persistent vomiting, hypoglycaemic or hypotensive 'dumping' syndromes, and micronutrient deficiencies, particularly of folate, vitamin B_{12} and iron. These nutrient deficiencies are of special concern to women contemplating pregnancy and this should be delayed for at least 2 years following surgery.

Cosmetic surgical procedures may be needed for a full physical and mental recovery after major weight loss. Apronectomy is a major operation to remove an overhang of unsightly, infected or ulcerated abdominal skin, a common problem in obese women after the menopause. This operation is not without risks and is of no value for long-term weight reduction if food intake remains unrestricted.

Treatment of additional risk factors

Obesity must not be treated in isolation. Other risk factors must be addressed, including smoking, excess alcohol consumption, diabetes, hyperlipidaemia, hypertension and obstructive sleep apnoea.

Under-nutrition

Severe malnutrition and famine

The BMI cut-offs for under-nutrition in adults are shown in Box 5.12. There remain regions of the world, particularly rural Africa and in war zones, where under-nutrition due to famine is endemic, such that up to 20% of adults have BMI $<18.5\,kg/m^2$ and stunting due to under-nutrition affects 50% of children. Famine is defined as a condition when, in a specific area, a large part of the population is unable to access an adequate amount of food leading to acute severe malnutrition and associated diseases. The World Health Organization (WHO) reports that chronic under-nutrition is responsible for more than half of all childhood deaths worldwide. Severe acute under-nutrition can manifest as marasmus (malnutrition of all macronutrients with marked muscle wasting and fat loss) or kwashiorkor (malnutrition primarily of protein with oedema). There is still much debate about why children with kwashiorkor develop oedema and those with marasmus do not. The likely explanation is the greater burden of infection in kwashiorkor, particularly intestinal infection, leading to protein-losing enteropathy, coupled with sodium retention and fluid overload.

Growth retardation is due to deficiencies of key nutrients (protein, zinc, potassium, phosphate and sulphur). Treatment of these childhood conditions is not discussed in this adult medical textbook. In adults, there are many causes of under-nutrition, as summarised in Box 5.13. These result in chronic sustained negative energy (calorie) balance and are commonly accompanied by micronutrient deficiencies.

Clinical features

In starvation, the severity of malnutrition can be assessed by anthropometric measurements, such as BMI. Measurements of mid-arm circumference are useful in monitoring progress during treatment. The clinical features of severe under-nutrition in adults are listed in Box 5.14.

Under-nutrition often includes vitamin deficiencies, especially of thiamin, folate and vitamin C (see below). Diarrhoea can lead to depletion of sodium, potassium and magnesium. The high mortality rate in famine situations is often due to outbreaks of infection, such as gastroenteritis, typhus or cholera (Box 5.15), but the usual signs of infection, such as fever and tachycardia, may not be apparent. In advanced starvation, patients shut down non-essential metabolism, with hypothermia and bradycardia, and become physically inactive in a flexed, fetal position, minimising heat loss. In the last stage of starvation, death comes quietly and often quite suddenly, commonly through asymptomatic pneumonia or primary arrhythmia. The very old are most vulnerable: younger people may be able to adapt to prolonged under-nutrition. At necropsy all organs are atrophied, except the brain, which tends to maintain its weight.

5.12 Classification of under-nutrition in adults by body mass index (BMI)

BMI (kg/m^2)	Classification
>20	Adequate nutrition
18.5–20	Marginal
<18.5	Under-nutrition
17–18.4	Mild
16–17	Moderate
<16	Severe

5.13 Causes of under-nutrition and weight loss in adults

Decreased energy intake

- Famine
- Persistent regurgitation or vomiting
- Anorexia related to mental health disorders (depression, dementia)
- Anorexia secondary to medication
- Anorexia nervosa
- Addison disease

Malabsorption

- Small intestinal disease
- Short gut syndrome
- Pancreatic exocrine insufficiency

Increased energy expenditure

- Increased basal metabolic rate (thyrotoxicosis, trauma, inflammation, fever, cancer cachexia, anxiety)
- High physical activity
- Parkinson disease
- COPD

Loss of nutrients

- Sustained glycosuria

(COPD = chronic obstructive pulmonary disease)

5.14 Clinical features of severe under-nutrition in adults

- Unintentional weight loss of > 10%
- Thirst, craving for food
- Weakness and feeling cold
- Nocturia, amenorrhoea or impotence
- Lax, pale, dry skin with loss of turgor and, occasionally, pigmented patches
- Cold and cyanosed extremities, pressure sores
- Hair thinning (lanugo) or loss (except in adolescents)
- Muscle-wasting, best demonstrated by the loss of the temporalis and periscapular muscles and reduced mid-arm circumference
- Loss of subcutaneous fat, reflected in reduced skin-fold thickness and mid-arm circumference
- Hypothermia, bradycardia, hypotension and small heart
- Oedema, usually but not always with hypoalbuminaemia ('famine oedema')*
- Distended abdomen with diarrhoea
- Diminished tendon jerks
- Apathy, loss of initiative, depression, introversion, aggression if food is nearby
- Susceptibility to infections (see Box 5.15)

5.15 Infections associated with severe under-nutrition

- Gastroenteritis and gram-negative sepsis
- Respiratory infections, especially bronchopneumonia
- Certain viral diseases, especially measles and herpes simplex
- Tuberculosis
- Human immunodeficiency virus (HIV)
- Streptococcal and staphylococcal skin infections
- Helminthic infestations – cestodes (tapeworms), trematodes (flukes), nematodes (roundworms) and acanthocephalans

Investigations

In severe malnutrition due to starvation, laboratory investigations may be impractical but, when they are available, show an increase in plasma free fatty acids, a ketosis and a mild metabolic acidosis. Plasma glucose is low, but albumin concentration is maintained because the liver still functions reasonably normally. Insulin secretion is diminished, glucagon and cortisol tend to increase, and reverse T_3 replaces normal triiodothyronine. The resting metabolic rate falls, partly because of falling lean body mass, and partly because of hypothalamic compensation. The urine has a fixed specific gravity and creatinine excretion is reduced. There may be mild pancytopenia or even hepatic steatosis (fatty liver of starvation) that can lead to liver impaired function. The erythrocyte sedimentation rate (ESR) is normal unless there is infection. Tests of delayed skin hypersensitivity, such as tuberculin testing, can become falsely negative. The electrocardiogram shows sinus bradycardia and low voltage.

Management

Under-nutrition in a famine, or in anorexia nervosa, tends to preserve muscle mass, while with prolonged infections and inflammation, muscle tends to be lost more rapidly, reflected in measurements of the mid upper arm circumference. Severe under-nutrition presents the only true emergency in clinical nutrition. Starvation kills, but usually slowly: an average man or woman has enough body fat to live on for about 40 days, provided fluids are still consumed. However, ill-guided attempts at treating severe under-nutrition can rapidly kill an otherwise healthy patient, as the result of the refeeding syndrome (see below).

People with mild under-nutrition are not in great danger; those with moderate under-nutrition need extra feeding; and those who are severely underweight need hospital care, particularly to avoid death from refeeding syndrome, which refers to the situation whereby hypokalaemia, hypophosphataemia and hypomagnesaemia occur as the result of reinstitution of nutrition in people who are severely malnourished. The principles of refeeding people with severe malnutrition are summarised in Box 5.16.

5.16 Refeeding in severe malnutrition

- Refeeding after under-nutrition is essential, but hazardous
- Refeeding without correcting K/Mg/PO_4 is a common cause of death
- Refeeding without correcting subclinical thiamin deficiency causes permanent brain injury (Korsakoff psychosis)

Patients at highest risk

- Kwashiorkor/marasmus, chronic malnutrition, alcoholism
- Low-carbohydrate diet with avoidance of cereal foods
- BMI < 16 kg/m^2; unintentional weight loss $> 15\%$ in 3–6 months; little/no oral intake for > 10 days; low K^+, Mg^{++}, PO_4 before feeding

General treatment measures

- Administer 200–300 mg thiamin IV for 3–5 days before commencing refeeding – do not wait for biochemical confirmation of deficiency. Follow with oral thiamin 100 mg daily for 7 days
- Start refeeding at 10–20 kcal/kg daily increasing to meet energy and micronutrient needs over 5–7 days
- Avoid high lactose milk products initially and reintroduce slowly
- Give repeated IV infusions of small doses of PO_4 phosphate (10–20 mmol)
- Infuse K^+ and Mg^{++} as necessary to correct hypokalaemia and hypomagnesaemia
- Consider adding zinc and multivitamin supplements

Monitoring

- Check electrolytes 2–4 hourly
- Record daily weight and the presence or absence of oedema
- Institute cardiac monitoring if a bradycardia, a prolonged QTc or other ECG abnormality is present before refeeding.

Refeeding syndrome can occur with lesser degrees of weight loss and higher BMI levels and in ‘sarcopenic obesity’.
(BMI = body mass index; ECG = electrocardiogram; IV = intravenous)

It is important to replace nutrients and fluids cautiously, avoiding a high burden of sodium and to correct electrolytes, with careful monitoring for at least 7 days of refeeding. There is often marked depletion of potassium, phosphate and magnesium after starvation. If insulin is stimulated by feeding without correcting these electrolyte deficiencies, sudden movement of ions from the extracellular fluid into cells can cause a sudden arrhythmic death. Specific attention should be placed on replacement and monitoring of phosphate, since severe hypophosphataemia can develop rapidly with catastrophic consequences with cardiac, skeletal and smooth muscle dysfunction, encephalopathy, platelet dysfunction and ultimately death.

It is also essential to give thiamin to all severely under-nourished patients (initially parenterally to be sure of absorption) to correct possible deficiency before food is administered, to avoid precipitating beriberi. Thiamin should be given 200–300 mg IV daily for 2–3 days, followed by 100 mg daily orally for 7 days without waiting for confirmatory blood tests. Any delay could be catastrophic, with permanent neurological sequelae.

When food becomes available, and can be taken, it should be given enterally in small, frequent amounts at first, using a suitable preparation (Box 5.17). Gastrointestinal involvement, and in some cases oedema, often causes a degree of malabsorption, and diarrhoea, initially. Secondary lactose intolerance is common so low lactose milk is preferred. Individual energy requirements can vary by 30%, but minor over-feeding is more hazardous, causing fatty liver, than modest under-feeding, so rapid refeeding should be avoided. During rehabilitation, more concentrated formula can be given with additional more palatable foods similar to the usual staple meal. Salt should be restricted. Micronutrient supplements (potassium, magnesium, zinc and multivitamins) are also required. Once the risk of refeeding syndrome has been mitigated, between 6.3 and 8.4 MJ/day (1500–2000 kcal/day) will arrest progressive under-nutrition but additional energy may be required for regain of weight. During refeeding, a weight gain of 5% body weight per month indicates satisfactory progress. Other care is supportive and includes attention to the skin, adequate hydration, treatment of infections and careful monitoring of body temperature, since thermoregulation may be impaired.

Circumstances and resources are different in every famine, but many problems are non-medical and concern organisation, infrastructure, liaison, politics, procurement, security and ensuring that food is distributed on the basis of need. Lastly, plans must be made for the future for prevention and/or earlier intervention if similar circumstances prevail.

5.17 World Health Organization recommended diets for refeeding

Nutrient (per 100 mL)	F-75 diet[1]	F-100 diet[2]
Energy	315 kJ (75 kcal)	420 kJ (100 kcal)
Protein (g)	0.9	2.9
Lactose (g)	1.3	4.2
Potassium (mmol)	3.6	5.9
Sodium (mmol)	0.9	1.9
Magnesium (mmol)	0.43	0.73
Zinc (mg)	2.0	2.3
Copper (mg)	0.25	0.25
Percentage of energy from:		
Protein	5	12
Fat	32	53
Osmolality (mOsmol/kg)	333	419
Dose	170 kJ/kg (40 kcal/kg)	630–920 kJ/kg (150–220 kcal/kg)
Rate of feeding by mouth	100–130 mL/kg/day	150–220 mL/kg/day

[1] The F-75 diet is prepared from milk powder (25 g), sugar (70 g), cereal flour (35 g), vegetable oil (27 g) and vitamin and mineral supplements, made up to 1 L with water.

[2] The F-100 diet contains milk powder (80 g), sugar (50 g), vegetable oil (60 g) and vitamin and mineral supplements made up to 1 L with water.

Under-nutrition in hospital

Under-nutrition remains a serious issue in high-income countries, particularly for older people and those who are less independent. In the UK, 30% of people requiring acute admission to hospital show evidence of under-nutrition and 65% of those admitted lose an average of 5% of their total body weight during that admission. In the older population, levels of under-nutrition and vitamin deficiencies parallel levels of independent living. In Scotland, about one-third of those aged over 65 who are living in their own home are deficient in folic acid and about 10% are deficient in vitamin C. The prevalence of vitamin deficiencies and under-nutrition rises further in less independent groups in residential homes.

Under-nutrition is poorly recognised and not well documented in hospital admissions and discharges, with potentially serious medical and medico-legal consequences. Physical effects include impaired immunity, and muscle weakness, which in turn affects cardiac and respiratory function, and causes delayed wound healing with an increased risk of secondary infection. The under-nourished patient is often withdrawn, and this may be mistaken for depressive illness. Engagement with treatment and rehabilitation can be adversely affected. Much of this can be avoided through better awareness of under-nutrition, prompt nutritional assessment and monitoring with appropriate intervention. Screening systems, such as the Malnutrition Universal Screening Tool (MUST) (Fig. 5.10) raise awareness across multidisciplinary teams and encourage staff to assess and monitor food intake and weigh patients regularly. Note that MUST may not be accurate in all circumstances, such as in the presence of ascites, and clinical judgement should be employed when interpreting the results.

It is recognised that malnutrition is associated with longer stay in hospital, increased morbidities and mortality. This is true for acute but also elective treatments.

Causes are often multifactorial and complex (Box 5.18). Social issues impact on food choices and may cause or exacerbate disease. Social isolation, low levels of disposable income and a lack of knowledge or interest in healthy eating may increase reliance on calorie-dense convenience foods of poor nutritional quality. The non-specific effects of chronic inflammation, infection or malignancy, as well as specific gastrointestinal disorders, may adversely affect appetite, reducing food intake.

Loss of appetite is common with gastrointestinal diseases but occurs as a non-specific response to myriad other conditions or their treatments. The most frequent side-effects of many prescription drugs are nausea and gastrointestinal disturbance. Surgical resection of the gastrointestinal tract can have major nutritional sequelae in the years following, ranging from intolerance of normal volumes of food, or specific nutrient malabsorption, to intestinal failure (where there is partial or complete failure of the intestine to perform its vital functions). This is especially so after partial or total gastrectomy, extensive small bowel surgery or pancreatic (Whipple) resection. It helps to consider systematically where the problem(s) might lie (see Box 5.18).

Malnutrition and weight loss in acute illness have different characteristics when compared to starvation as described above. In illness, increased energy expenditure driven by systemic inflammatory response syndrome (SIRS) accompanied by appetite depression leads to muscle breakdown to facilitate ketogenesis, thus aggravating a catabolic state.

An approach to assisted nutrition in hospital patients

All patients in hospital or a care home should be screened periodically for possible malnutrition using the MUST tool (see Fig. 5.10), and formally assessed if indicated. Poor appetite, immobility, poor dentition or even being kept 'nil by mouth' for hospital procedures all contribute to weight loss. A decision to intervene to tackle and reverse nutritional difficulties may involve simply ensuring that adequate supplies of suitable food are delivered accessibly (it is difficult to eat lying down) or that dentures fit

5.18 Factors affecting adequacy of nutritional intake in hospitalised patients

Factors affecting appetite

- Unfamiliar or ill-prepared food
- Altered taste or smell
- Anxiety (social, cultural, financial, general and mental health issues may all be relevant, individually or in combination)
- Nausea and/or vomiting
- Non-specific effects of illness and/or drugs

Issues of quantity

- Insufficient food on the plate
- Reliance on 3 meals a day without the normal 4th meal or snacks
- Missing meals because of procedures/investigations, being kept 'nil by mouth'

Getting the food from the plate to the mouth

- Generalised reduced mobility
- Reduced manual dexterity
- Horizontal posture, bedrest
- Loss of upper limb or hand function

Difficulties chewing food and initiating swallow

- Tooth loss
- Poorly fitting dentures
- Pain in the teeth, mouth, tongue or jaws
- Respiratory failure, chest-bellows disease
- Neurological conditions affecting swallowing

Problems with the oesophagus and gastrointestinal tract

- Obstruction (intrinsic or extrinsic)
- Ischaemia
- Inflammation
- Malabsorption
- Achalasia, pseudo-obstruction and other motility disorders

Cultural issues

- Is the food provided appropriate to the patient's ethnic background and beliefs?

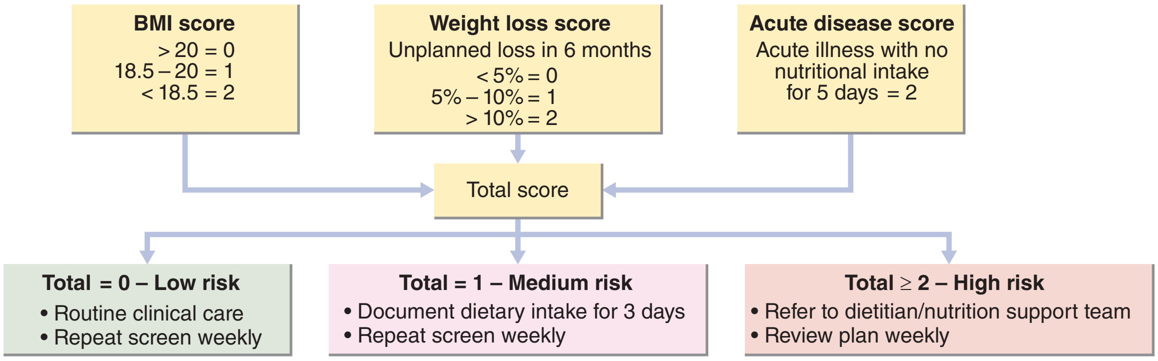

Fig. 5.10 Screening hospitalised patients for risk of malnutrition. Acute illnesses include decompensated liver disease, cancer cachexia or being kept 'nil by mouth'. *Adapted from the British Association for Parenteral and Enteral Nutrition Malnutrition Universal Screening Tool (www.bapen.org.uk).*

properly, or that food choices are palatable (taste and smell acuity diminish with age), but may require an assessment of a patient's swallow or of the intestine's ability to digest foods. Whenever possible, it is best to use the most physiological means of feeding, reserving more invasive interventions for when swallowing and digestion are impaired or absent. Enteral feeding is always preferred to parenteral, provided the intestine is accessible and functioning. Nutrition is a fundamental human right but artificial nutrition (through a feeding tube enterally or parenterally) is a medical treatment.

Oral nutritional supplements

Where swallow and intestinal function remain intact, the simplest form of assisted nutrition is the use of oral nutritional supplements, starting with attractive foods. Most branded supplement products are nutritionally complete (fortified with the daily requirements of vitamins, minerals and trace elements) and come in various formulations and textures, including 'shakes' and 'puddings' with a thicker consistency. They are expensive but can be cost-effective and useful for people who require just a small number of additional calories each day to maintain or gain weight in the short or longer term. However, they should not be used to replace normal meals or snacks. And their use and effect must be monitored. Despite their nutritional value, small volume and range of flavours, many people find them unpalatable or difficult to tolerate, in which case they will be ineffective, but patients may not volunteer this information.

Enteral feeding

Where swallowing or food ingestion is impaired but intestinal function remains intact, enteral tube feeding is the next choice (naso-enteral, gastrostomy or jejunostomy feeding). There are a number of theoretical advantages to enteral feeding, as opposed to parenteral, with uncertain evidence. These include:

- preservation of intestinal mucosal architecture and barrier function, gut-associated lymphoid tissue and hepatic and pulmonary immune function
- reduced levels of systemic inflammation and hyperglycaemia
- interference with pathogenicity of gut microorganisms.

However, the areas in which advantage has been consistently proven are:

- fewer episodes of infection
- lower cost
- earlier return to intestinal function
- shorter length of hospital stay.

The risks of enteral feeding are those related to tube insertion and diarrhoea.

Nasogastric tube feeding

This is simple, readily available, comparatively low-cost and most suitable for short-term feeding. Insertion of a nasogastric tube requires care and training (see Ch. 22, Box 22.41) and can be associated with adverse effects (Box 5.19) and diarrhoea (Box 5.20). Patients with reduced conscious level may pull at tubes and displace them: a nasal 'bridle' device can help by fixing the tube around the nasal septum, unless forcible tugging is likely.

Gastrostomy feeding

Gastrostomy is a more invasive technique, but easier to manage when longer-term feeding (> 4 weeks) is required. Gastrostomies are less liable to displacement than nasogastric tubes and allow for fewer feed interruptions, so more of the prescribed feeds can be administered. An endoscopic, minimally invasive, technique is usual. Both endoscopic and radiological gastrostomy insertion involve inflating the stomach, thus opposing it to the anterior abdominal wall. The stomach is then punctured percutaneously and a suitable tube placed (Fig. 5.11) with an internal retainer device (plastic 'bumper' or balloon) that sits snugly against the gastric mucosa, and an external retainer to limit movement. These retainers hold the gastric wall against the abdominal wall, effectively creating a controlled gastrocutaneous ('Eck') fistula that matures over 2–4 weeks. Patient assessment and selection prior to gastrostomy placement should be done by a multidisciplinary nutrition support team, taking ethical and legal considerations into account (Box 5.21) and to weigh potential benefits against adverse effects and complications (Box 5.22).

i 5.19 Complications of nasogastric tube feeding

- Tube misplacement
    - Tracheal placement
    - Bronchial placement
    - Intracranial placement (rare)
- Reflux of gastric contents and pulmonary aspiration
- Interrupted feeding or inadequate feed volumes

i 5.20 Diarrhoea related to enteral feeding

Factors contributing to diarrhoea

- Fibre-free feed may reduce short-chain fatty acid production in colon
- Fat malabsorption
- Inappropriate osmotic load
- Pre-existing primary gut problem (such as lactose intolerance)
- Infection

Management

- Often responds well to a fibre-containing feed or a switch to an alternative feed
- Simple antidiarrhoeal agents like loperamide can be very effective

Post-pyloric feeding

In patients with a high risk of pulmonary aspiration or gastroparesis, it may be preferable to feed into the jejunum through a nasojejunal tube, gastrostomy with jejunal extension or direct placement into jejunum by radiological, endoscopic or surgical means. Feeding direct into the jejunum can alter hormone release by the gut, leading to early satiety and increased nausea.

Parenteral nutrition

This is strictly reserved for clinical situations where the absorptive functioning or accessibility of the intestine is severely impaired, usually by resection. Nutrition is delivered directly into a large-diameter systemic vein, completely bypassing the intestine and portal venous system. As well as being more invasive, more expensive and less physiological than the enteral route, parenteral nutrition has many more complications (Box 5.23), mainly infective and metabolic (disturbances of electrolytes, hyperglycaemia). Strict adherence to aseptic practice in handling catheters and careful monitoring of clinical (pulse, blood pressure and temperature) and biochemical (urea, electrolytes, glucose and liver function tests) parameters are necessary to minimise risk (Box 5.24). Overfeeding is a particular hazard, causing fatty liver and potentially liver failure and death. Accurate estimation of energy requirements is needed, preferably measured using a metabolic cart. It is also to note that the majority of calories in parenteral nutrition are delivered in the form of sugars and fat, and the protein component is minimal.

The parenteral route is most often required in acutely ill patients with multi-organ failure, in severely under-nourished patients undergoing surgery which cannot be delayed, and with short bowel syndrome following resection. Gradually, previous indications for parenteral feeding, such as thoracic duct rupture, have been found to be responsive to enteral feeding.

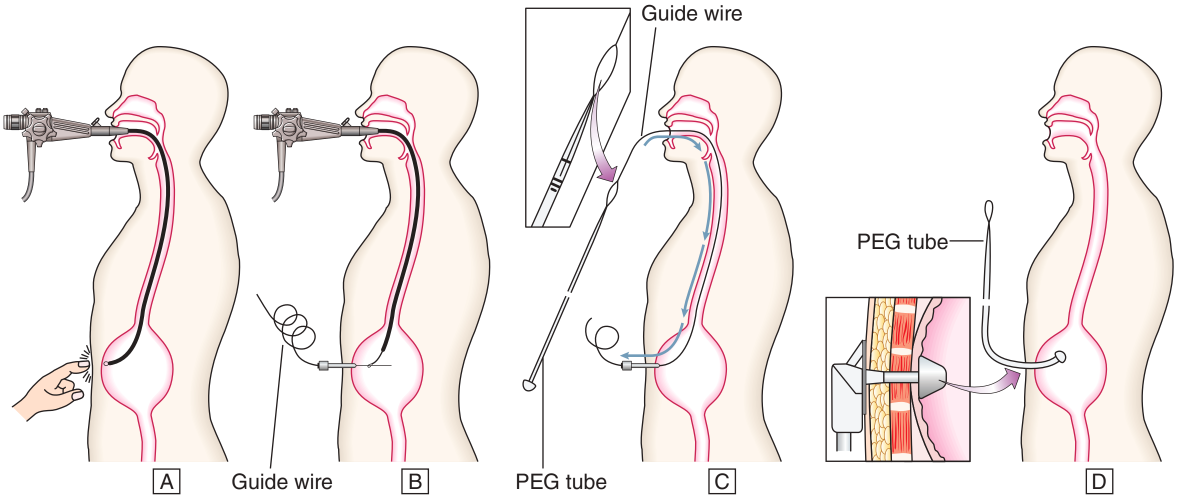

Fig. 5.11 Percutaneous endoscopic gastrostomy (PEG) placement. **A** Finger pressure on the anterior abdominal wall is noted by the endoscopist. **B** Following insertion of a cannula through the anterior abdominal wall into the stomach, a guidewire is threaded through the cannula and grasped by the endoscopic forceps or snare. **C** The endoscope is withdrawn with the guidewire. The gastrostomy tube is then attached to the guidewire. **D** The guidewire and tube are pulled back through the mouth, oesophagus and stomach to exit on the anterior abdominal wall, and the endoscope is repassed to confirm the site of placement of the retention device. The latter closely abuts the gastric mucosa; its position is maintained by an external fixation device (see inset). It is also possible to place PEG tubes using fluoroscopic guidance when endoscopy is difficult (radiologically inserted gastrostomy).

5.21 Ethical and legal considerations in the management of artificial nutritional support*

- Care of the sick involves the duty to provide adequate fluid and nutrients
- Food and fluid should not be withheld from a patient who expresses a desire to eat and drink, unless there is a medical contraindication. Where aspiration is a concern, trial of swallow should be readily available with trained staff, to allow feeding to resume as early as possible.
- A treatment plan should include consideration of nutritional issues and should be agreed by all members of the health-care team
- In the situation of palliative care, tube feeding should be instituted if it is needed to relieve symptoms or spend defined quality time with family
- Tube feeding is regarded in law as a medical treatment. Like other treatments, the need for such support should be reviewed on a regular basis and changes made in the light of clinical circumstances
- A competent adult patient must give consent for any invasive procedures, including passage of a nasogastric tube or insertion of a central venous cannula
- If a patient is unable to give consent, the health-care team should act in that person's best interests, taking into account any wishes previously expressed by the patient and the views of family
- Under certain specified circumstances such as anorexia nervosa, it is appropriate to provide artificial nutritional support to the unwilling patient applying appropriate legal framework

**Adapted from British Association for Parenteral and Enteral Nutrition guidelines, www.bapen.org.uk.*

5.22 Complications of gastrostomy tube feeding

- Reflux of gastric contents and pulmonary aspiration (same as nasogastric tube)
- Risks of insertion
  - Pain
  - Damage to intra-abdominal structures, including intestinal perforation
  - Pulmonary aspiration
  - Infection
  - Bleeding
  - Death
- Risk of tumour 'seeding' if an endoscopic 'pull-through' technique is used in head and neck or oesophageal cancer patients

5.23 Complications of parenteral nutrition

Intravenous catheter complications

- Pneumothorax, haemothorax, arterial puncture
- Infection
  - Catheter infection
  - Systemic sepsis
  - Discitis
  - Pulmonary or cerebral abscess
- Central venous thrombosis

Metabolic complications

- Refeeding syndrome
- Electrolyte imbalance
- Hyperglycaemia
- Hyperalimentation
- Fluid overload
- Hepatic steatosis/fibrosis/cirrhosis
- Metabolic bone disease

5.24 Monitoring of patients on parenteral nutrition

Parameter	Monitoring requirement
Electrolytes (sodium, potassium, magnesium) **Bone profile** (calcium, phosphate) **Liver function tests** (bilirubin, alanine aminotransferase, alkaline phosphatase, γ-glutamyl transferase) **Markers of inflammation** (C-reactive protein, leucocyte count)	Daily until stable and then 2–3 times per week
Blood glucose	At least twice daily until stable and then daily
Cholesterol and triglycerides	Weekly initially, reducing to every 3 months when stable

Intestinal failure and 'short bowel syndrome'

Intestinal failure (IF) is defined as a reduction in gut function to below the minimum necessary for both adequate absorption of macronutrients and/or water and electrolytes. Intravenous supplementation is then required to support health and/or growth.

IF can be classified according to its onset, metabolic consequences and expected outcome.

- *Type 1 IF*: a common acute-onset, usually self-limiting condition with few long-term sequelae. It is most often seen following abdominal surgery or in the context of critical illness. Intravenous fluid and electrolyte support may be required for a few days to weeks.
- *Type 2 IF*: far less common, following an acute intra-abdominal event (ischaemia, volvulus, trauma or perioperative complication) often with septic and metabolic problems, creating complex nutritional issues, requiring support for weeks to months with multidisciplinary input (nursing, dietetic, medical, biochemical, surgical, radiological and microbiological).
- *Type 3 IF*: a chronic condition in which patients are metabolically stable but require intravenous nutrition support over months to years. It may or may not be reversible.

Management

Intestinal failure is a complex clinical problem with profound and wide-ranging physiological and psychological effects, which is best cared for by a dedicated multidisciplinary team. Most IF results from short bowel syndrome (Box 5.25) with chronic intestinal dysmotility and chronic intestinal pseudo-obstruction accounting for most of the remainder. The severity of the physiological upset correlates well with how much functioning intestine remains (rather than how much has been removed). Measuring the remaining small bowel (from the duodeno-jejunal flexure) at the time of surgery is essential to plan future therapy (Box 5.26). The aims of treatment are to:

- provide nutrition, water and electrolytes to maintain health with normal body weight (and allow normal growth in affected children)
- utilise the enteral or oral routes as much as possible
- minimise the burden of complications of the underlying disease, as well as the IF and its treatment
- allow a good quality of life.

If the ileum and especially the ileum and colon remain intact (including the ileocaecal valve), long-term nutritional support can usually be avoided. Unlike the jejunum, the ileum can adapt to increase absorption of water and electrolytes over time. The presence of the colon (part or wholly intact) further improves fluid absorption and can contribute energy from absorption of bacterially produced short-chain fatty acids.

Jejunum–colon patients

Those with an anastomosis between jejunum and residual colon (jejunum–colon patients) may look well in the days or initial weeks following the acute insult but develop protein-energy malnutrition and significant weight loss, becoming seriously under-nourished over weeks to months.

Stool volume is determined by oral intake, with higher intakes causing more diarrhoea and the potential for dehydration, sodium and magnesium depletion and acute renal failure. The absence of the ileum leads to deficiencies of vitamin B_{12} and fat-soluble vitamins. The absorption of various drugs, including thyroxine, digoxin and warfarin, can be reduced. Approximately 45% of patients will develop gallstones due to disruption of the enterohepatic circulation of bile acids, and 25% develop calcium oxalate renal stones due to increased colonic absorption of oxalate (see Ch. 22, Fig. 22.42).

Jejunostomy patients

Patients left with a stoma (usually a jejunostomy) behave very differently, although stool volumes are again determined by oral intake. The jejunum is intrinsically highly permeable, and in the absence of the ileum and its net absorptive role, high losses of fluid, sodium and magnesium dominate the clinical picture from the outset. Ingested solutions with sodium concentration less than 90 mmol/L cause net secretion of sodium and water in the jejunal lumen, leading to further electrolyte and volume loss. Dehydration, hyponatraemia, hypomagnesaemia and acute renal failure are the most immediate problems, but protein-energy malnutrition will also develop. The jejunum has no real potential for adaptation in terms of absorption, so it is essential to recognise and address dehydration and electrolyte disturbance early as it is likely to be permanent (Box 5.27).

5.25 Causes of short bowel syndrome in adults

- Mesenteric ischaemia
- Post-operative complications
- Crohn disease
- Trauma
- Neoplasia

5.26 Likely requirements for support according to length of intact residual small bowel

Residual length of jejunum	Oral fluid restriction	Oral glucose/ electrolyte solution	Intravenous fluids	Parenteral nutrition
< 200 cm	Yes	Yes	May not be required	May not be required
< 100 cm	Yes	Yes	Yes	May not be required
< 75 cm	Yes	Yes	Yes	Yes

5.27 Management of patients with short bowel syndrome and a high stoma output

Accurately chart fluid intake and losses

- Monitor stoma output for 24 hrs on free oral intake and for 24 hrs while on nil by mouth (allow IV fluid)

Correct dehydration and hyponatraemia

- If necessary, give intravenous fluids to restore circulating volume and reduce thirst
- Give intravenous fluids if required to correct ongoing imbalance between oral intake and stool loss

Reduce stool volume

- Restrict oral fluid intake to < 1000 mL hypotonic fluid/24 hrs
- Give a further 1000 mL fluid as oral rehydration solution containing 90–120 mmol Na/L through the day (for example St Mark's solution*)
- Consider loperamide up to 16 mg 4 times daily or codeine phosphate 30–60 mg 4 times daily to slow intestinal transit and maximise opportunities for absorption
- Consider omeprazole 20 mg daily to reduce gastric acid secretion
- Consider octreotide 50–100 μg 3 times daily SC to reduce intestinal secretions

Increase absorption of nutrients

- Consider teduglutide 0.05 mg/kg SC once daily, to reduce requirement for intravenous fluids and nutritional support in a patient on HPN after achieving bowel adaptation

Adapted from Nightingale JMD. How to manage a high-output stoma. Frontline Gastroenterol 2021;13(2):140–151.

*St Mark's solution: 20 g glucose, 3.5 g sodium chloride, 2.5 g sodium bicarbonate, made up to 1 L with water.

(HPN = home parenteral nutrition; SC = subcutaneous)

Patients with IF can benefit from treatment with long-acting recombinant human GLP-2 analogues, such as teduglutide and apraglutide. These medicines enhance intestinal absorption by:

- increasing intestinal blood flow to the intestine
- stimulating intestinal mucosal proliferation, increasing absorptive surface area
- increasing portal blood flow away from the intestine
- slowing intestinal transit times
- reducing gastric acid secretion.

In such patients the increased intestinal absorptive function induced by teduglutide can significantly reduce the volumes of parenteral fluids and nutrition required and may allow some patients to regain independence from parenteral support. Side-effects include abdominal cramps and distension (seen in 50%), peristomal swelling, pain, nausea, vomiting and local injection site reactions. Since teduglutide stimulates proliferation of the intestinal epithelium, it should be avoided in those with history of gastrointestinal malignancy. In patients with a colon, a pre-treatment screening colonoscopy should be undertaken to detect and remove any polyps.

Small bowel and multivisceral transplantation

Long-term intravenous nutritional support is the mainstay of therapy for chronic IF but has its own morbidity and mortality. The 10-year survival for patients on long-term home parenteral nutrition is approximately 90%. Most deaths are due to the underlying disease process but 5%–11% die from direct complications of parenteral nutrition itself (especially catheter-related sepsis). A minority of patients with chronic IF, for whom the safe administration of parenteral nutrition has become difficult or impossible, may benefit from small bowel transplantation (Box 5.28). The first successful small bowel transplant was carried out in 1988. The introduction of tacrolimus allowed a satisfactory balance of immunosuppression, avoiding rejection while minimising sepsis. Since then, over 2000 transplants have been performed worldwide. Survival rates continue to improve, for both isolated small bowel and multivisceral transplantation (small bowel along with a combination of liver and/or kidney and/or pancreas), although major complications are still frequent (Box 5.29). Current 5-year survival rates are 50%–80%, with better outcomes for younger patients and those receiving isolated small bowel procedures. Isolated small bowel transplant has higher survival than liver-containing grafts. For these reasons, assessment of liver disease and referral to transplant centres should be timely.

5.28 Indications for small bowel and multivisceral transplantation

Complications of central venous catheters

- Central venous thrombosis leading to loss of two or more intravenous access points
- Severe or recurrent line sepsis
- Recurrent acute kidney injury related to dehydration

Metabolic complications of parenteral nutrition

- Liver fibrosis, cirrhosis and liver failure

5.29 Complications of small bowel and multivisceral transplantation

- Sepsis:
  - Severe or recurrent line sepsis
  - Enteric bacterial species
  - Staphylococci
  - Fungal species
- Cytomegalovirus infection
- Post-transplantation lymphoproliferative disease (PTLD)
- Graft-versus-host disease
- Acute and chronic rejection
- Chronic renal impairment

Artificial nutrition at the end of life

In some situations, assisted nutrition may not reverse weight loss or improve quality and duration of life. Such scenarios may present when approaching the end of life, or with weight loss due to progressive incurable disease, such as advanced respiratory or cardiac failure or dementia. A decision not to intervene may then be appropriate. An intervention that merely prolongs life without preserving or adding to its quality is seldom justified as in the patient's best interest, particularly if the intervention is not without risk itself. However, in certain cases artificial nutrition can be appropriate for a defined period at the end of life (both enteral and parenteral) and thoughtful and sensitive discussion explaining what artificial nutrition can and cannot achieve is vital, involving the multidisciplinary team looking after the patient, along with carers, next of kin and, in some cases, legal representatives (see Box 5.21).

Nutrition and dementia

Weight loss is seen commonly in older people (Box 5.30) or in those with dementia, and nutritional and eating problems are a significant source of concern for those caring for them. It is appropriate to:

- screen for malnutrition including micronutrients and vitamin deficiencies
- assess specific eating difficulties (for example the Edinburgh Feeding Evaluation in Dementia questionnaire)
- monitor and document body weight
- encourage adequate intake of food
- therapeutic trial of oral nutritional supplements.

Under-nutrition can be distressing and there may be specific circumstances where a trial of enteral feeding can be justified (see Box 5.21). However, in dementia, artificial nutrition does not improve quality of life or survival (Fig. 5.12).

5.30 Energy balance in old age

- **Body composition**: muscle mass falls with inactivity, and percentage of body fat increases.
- **Energy expenditure**: with lower lean body mass, basal metabolic rate is decreased, and energy requirements are reduced.
- **Weight loss**: after weight gain throughout adult life, weight often falls beyond the age of 75–80 years. This may reflect decreased appetite, loss of smell and taste, and decreased interest in and financial resources for food preparation, especially after loss of a partner.
- **BMI**: less reliable in old age as muscle is often replaced by fat, and height is lost and difficult to measure (due to kyphosis, osteoporotic crush fractures, loss of intervertebral disc spaces, and difficulty in standing). Alternative measurements include arm demispan and knee height, which can be extrapolated to estimate height.

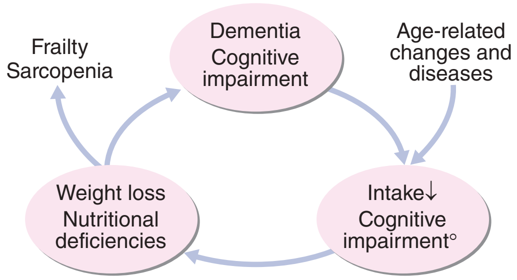

Fig. 5.12 Malnutrition in dementia – a vicious circle. *From Volkert D, Chourdakis M, Faxen-Irving G, et al. ESPEN guidelines on nutrition in dementia. Clin Nutr 2015;34:1052–1073.*

Anorexia nervosa

Anorexia nervosa (AN) can lead to extreme under-nutrition. Weight loss occurs is similar fashion to starvation with homogeneous loss of body composites (muscle and fat). Anorexia nervosa has the highest mortality both due to complications of malnutrition (including predisposition to life-threatening infections) and suicide. Treatment of anorexia nervosa is aimed at sustained normalised BMI, but micronutrient deficiencies must also be considered, as zinc or iron deficiency can suppress appetite. Nutrition intervention should be initiated promptly. Acute hospital management of patient with severe malnutrition due to AN should follow Medical Emergency in Eating Disorders (MEED) guidelines. Involvement of the psychiatry team during admission is fundamental to ensure good outcomes and navigate legal frameworks in event of refusal of treatment (Ch. 27).

Diseases associated with deficiency and excess of vitamins and minerals

Vitamins

Vitamins are organic compounds with vital roles as co-factors in certain metabolic pathways (Box 5.31). They are categorised into fat-soluble (vitamins A, D, E and K) and water-soluble (vitamins of the B complex group and vitamin C).

Recommended daily intakes vary between countries. In the UK, the reference nutrient intake (RNI) has been calculated as the mean plus two standard deviations (SD) of daily intake in the population, which describes intake that satisfies 97.5% of the population. The lower reference nutrient intake (LRNI) is the mean minus 2 SD, below which may be insufficient for 2.5% of the population. These dietary reference values have superseded the terms RDI (recommended daily intake) and RDA (recommended daily amount) still used in other countries. Increased amounts of some micronutrients may be required in pregnancy and lactation (Box 5.32).

Diseases caused by vitamin deficiency are most prevalent in lower-income countries, but still occur in high-income countries. Older people are at risk of deficiencies in B vitamins and in vitamins D and C (Box 5.33), as are alcohol misusers. Darker-skinned individuals living at higher latitude, and those who cover up or do not go outside are at increased risk of vitamin D deficiency due to inadequate sunlight exposure. Fat-soluble deficiencies, notably and catastrophically vitamin E, can result from abetalipoproteinaemia caused by homozygous loss-of-function mutations in *MTTP*, which encodes microsomal triglyceride transfer protein (see Ch. 19). Deficiencies of vitamins occur with intestinal malabsorption, both primary gastrointestinal problems and secondary to hepatic or pancreatic diseases or to autoimmune conditions like coeliac disease and pernicious anaemia (Box 5.34). Routine dietary supplements are recommended for these at-risk groups. Doctors must also be alert to micronutrient deficiencies induced by some drugs and from extreme diets. Severe carbohydrate restriction limits thiamin consumption and beri-beri can develop. Some extreme, non-evidence-based, diets can jeopardise vitamin A status.

There is a great deal of unscrupulous marketing and claims about vitamins. Some vitamins may have pharmacological actions when given at supraphysiological doses, such as vitamin A for acne. Taking vitamin supplements is promoted for commercial reasons, and fashionable in many population sectors, although there is no evidence of benefit unless someone is deficient in that vitamin. Serious toxic effects can occur with high dosages of vitamins A, B_6 and D. Cocktails of micronutrients referred to as antioxidant supplements (vitamin C, beta-carotene and selenium or zinc) are still marketed as remedies to prevent heart disease, although large clinical trials have shown more, not less, heart disease in supplemented groups.

Investigation of suspected vitamin deficiency or excess may involve biochemical assessment of body stores (Box 5.35). Measurements in blood should be interpreted carefully, however, in conjunction with the clinical presentation.

i 5.31 Summary of clinically important vitamins and WHO recommended daily intakes

	Rich sources	Important sources	Reference nutrient intake (RNI)*
Fat-soluble			
A (retinol)	Liver	Milk and milk products, eggs, fish oils	700 μg men 600 μg women
D (cholecalciferol)	Ultraviolet exposure to skin Fish oils	Egg yolks, margarine, fortified cereals	10 μg if > 65 years or no sunlight exposure
E (tocopherol)	Sunflower oil	Vegetables, nuts, seed oils	No RNI. Safe intake: 4 mg men 3 mg women
K (phylloquinone, menaquinone)	Soya oil, menaquinones produced by intestinal bacteria	Green vegetables	No RNI. Safe intake: 1 μg/kg
Water-soluble			
B_1 (thiamin)	Pork	Cereals, grains, beans	0.8 mg per 9.68 MJ (2000 kcal) energy intake
B_2 (riboflavin)	Milk	Milk and milk products, breakfast cereals, bread	1.3 mg men 1.1 mg women
B_3 (niacin, nicotinic acid, nicotinamide)	Meat, cereals		17 mg men 13 mg women
B_6 (pyridoxine)	Meat, fish, potatoes, bananas	Vegetables, intestinal microflora synthesis	1.4 mg men 1.2 mg women
Folate	Liver	Green leafy vegetables, fortified breakfast cereals	200 μg
B_{12} (cobalamin)	Animal products	Bacterial colonisation	1.5 μg
Biotin	Egg yolk	Intestinal flora	No RNI. Safe intake: 10–200 μg
C (ascorbic acid)	Citrus fruit	Fresh fruit, fresh and frozen vegetables	40 mg

Rich sources contain the nutrient in high concentration but are not generally eaten in large amounts; important sources contain less but contribute most because larger amounts are eaten.
*Requirements vary by age, and recommendations differ between countries. These figures are mostly generous: deficiency is unlikely unless intakes are well below them.
Adapted from WHO Vitamin and mineral requirements in human nutrition: https://iris.who.int/bitstream/handle/10665/42716/9241546123.pdf.

5.32 Nutrition in pregnancy and lactation

Weight gain. The desired weight gain depends on pre-pregnancy BMI:

Pre-pregnancy BMI	*Desired weight gain*
Underweight (< 18.5 kg/m^2):	12.5–18.0 kg
Normal weight: (18.6–24.9 kg/m^2)	11.5–16.0 kg
Overweight: (25–29.9 kg/m^2)	7–11.5 kg
Obese: (> 30 kg/m^2)	5–9.1 kg

Obesity: is associated with gestational diabetes and fetal abnormalities, but weight loss is undesirable during pregnancy. Overweight women should reach a healthier weight before pregnancy.

Energy requirements: increased in both mother and fetus. Pregnant women should be advised to exercise normally (or as able in the later stages of pregnancy).

Micronutrient requirements: adaptive mechanisms ensure increased uptake of minerals in foods in pregnancy, but extra increments of some vitamins and minerals are recommended during pregnancy and lactation:

- **Vitamin A**: supplements not usually required except in the presence of vitamin A deficiency since vitamin D can be teratogenic in excessive amounts
- **Vitamin D**: supplements advised in all pregnant and breastfeeding women, to ensure bone and dental development in the infant. Higher incidences of hypocalcaemia and defective dental enamel have been seen in infants of women not taking vitamin D supplements at > 50° latitude.
- **Folate**: Supplements given routinely before and during pregnancy to reduce the risk of neural tube defects
- **Vitamin B$_{12}$**: supplementation may be indicated in those with pre-existing or new deficiency
- **Thiamin**: requirements increase but supplements not given routinely except in those at risk of deficiency
- **Riboflavin**: requirements increase but supplements not given routinely except in those at risk of deficiency
- **Niacin**: requirements increase during lactation, but supplements not given routinely except in those at risk of deficiency
- **Vitamin C**: supplements or increased dietary intake are recommended throughout pregnancy to maintain maternal stores as fetal demands increase
- **Iron:** requirement increases, and iron deficiency is the leading cause of anaemia worldwide and is associated with low birth weight and poor pregnancy outcome. Supplementation should be given to women at risk but reserved for those with iron deficiency, as a mildly reduced haemoglobin may indicate normal haemodilution of pregnancy. Iron supplementation can interfere with zinc absorption
- **Calcium**: increased intake is recommended to meet the demands of fetal growth and lactation
- **Iodine**: in countries with high consumption of foods that contain goitrogens (thiocyanates or perchlorates) which interfere with iodine uptake, supplements should be given to prevent infants being born with neonatal hypothyroidism.

(BMI = body mass index)

5.33 Vitamin deficiency in old age

- **Requirements**: although requirements for energy fall with age, those for micronutrients do not. If dietary energy intake falls, a vitamin-rich diet is required to compensate.
- **Vitamin D**: levels are commonly low due to low total dietary intake, low sun exposure and less efficient skin conversion. This leads to bone loss and fractures. Supplements are not effective at preventing fractures, so should be given to those with proven vitamin D deficiency. Other measures to prevent falls are vital.
- **Vitamin B$_{12}$ deficiency**: a causal relationship with dementia has not been identified, but it does produce neuropsychiatric effects and should be checked in all those with declining cognitive function.

5.34 Gastrointestinal disorders associated with malabsorption of fat-soluble vitamins

- Biliary obstruction
- Pancreatic exocrine insufficiency
- Coeliac disease
- Ileal inflammation or resection

5.35 Biochemical assessment of vitamin status

Nutrient	Biochemical assessments of deficiency or excess
Vitamin A	Serum retinol may be low in deficiency Serum retinyl esters: when vitamin A toxicity is suspected
Vitamin D	Serum 25-hydroxyvitamin D (25(OH)D) reflects body stores (liver and adipose tissue) Influenced by levels of vitamin D binding protein
Vitamin E	Serum tocopherol/cholesterol ratio
Vitamin K	Plasma vitamin K Prothrombin time
Vitamin B$_1$ (thiamin)	Whole-blood vitamin B$_1$ or red blood cell transketolase activity
Vitamin B$_2$ (riboflavin)	Red blood cell glutathione reductase activity or whole-blood vitamin B$_2$
Vitamin B$_3$ (niacin)	Urinary metabolites: 1-methyl-2-pyridone-5-carboxamide, 1-methylnicotinamide
Vitamin B$_6$	Serum pyridoxal phosphate or erythrocyte transaminase activation coefficient
Vitamin B$_{12}$	Serum B$_{12}$: poor measure of overall vitamin B$_{12}$ status but will detect severe deficiency
Folate	Red blood cell folate Serum folate: reflects recent intake but also detects unmetabolised folic acid from foods and supplements
Vitamin C	Leucocyte ascorbic acid: assesses vitamin C tissue stores Serum ascorbic acid: reflects recent (daily) intake

Fat-soluble vitamins

Vitamin A (retinol)

Pre-formed retinol is found only in foods of animal origin. Vitamin A can also be derived from carotenes, which are present in green and coloured vegetables and some fruits. Carotenes provide most of the total vitamin A in the UK and constitute the only supply in vegans. Retinol is converted to several other important molecules:

- *11-cis-retinaldehyde* is part of the photoreceptor complex in rods of the retina.
- *Retinoic acid* induces differentiation of epithelial cells by binding to specific nuclear receptors, which induce responsive genes. In vitamin A deficiency, mucus-secreting cells are replaced by keratin-producing cells.
- *Retinoids* are necessary for normal growth, fetal development, fertility, haematopoiesis and immune function.

The most important consequence of vitamin A deficiency is irreversible blindness in young children, and it also contributes to worse outcomes from many infections, such as measles. Vitamin A deficiency is most common in Africa and South-east Asia. In some countries the problem is being addressed through widespread vitamin A supplementation programmes. Adults are not usually at risk because liver stores can supply vitamin A when foods containing vitamin A are unavailable.

Early deficiency causes impaired adaptation to the dark (night blindness), but this is rarely recognised. Keratinisation of the cornea (xerophthalmia) gives rise to characteristic Bitot spots and progresses to keratomalacia, with corneal ulceration, scarring and irreversible blindness (Fig. 5.13). In countries where vitamin A deficiency is endemic, pregnant women should be advised to eat dark green, leafy vegetables and yellow fruits (to build up stores of retinol in the fetal liver), and infants should be advised to do the same. The WHO is according high priority to prevention in communities where xerophthalmia occurs, giving single

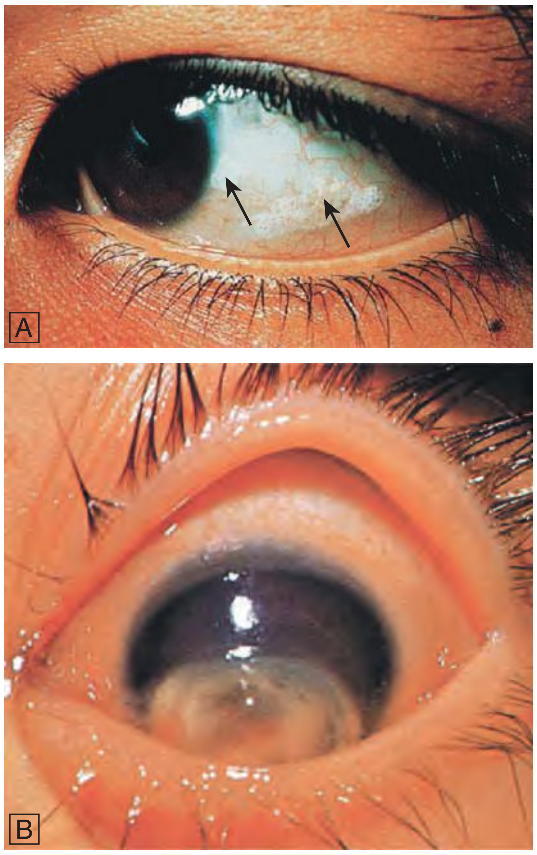

Fig. 5.13 **Eye signs of vitamin A deficiency.** **A** Bitot spots in xerophthalmia, showing the white triangular plaques (arrows). **B** Keratomalacia in a 14-month-old child. There is liquefactive necrosis affecting the greater part of the cornea, with typical sparing of the superior aspect. *(A) Courtesy of Institute of Ophthalmology, Moorfields Eye Hospital, London. (B) From WHO. Report of a joint WHO/USAID meeting, vitamin A deficiency and xerophthalmia (WHO technical report series no. 5W); 1976.*

prophylactic oral doses of 60 mg retinyl palmitate (providing 200 000 U retinol) to pre-school children. This also reduces mortality from gastroenteritis and respiratory infections.

Repeated moderate or high doses of retinol can cause liver damage, hyperostosis and teratogenicity. Women in countries where deficiency is not endemic are therefore advised not to take vitamin A supplements in pregnancy. Acute overdose leads to nausea and headache, increased intracranial pressure and skin desquamation. Excessive intake of carotene causes harmless orange pigmentation of the skin (hypercarotenosis).

Vitamin D

Vitamin D is required for optimal absorption of dietary calcium and to prevent rickets and osteomalacia. The natural form of vitamin D, cholecalciferol, is formed in the skin by the action of ultraviolet (UV) light on 7-dehydrocholesterol, a metabolite of cholesterol. Vitamin D is converted in the liver to 25-hydroxyvitamin D (25(OH)D), which is further hydroxylated in the kidneys to 1,25-dihydroxyvitamin D (1,25(OH)$_2$D), the active metabolite (see Ch. 25, Fig. 25.60). The 1,25(OH)$_2$D binds to the vitamin D receptor, which plays a role in regulating intestinal calcium absorption, mineralisation of bone and cell differentiation. The synthetic form, ergocalciferol or vitamin D$_2$, is considered to be less potent than vitamin D$_3$.

Skin exposure to sunlight is the main source of vitamin D in most countries. Moving away from the equator, the intensity of UV light decreases, so that at a latitude above 50° (including northern Europe), vitamin D is not synthesised in winter, and even above 30° there is seasonal variation. The large body store, in the liver, normally accumulated during the summer, is depleted during the winter. The limited sunlight exposure in the UK has led to recommendations that everyone over the age of 1 should be given 10 µg vitamin D supplement daily, with a lower dose of 8.5–10 µg in breastfed babies under 1 year of age. Formula milk is fortified with vitamin D so further supplements are only necessary when < 500 mL of formula milk is consumed daily. Supplementation at these doses is appropriate for babies and people in old age who are confined indoors, and those who habitually cover up their skin when outdoors. The richest food sources are oily fish such as salmon, sardines, herring and mackerel, red meat, liver and eggs. Breakfast cereals, margarines and milk products are widely fortified with vitamin D in some parts of Europe and in North America.

The effects of vitamin D deficiency are described in Chapter 25. Excessive doses of cholecalciferol, ergocalciferol or the hydroxylated metabolites can cause hypercalcaemia. As vitamin D receptors are present in most tissues, commercial companies have proposed a role for vitamin D in nearly every human disease, and market supplements to treat or prevent a variety of illnesses. However, large scale randomised trials of vitamin D supplements have found no evidence of benefit for major health outcomes such as cancer, cardiovascular events, falls, or progression to type 2 diabetes mellitus.

Vitamin E

There are eight related fat-soluble substances with vitamin E activity. The most important dietary form is α-tocopherol. Vitamin E has many direct metabolic actions:

- It prevents oxidation of polyunsaturated fatty acids in cell membranes by free radicals.
- It helps maintain cell membrane structure.
- It affects DNA synthesis and cell signalling.
- It is involved in the anti-inflammatory and immune systems.

Human deficiency is rare and has been described only in premature infants, in generalised malabsorption and in abetalipoproteinaemia. It can cause a mild haemolytic anaemia, ataxia and visual scotomas. Vitamin E intakes of up to 3200 mg/day (1000-fold greater than recommended intakes) are considered safe. Diets rich in vitamin E (such as vegetable oils, nuts and seeds) are consumed in countries with lower rates of coronary heart disease, but randomised controlled trials have not demonstrated cardioprotective effects of vitamin E or other antioxidants.

Vitamin K

Vitamin K is supplied in the diet mainly as vitamin K$_1$ (phylloquinone) in the UK, or as vitamin K$_2$ (menaquinone) from fermented products in parts of Asia. Vitamin K$_2$ is also synthesised by bacteria in the colon. Vitamin K is a co-factor for carboxylation reactions, in particular, the production of γ-carboxyglutamate (Gla). Gla residues are found in four of the coagulation factor proteins (II, VII, IX and X; see Ch. 24), allowing them to bind to phospholipids in the presence of calcium. Other important Gla proteins are osteocalcin and matrix Gla protein, which are important in bone health.

Vitamin K deficiency leads to delayed coagulation and bleeding. In obstructive jaundice, dietary vitamin K is not absorbed, and it is essential to administer the vitamin in parenteral form before surgery. Warfarin and related anticoagulants act by antagonising vitamin K. Vitamin K is given routinely to newborn babies to prevent haemorrhagic disease. Symptoms of excess have been reported only in infants, with synthetic preparations linked to haemolysis and liver damage.

Water-soluble vitamins

Thiamin (vitamin B$_1$)

Thiamin is mainly supplied by nuts and seeds, including legumes and whole-grain cereals. Thiamin pyrophosphate (TPP) is a co-factor for enzyme reactions involved in the metabolism of macronutrients (carbohydrate, fat and alcohol), including:

- decarboxylation of pyruvate to acetyl-co-enzyme A, which bridges between glycolysis and the tricarboxylic acid (Krebs) cycle
- transketolase activity in the hexose monophosphate shunt pathway
- decarboxylation of α-ketoglutarate to succinate in the Krebs cycle.

In thiamin deficiency, cells cannot metabolise glucose aerobically to generate energy as ATP. Neuronal cells are most vulnerable because they depend almost exclusively on glucose for energy requirements. Impaired glucose oxidation also causes an accumulation of pyruvic and lactic acids, which produce vasodilatation and increased cardiac output.

Beri-beri

Beri-beri caused by thiamin deficiency constitutes a clinical emergency, causing catastrophic and often permanent damage if treatment is delayed. It occurs when sufficient whole-grain cereals or other seeds and nuts are not consumed, classically in the developing world, from diets based on polished rice. It also occurs among people who follow extreme low-carbohydrate diets, for example for weight loss. It is especially encountered in chronic alcohol misusers, among whom poor diet, impaired absorption, storage and phosphorylation of thiamin in the liver, and the increased requirements for thiamin to metabolise ethanol, all contribute to deficiency.

The body has very limited stores of thiamin, so deficiency can develop after only 1 month on a thiamin-free diet. There are two forms of the disease in adults, which may coexist:

- *Dry (or neurological) beri-beri* may manifest with chronic peripheral neuropathy and with wrist and/or foot drop. However, its most dramatic presentation is with Wernicke encephalopathy, the triad of ophthalmoplegia, ataxia and confusion, which may progress to permanent Korsakoff psychosis.
- *Wet (or cardiac) beri-beri* causes generalised oedema due to biventricular heart failure with pulmonary congestion and ECG changes.

Wet beri-beri usually recovers fully and swiftly with thiamin replacement. However, with dry beri-beri, the response to thiamin administration is often incomplete. Multivitamin and mineral therapy seems to produce some improvement, however, suggesting that other dietary deficiencies may be involved, with zinc particularly incriminated.

Possible thiamin deficiency, and any clinical suggestions of Wernicke encephalopathy or wet beri-beri, should be treated on suspicion, immediately, without waiting for biochemical confirmation of the diagnosis, with intravenous thiamin. Korsakoff psychosis, brain damage with failure to create memory, can develop rapidly, and is irreversible and does not respond to thiamin treatment.

Riboflavin (vitamin B_2)

Riboflavin is required for the flavin co-factors involved in oxidation–reduction reactions. It is widely distributed in animal and vegetable foods. Levels are low in staple cereals but germination, such as occurs in bean sprouts, increases its content. It is destroyed under alkaline conditions by heat and by exposure to sunlight. Deficiency is rare in developed countries. It mainly affects the tongue and lips and manifests as glossitis, angular stomatitis and cheilosis. The genitals may be involved, as well as the skin areas around the nasolabial area, where numerous follicular papules, consisting of plugs of inspissated sebum, may be observed. Rapid recovery usually follows administration of riboflavin 10 mg daily by mouth.

Niacin (vitamin B_3)

Niacin encompasses nicotinic acid and nicotinamide. Nicotinamide is an essential part of the two pyridine nucleotides, nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP), which play a key role as hydrogen acceptors and donors for many enzymes. Niacin can be synthesised in the body in limited amounts from the amino acid tryptophan.

Pellagra

Pellagra is the syndrome caused by deficiency of niacin. It was formerly endemic among poor people who subsisted chiefly on maize, which contains niacytin, a form of niacin that the body is unable to utilise. Pellagra can develop in only 8 weeks in individuals eating diets that are very deficient in niacin and tryptophan. It remains a problem in parts of Africa and is occasionally seen in alcohol misusers and in patients with chronic small intestinal disease in developed countries. Pellagra can occur in Hartnup disease, a genetic disorder characterised by impaired absorption of several amino acids, including tryptophan. It is also seen occasionally in carcinoid syndrome, when tryptophan is consumed in the excessive production of 5-hydroxytryptamine (5-HT, serotonin). Pellagra is the 'disease of the three Ds':

- *Dermatitis*. Characteristic erythema resembling severe sunburn, appearing symmetrically over the parts of the body exposed to sunlight, particularly the limbs (Fig. 5.14) and especially on the neck but not the face (Casal necklace). The skin lesions may progress to vesiculation, cracking, exudation and secondary infection.
- *Diarrhoea*. Often associated with anorexia, nausea, glossitis and dysphagia, reflecting the presence of a non-infective inflammation that extends throughout the gastrointestinal tract.
- *Dementia*. In severe deficiency, delirium occurs acutely, and dementia develops if untreated.

Treatment is with nicotinamide, 100 mg 3 times daily orally or parenterally. The response is usually rapid. Within 24 hours the erythema diminishes, the diarrhoea ceases, and a striking improvement occurs in the patient's mental state.

Toxicity

Excessive intakes of niacin may lead to reversible hepatotoxicity. Nicotinic acid is a lipid-lowering agent but doses above 200 mg a day cause vasodilatory symptoms such as flushing and/or hypotension.

Pyridoxine (vitamin B_6)

Pyridoxine, pyridoxal and pyridoxamine are different forms of vitamin B_6 that undergo phosphorylation to produce pyridoxal 5-phosphate (PLP) which is the co-factor for a large number of enzymes involved in the metabolism of amino acids. Vitamin B_6 is available in most foods.

Deficiency is rare, although certain drugs, such as isoniazid and penicillamine, act as chemical antagonists to pyridoxine. Pyridoxine administration is effective in isoniazid-induced peripheral neuropathy and some cases of sideroblastic anaemia. Large doses of vitamin B_6 have an

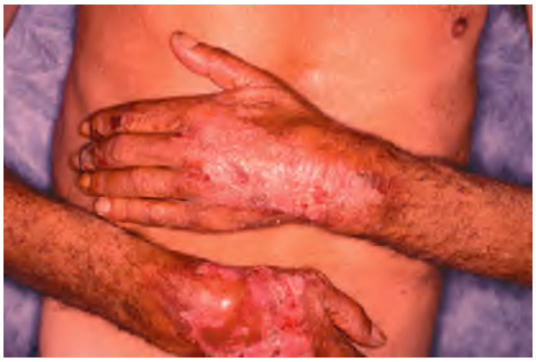

Fig. 5.14 Dermatitis in niacin deficiency (pellagra). There are red, scaly, cracked areas with sharply demarcated borders and surrounding pigmented skin. *From Piqué-Duran E, Pérez-Cejudo JA, Cameselle D, et al. Pellagra: A clinical, histopathological, and epidemiological study of 7 cases. Actas Dermosifiliogr 2012;103(1):51–58.*

antiemetic effect in radiotherapy-induced nausea. Although vitamin B_6 supplements have become popular in the treatment of nausea in pregnancy, carpal tunnel syndrome and pre-menstrual syndrome, there is no convincing evidence of benefit. Very high doses of vitamin B_6 taken for several months can cause unpleasant sensory polyneuropathy, which may become permanent.

Biotin

Biotin is a co-enzyme in the synthesis of fatty acids, isoleucine and valine, and is also involved in gluconeogenesis. Deficiency results from consuming very large quantities of raw egg whites (>30% energy intake) because the avidin they contain binds to and inactivates biotin in the intestine. It may also be seen after long periods of total parenteral nutrition. The clinical features of deficiency include scaly dermatitis, alopecia and paraesthesia.

Folate

Folate exists in many forms. The main circulating form is 5-methyltetrahydrofolate. The natural forms, in plant foods, are prone to oxidation. Folic acid is the stable synthetic form. Folate works as a methyl donor for cellular methylation and protein synthesis, particularly for haematopoiesis. It is also directly involved in DNA and RNA synthesis, and requirements increase during embryonic development. Deficiency is most often caused by dietary insufficiency but may rarely arise as the result of inherited abnormalities in the genes that regulate folate metabolism.

The commonest clinical presentation of folate deficiency is as macrocytic anaemia, which may extend to pancytopenia, in people with poor consumption of fruit and green vegetables. It is particularly frequent among alcohol misusers. Folate deficiency in early pregnancy may cause three major birth defects (spina bifida, anencephaly and encephalocele) resulting from imperfect closure of the neural tube, which takes place 3–4 weeks after conception. Women who have experienced a pregnancy affected by a neural tube defect should take 5 mg of folic acid daily from before conception and throughout the first trimester; this reduces the incidence of these defects by 70%. All women planning a pregnancy are advised to include good sources of folate in their diet, and to take folate supplements throughout the first trimester. Liver is the richest source of folate but an alternative source, such as leafy vegetables, is advised in early pregnancy because of the high vitamin A content of liver. Folate deficiency has also been associated with heart disease, dementia and cancer. There is mandatory fortification of flour with folic acid in the United States and voluntary fortification of many foods across Europe. Neural tube defects have declined dramatically, but there are some concerns about increased incidence of colon cancer, through accelerating the growth of polyps.

Hydroxycobalamin (vitamin B_{12})

Hydroxycobalamin is a co-factor in folate co-enzyme recycling and nerve myelination. Vitamin B_{12} and folate are particularly important in DNA synthesis in red blood cells. The haematological disorders (macrocytic or megaloblastic anaemias) caused by their deficiency are discussed in Chapter 24. Vitamin B_{12}, but not folate, is needed for the integrity of myelin, so that vitamin B_{12} deficiency is also associated with neurological disease.

In older people and chronic alcohol misusers, or after bowel surgery, vitamin B_{12} deficiency arises from insufficient intake and/or from malabsorption, but purely dietary deficiency is rare, as it is synthesised by colonic bacteria. The classic cause is malabsorption through pernicious anaemia. Several drugs, including neomycin, can render vitamin B_{12} inactive. Adequate intake of folate maintains erythropoiesis and there is a concern that fortification of foods with folate may delay recognition of underlying vitamin B_{12} deficiency.

In severe deficiency there is insidious, diffuse and uneven demyelination. It may be clinically manifest as peripheral neuropathy or spinal cord degeneration affecting both posterior and lateral columns (subacute combined degeneration of the spinal cord), or there may be cerebral manifestations (resembling dementia) or optic atrophy. Vitamin B_{12} therapy improves symptoms in most cases.

Vitamin C (ascorbic acid)

Ascorbic acid is a natural antioxidant in fruit and vegetables. It serves as an essential co-factor in the hydroxylation of proline and lysine in pro-collagen, to hydroxyproline and hydroxylysine in mature collagen. It is also an active reducing agent in the aqueous phase of living tissues and is involved in intracellular electron transfer. It is easily destroyed by heat, high pH and light, and is very soluble in water; hence many traditional cooking methods destroy the vitamin. Claims that high-dose vitamin C improves immune function (including resistance to the common cold), prevents cancers or heart disease and cholesterol turnover are unsubstantiated.

Scurvy

Scurvy is the disease caused by vitamin C deficiency. There is defective formation of collagen with impaired healing of wounds, capillary haemorrhage and reduced platelet adhesiveness (normal platelets are rich in ascorbate) (Fig. 5.15). Precipitants and clinical features of scurvy are shown in Box 5.36. A dose of 250 mg vitamin C daily for 3–5 days rapidly restores tissue concentrations. The deficiencies in the patient's food choices also need to be corrected, and other vitamin supplements given, if necessary. Daily intakes above 1 g/day can cause diarrhoea and the formation of renal oxalate stones.

Other bioactive dietary compounds

There are a number of non-essential organic compounds found in vegetable foods with purported health benefits, such as reducing risk of heart disease or cancers. Groups of compounds such as the flavonoids and phytoestrogens have bioactivity through their antioxidant and oestrogenic or anti-oestrogenic activities. Flavonoids (of which there are many different classes) are potent antioxidants found in fruit and vegetables, tea and wine; phytoestrogens are found in soy products (with higher intakes in parts of Asia compared to Europe and the United States) and other pulses. Caffeine and related compounds in tea and coffee can, with habituation, improve mental performance in

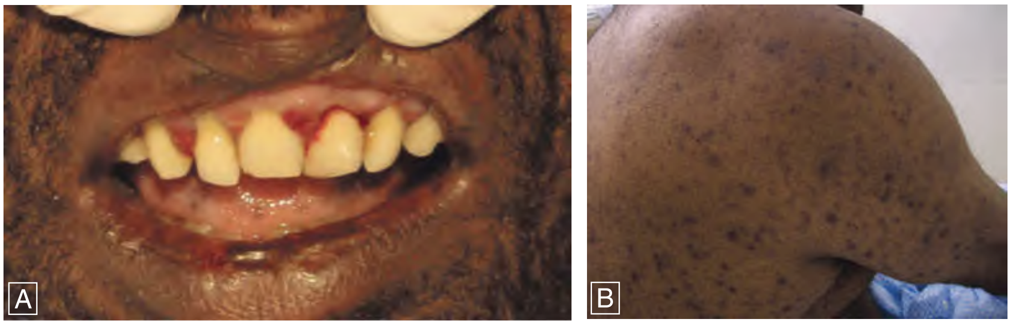

Fig. 5.15 **Scurvy.** **A** Gingival swelling and bleeding. **B** Perifollicular hyperkeratosis. *(A,B) From Ho V, Prinsloo P, Ombiga J. Persistent anaemia due to scurvy. J NZ Med Assoc 2007;120:62. Reproduced with permission.*

5.36 Cause and clinical features of scurvy

Precipitants

Increased requirement

- Trauma, surgery, burns, infections
- Smoking
- Drugs (glucocorticoids, aspirin, indomethacin, tetracycline)
- Infants fed exclusively on boiled milk

Dietary deficiency

- Lack of dietary fruit and vegetables for > 2 months

Clinical features

- Swollen gums that bleed easily
- Perifollicular and petechial haemorrhages
- Ecchymoses
- Haemarthrosis
- Gastrointestinal bleeding
- Anaemia

the short term, with adverse effects including agitation and tachycardia at higher intakes. Acute withdrawal of usual caffeine intake (such as during a hospital admission) can provoke headaches, indicating its addictive quality.

Inorganic micronutrients

A number of inorganic elements are necessary for structure and growth, as electrolytes, or as co-factors in enzymes and are essential dietary constituents for humans (Box 5.37). Deficiency is seen when there is inadequate dietary intake or excessive loss from the body. Toxic effects have also been observed from self-medication and disordered absorption or excretion. Examples of clinical toxicity include excess of iron (haemochromatosis or haemosiderosis), fluoride (fluorosis), copper (Wilson disease) and selenium (selenosis, seen in parts of China). For most minerals, the available biochemical plasma markers do not accurately reflect whole-body status or dietary intake, and dietary assessment is required.

Calcium

Calcium is the most abundant cation in the body and powerful homeostatic mechanisms control circulating ionised calcium levels. Dietary guidelines for calcium intake differ between countries, but in the UK a daily intake of 700 mg is recommended. Between 20% and 30% of calcium in the diet is absorbed, depending on vitamin D status and food source. Calcium requirements depend on phosphorus intakes, with an optimum molar ratio (Ca:P) of 1:1. Excessive phosphorus intake (1–1.5 g/day) with a Ca:P ratio of 1:3 have been shown to cause hypocalcaemia and secondary hyperparathyroidism. Calcium absorption may be impaired in vitamin D deficiency and in malabsorption secondary to small intestinal disease. Calcium deficiency causes secondary hyperparathyroidism, which if prolonged, can lead to osteomalacia in adults. Too much calcium can lead to constipation and increase the risk of renal stone disease. Historically, large amounts of calcium, when taken with sodium bicarbonate to treat dyspepsia, caused toxicity in the form of the milk-alkali syndrome. This has become very rare with the advent of proton pump inhibitors.

Phosphorus

Dietary insufficiency of phosphorus is rare as a cause of deficiency because it is present in nearly all foods and phosphates are added to a number of processed foods. Phosphate deficiency in adults may occur under the following circumstances:

- in patients with renal tubular phosphate loss
- in patients with diabetic ketoacidosis
- in patients receiving a prolonged high dosage of aluminium hydroxide
- in alcohol misusers, sometimes when they are fed with high-carbohydrate foods
- in patients receiving parenteral nutrition if inadequate phosphate is provided
- in elderly people with a poor diet
- in severe starvation.

5.37 Summary of clinically important inorganic nutrients

Mineral	Rich	Important	Reference nutrient intake
Calcium	Dairy products, tofu	Bony fish Green vegetables	700 mg
Phosphorus	Marmite and dry-roasted peanuts	Dairy products, cereals, bread and meat	550 mg
Magnesium	Whole grains, nuts	Unprocessed and whole grain foods	300 mg (male) 270 mg (female)*
Iron	Red meat Liver	Vegetables Wholemeal bread	8.7 mg (male) 14.8 mg (women menstruating)
Zinc	Red meat Seafood	Dairy products Wholemeal bread	9.5 mg (men) 7 mg (women)*
Iodine	Edible seaweeds Sea fish	Dairy products Seafood products	140 µg
Selenium	Fish Meat	Oatmeal, rice, beans Mushrooms	75 µg (men) 60 µg (women)
Copper	Shellfish Liver	Bread, cereal products, vegetables	1.2 mg
Fluoride	Tea	Drinking water	No RNI Safe intake: 0.5 mg/kg
Potassium	Dried fruit, potatoes, coffee	Fresh fruit and vegetables, meat and dairy foods	3500 mg
Sodium	Table salt, anchovies	Processed foods, bread, bacon	1600 mg

*Increased amounts are required in women during lactation.
Rich sources contain the nutrient in highest concentration but are not generally eaten in large amounts; important sources contain less but contribute most because larger amounts are generally eaten.
(RNI = reference nutrient intake)

People with phosphate deficiency may experience muscle pain and weakness, bone pain, neurological symptoms respiratory failure, heart failure and seizures. If severe it should be treated with intravenous phosphate. Oral phosphate supplements or dietary modifications are indicated for mild or moderate phosphate deficiency. The treatment of conditions associated with defects in renal tubular reabsorption of phosphate are discussed in Chapter 25.

Iron

Iron is involved in the synthesis of haemoglobin and is required for the transport of electrons within cells and for various enzyme reactions. Non-haem iron in cereals and vegetables is poorly absorbed but makes a greater contribution to overall intake, compared to the well-absorbed haem iron from animal products. Fruits and vegetables containing vitamin C enhance iron absorption, while the tannins in tea reduce it. Dietary calcium reduces iron uptake from the same meal, which may precipitate iron deficiency in those with borderline iron stores. There is no physiological mechanism for excretion of iron, so homeostasis depends on the regulation of iron absorption (see Ch. 24, Fig. 24.21). This is regulated at the level of duodenal enterocytes by hepcidin (a peptide secreted by hepatocytes in the duodenum). The normal daily loss of iron is 1 mg, arising from desquamated surface cells and intestinal losses. A regular loss of only 2 mL of blood per day doubles the iron requirement. On average, an additional 20 mg of iron is lost during menstruation, so pre-menopausal women require about twice as much iron as men (and more if menstrual losses are heavy).

The major consequence of iron deficiency is anaemia. This is one of the most important nutritional causes of ill health in all parts of the world. In the UK, it is estimated that 10% women are iron-deficient. Dietary iron overload is occasionally observed and results in iron accumulation in the liver and, rarely, cirrhosis. Haemochromatosis results from an inherited increase in iron absorption.

Normally, only a small proportion of dietary iron is absorbed. Iron absorption mechanisms are up-regulated, to absorb a greater proportion if dietary provision is low. Iron shares and competes for a pathway for absorption with zinc. Indiscriminate iron supplementation can therefore impair zinc status. In overdosage, iron supplements are highly toxic and can be fatal for children.

Iodine

Iodine is required, in very small amounts, for synthesis of thyroid hormones and thus for neurodevelopment. It is present in sea fish, seaweed and most plant foods grown near the sea. The amount of iodine in soil and water influences the iodine content of plant foods, and of animals grazing on them. Iodine is lacking, giving rise in older times to endemic goitre and neonatal hypothyroidism, in the highest mountainous areas of the world like the Alps and the Himalayas. In the UK, fish and dairy products are now the main sources, but many people have inadequate intakes.

About a billion people in the world are estimated to have an inadequate iodine intake and hence are at risk of iodine deficiency disorder. Goitre is the most common manifestation, affecting about 200 million people.

In areas where women have endemic goitre, 1% or more of babies are born with neonatal hypothyroidism which is characterised by impaired growth and neurological development and physical deformities. There is a higher than usual prevalence of deafness, slowed reflexes and poor learning in the remaining population. The best way of preventing this disorder is to ensure adequate levels of iodine during pregnancy. This can be achieved by intramuscular injections with 1–2 mL of iodised poppy seed oil (475–950 mg iodine) to women of child-bearing age every 3–5 years, by administration of iodised oil orally at 6-monthly or yearly intervals to adults and children.

In many countries, foods are fortified with iodine to avoid iodine deficiency, especially reported among young people who avoid fish and/or dairy products. Iodised salt is most common, but with health advice to minimise sodium consumption, other common foods such as milk and breads can be fortified, provided their cumulative consumption does not become excessive.

Zinc

Zinc is present in most foods of vegetable and animal origin and is stored in the liver. It is an essential component of many enzymes, including carbonic anhydrase, alcohol dehydrogenase and alkaline phosphatase.

Acute zinc deficiency has been reported in patients receiving prolonged zinc-free parenteral nutrition and causes diarrhoea, mental apathy, a moist, eczematoid dermatitis, especially around the mouth, and loss of hair. Chronic zinc deficiency occurs in dietary deficiency, malabsorption syndromes, alcoholism and cirrhosis. It causes the clinical features seen in the very rare congenital disorder known as acrodermatitis enteropathica (growth retardation, hair loss and chronic diarrhoea). Zinc deficiency is thought to be responsible for one-third of the world's population not reaching their optimal height. In the Middle East, chronic deficiency has been associated with dwarfism and hypogonadism. In starvation, zinc deficiency causes thymic atrophy; zinc supplements may accelerate the healing of skin lesions, promote general well-being, improve appetite and reduce the morbidity associated with the under-nourished state, and lower the mortality associated with diarrhoea and pneumonia in children. There is good evidence that adding zinc supplements to the oral re-hydration preparation reduced duration, severity, and recurrence of diarrhoeal diseases.

Selenium

The family of seleno-enzymes includes glutathione peroxidase, which helps prevent free radical damage to cells, and monodeiodinase, which converts thyroxine to triiodothyronine. North American soil has a higher selenium content than European and Asian soil, and the decreasing reliance of Europe on imported American food in recent decades has resulted in a decline in dietary selenium intake.

Selenium deficiency can cause hypothyroidism, cardiomyopathy in children (Keshan disease) and myopathy in adults. Excess selenium can cause heart disease and has been linked to industrial pollution.

Fluoride

Fluoride is an essential nutrient necessary for normal dental enamel, and also incorporated as a component of bone mineral. Fluoride is most important for young children, before the permanent teeth erupt, while their enamel is being laid down, but also for healthy enamel recycling and repair after damage. Fluoride deficiency results in weakened dental enamel, vulnerable to attack by acid produced from sugars by oral bacteria, and thus to dental caries and tooth loss. Excessive intakes of fluoride cause a brown mottling of dental enamel, and may cause skeletal fluorosis. This is characterised by increased bone density, an increased risk of fractures, musculoskeletal pain and calcification of tendons and ligaments.

Fluoride is an unusual micronutrient in being supplied almost entirely from drinking water, including local water and that consumed from other areas as bottled or canned drinks. If the water supply contains more than 1 part per million (ppm) of fluoride, the incidence of dental caries is low. Very hard waters may contain over 10 ppm, presenting no problem other than some discoloration of teeth. However, soft waters contain little or no fluoride, so dental caries and loss are very frequent without supplementation. Almost no foods provide significant amounts of fluoride, an exception being tea, permitting strong teeth in areas where both tea and sugar cane are grown and consumed by children.

Adding of traces of fluoride to public water supplies, to maintain a normal healthful concentration of 1 ppm, is now a widespread practice but, where this is not policy, dental health must depend on education, supplementation to children, and provision of fluoride-containing toothpaste.

Chronic fluoride poisoning is occasionally seen where the water supply contains > 10 ppm fluoride. It can also occur in workers handling cryolite (aluminium sodium fluoride), used in smelting aluminium. Pitting of teeth is a result of excess fluoride intake as a child.

Sodium, potassium and magnesium

Most animal and plant foods are low in natural sodium, and rich in potassium and magnesium. Western diets are high in sodium due to the sodium chloride (salt) that is added to processed food. In the UK, it is recommended that daily salt intakes are kept well below 6 g, and potassium and magnesium intakes maintained at levels a little greater than currently, principally to prevent the common gradual rise in blood pressure which occurs if children are weaned onto a life-long higher sodium diet. The pathophysiological roles of sodium, potassium and magnesium are discussed in Chapter 19.

Other essential inorganic nutrients

These include chloride (a counter-ion to sodium and potassium), cobalt (required for vitamin B_{12}), sulphur (a constituent of methionine and cysteine), manganese (needed for or activates many enzymes) and chromium (necessary for insulin action). Deficiency of chromium presents as hyperglycaemia and has been reported in adults as a rare complication of prolonged parenteral nutrition.

Copper metabolism is abnormal in Wilson disease. Deficiency occasionally occurs but only in young children, causing microcytic hypochromic anaemia, neutropenia, retarded growth, skeletal rarefaction and dermatosis.

Multiple Choice Questions

5.1. Which of the following is true? In a clinical setting, overweight/obesity should be assessed using:

A. BMI
B. Waist circumference
C. Observation and clinical judgement
D. Plasma leptin concentration
E. A composite of BMI and full clinical evaluation

Answer: E.

The recommended approach to assess an individual is to measure BMI (and waist if BMI is $<35\,kg/m^2$), and to monitor progress using body weight and clinical staging based on evaluation of clinical status using a scheme such as the Edmonton Obesity Staging System. BMI alone provides a useful benchmark, but BMI has relatively poor correlation with body fat content ($R2 = 0.6$) and it does not capture the variable link with symptoms or medical conditions mediated by the disease process of obesity. Waist provides slightly better correlation with body fat content, and of secondary disease risk than BMI, but cannot be used reliably when BMI is above 35. Observation and clinical judgement are valuable, but do not provide a baseline to assess progress. Plasma leptin can now be measured, but only as a research tool. It correlates reasonably strongly with BMI or body fat content but is not accurate for individual assessment. Another technique – bio-impedance measurement – is simple and cheap, widely used in gyms, but it is not more accurate than using scales or a waist tape measure to estimate body fat content.

5.2. Which of the following is true? Parenteral (intravenous) feeding (TPN):

A. Is the gold-standard safe clinical practice after any bowel surgery
B. Can be established routinely using standard feed bags
C. Requires a central IV access line, which is also useful for blood sampling
D. Should be set up at weekends to save staff time during weekdays
E. Requires management by a dedicated nutrition support team

Answer: E.

Evidence shows that case selection and outcomes (particularly line infection rates) are greatly improved when a multidisciplinary nutrition support team is in place. Parenteral feeding incurs many potentially serious complications and should not be used if there is likelihood of a functional gut within 3–5 days. TPN cannot be established routinely using standard feed bags as a full nutritional assessment is required in order to determine the requirements of each individual patient. TPN requires a central line, but this should never be used for other procedures, such as blood testing, because of high risks of introducing infection. Setting up parenteral feeding is time-consuming and requires planning and full multidisciplinary coordination, which is rarely possible outside normal work hours and starting at a weekend is not advisable.

5.3. Which of the following is true? Vitamin C (ascorbic acid):

A. In large doses is effective for preventing colds
B. Is destroyed by cooking
C. Allows improved absorption of iron from foods
D. Contributes to antioxidant vitamin (ACE) treatment for prevention of heart disease
E. Is stored in the liver, to provide a buffer against periods of low intake

Answer: C.

When the iron content of foods is low, or when greater iron absorption is needed to counteract deficiency, consuming foods that contain iron and vitamin C together improves iron availability. There is weak evidence that suggests mega-doses of vitamin C might reduce duration of minor cold symptoms to a very small degree. Vitamin C content of foods is reduced but not entirely destroyed by cooking. Boiled potatoes are a major food source for many people. There is consistent evidence that antioxidant treatments with vitamins A, C and E do not reduce heart disease. Indeed this treatment actually increases mortality in large randomised trials. Vitamin C is a water-soluble vitamin, and as such has little or no storage in the body. Daily consumption is needed from fruits and vegetables.

5.4. Which of the following is true regarding artificial nutrition?

A. It is the term used to describe a man-made, enriched, liquid form of nutrition
B. It is the term used to describe nutrition delivered to an individual using feeding tubes (nasogastric, PEG, central venous catheters)
C. It should never be considered if an individual is capable of eating and drinking
D. It is reserved for patients in hospital
E. Children cannot receive artificial nutrition as it compromises growth

Answer: B.

Artificial nutrition refers to feeding tube nutrition, both enteral and parenteral. This includes blended diet (regular food mixed and blended). Artificial nutrition is used when oral diet does not allow an individual to meet their nutritional requirements. This also includes patients who can physically eat and drink but not enough to sustain them. Often artificial nutrition is initiated in hospital, but it can continue safely in the community with appropriate support from community and hospital nutrition teams. This is true for both enteral and parenteral nutrition. Artificial nutrition is a mode of delivering nutrition, with composition tailored to the individual needs. Children can thrive on artificial nutrition, and it is a safe way to deliver a balanced diet. Artificial nutrition is never started as an emergency, and it does incur risks. Line infection is a particular hazard with parenteral nutrition. It should therefore only ever be started by trained specialists, during working hours.

5.5. Nutritional status underpins growth, health, healing and well-being. How should nutritional status be assessed in routine clinical settings?

A. Look at the patient, talk to relatives and decide on first instinct
B. Ask a dietitian or clinical nutrition team to assess if BMI is below $18.5\,kg/m^2$, or if there is difficulty swallowing
C. Full history and physical examination
D. Send blood samples for full nutritional biochemistry
E. All of the above

Answer: E.

But not all of the above in every case. Nutritional status includes three components: diet intake, body composition (including biochemistry) and function, both physical and metabolic. All should be considered. With the exception of thiamin deficiency, poor nutritional status is never an emergency requiring immediate action. However, poor nutritional status can affect every disease course. Assessment is needed when there is a possibility that additional dietary or artificial nutrition support could improve outcomes. If a patient is visibly undernourished, cannot swallow or the gut cannot be used for a period of a week or so, no further assessment is needed before referral for specialist support. Full history (including diet history), examination and biochemistry can be used to explore the possibility of specific nutrient insufficiencies and whether or not the patient is underweight. Recent major weight loss should trigger more detailed assessment.

Global burden of disease and underlying risk factors

The Global Burden of Disease (GBD) exercise was initiated by the World Bank in 1992, with first estimates appearing in the World Development Report in 1993. Regular updated estimates have been published since that time together with projections of future disease burden. The aim of the exercise was to produce reliable and internally consistent estimates of burden for all diseases and injuries and to assess their physiological, behavioural and social risk factors so that this information could be made available to health workers, researchers and policy-makers.

The GBD exercise adopted the metric 'disability-adjusted life year' or DALY to describe population health. This combines information about premature mortality in a population (measured as years of life lost from an 'expected' life expectancy) and years of life lived with disability (YLD), which is weighted by a severity factor. The International Classification of Diseases (ICD) rules, which assign one cause to each death, are followed. All estimates are presented by age and sex groups and by regions of the world. Many countries now also report their own national burden of disease data.

Global life expectancy at birth increased from 61.7 years in 1980 to 73.0 years in 2017, an increase of about 0.3 years per calendar year. This change is due to a substantial fall in child mortality (mainly due to common infections) partly offset by rises in mortality from adult conditions such as diabetes and chronic kidney disease. Some areas have not shown these increases in life expectancy in men, often due to war and interpersonal violence.

Global causes of death and disability

Figure 6.1 shows a ranked list of the major causes of global deaths in 2021. Ischaemic heart disease remains the leading cause of mortality in 2021, followed by COVID-19. Communicable, maternal, neonatal and nutritional causes accounted for about one-quarter of deaths worldwide – down from about one-third in 1990. In contrast, deaths from non-communicable diseases are increasing in importance and now account for about two-thirds of all deaths globally, including about 18.5 million from cardiovascular disease (ischaemic heart disease and stroke), 10 million from cancer and about 4 million from chronic respiratory diseases. The age-standardised death rates for most diseases globally are falling. However, despite this, the numbers of deaths from many diseases are rising due to global population growth and the change in age structure of the population to older ages and this is placing an increasing burden on health systems.

GBD also provides estimates of disability from disease (Box 6.1). This has raised awareness of the importance of conditions like depression

i 6.1 Global disability – top 10 ranked causes 2021

	Cause	Percentage of all-cause YLDs
1	Low back pain	7.7% (6.5 to 9.1)
2	Depressive disorders	6.2% (5.0 to 7.8)
3	Headache disorders	5.2% (1.2 to 10.4)
4	Age-related and other hearing loss	4.9% (3.9 to 5.9)
5	Other musculoskeletal disorders	4.8% (3.6 to 6.2)
6	Anxiety disorders	4.7% (3.6 to 6.0)
7	Diabetes mellitus	4.5% (3.9 to 5.2)
8	Dietary iron deficiency	3.6% (2.8 to 4.2)
9	Blindness and vision loss	3.2% (2.4 to 4.4)
10	Gynaecological diseases	3.0% (2.5 to 3.7)

(YLDs = years lived with disability)

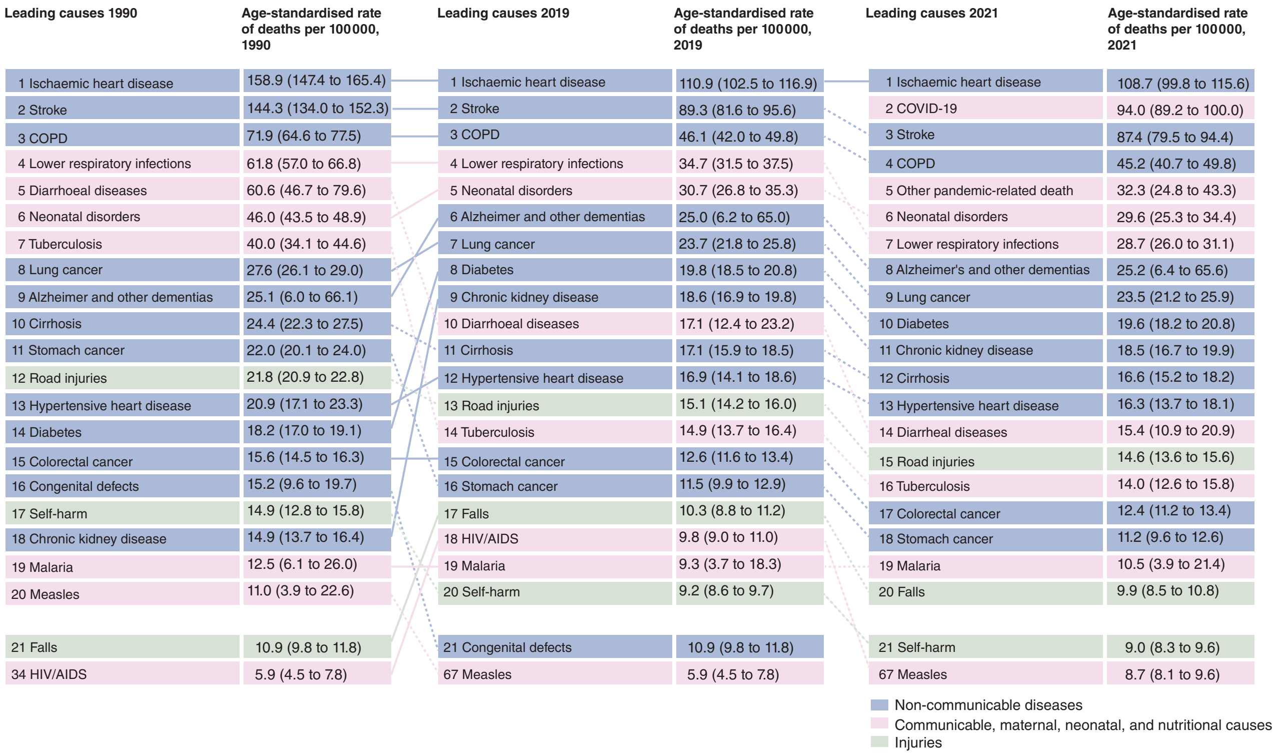

Fig. 6.1 **Global causes of death: top ranked causes from 1990 to 2021.** (COPD = chronic obstructive pulmonary disease)

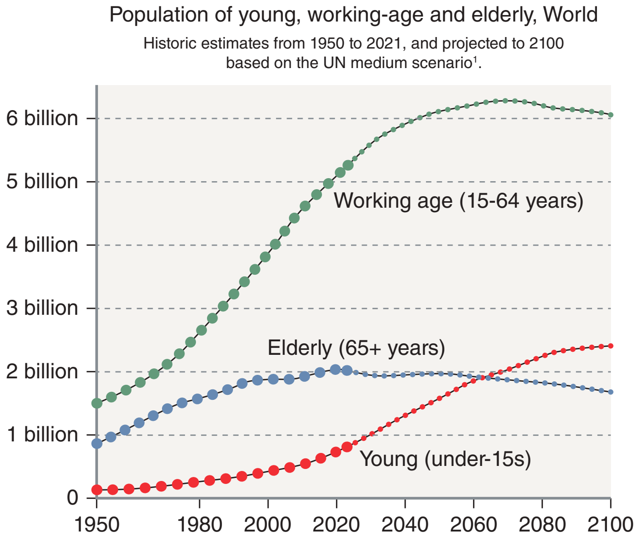
and other common mental health conditions, low back and neck pain and other musculoskeletal conditions, and asthma, which account for a relatively large disease burden but relatively few deaths. This in turn has resulted in greater health policy priority given to these conditions. Since the policy focus in national health systems is increasingly on keeping people healthy rather than only on reducing premature deaths, it is important to have measures of these health outcomes.

It is important to recognise that although these estimates represent the best overall picture of burden of disease globally, they are based on limited and imperfect data. Nevertheless, the quality of data underlying the estimates and the modelling processes are improving steadily over time and provide an increasingly robust basis for evidence-based health planning and priority setting.

Risk factors underlying disease

Figure 6.2 shows a ranked list of the main risk factors underlying GBD in 2021 and how this ranking has changed over the past 29 years. A number of key insights have been identified in this, the most recent, GBD exercise:

- Socio-demographic development has been progressing steadily since 1990 but it has increased faster in countries with the highest socio-demographic development index and thus gaps have been widening.
- Health systems need to transform to be better able to respond to the changing pattern of non-communicable diseases (NCDs) and disabilities.
- The Millennium Development Goal (MDG) programme from 2000 to 2015 has led to faster progress in reducing deaths from maternal, child and neonatal conditions/tuberculosis (TB)/HIV/malaria, but this level of attention now needs to be directed at NCDs.
- Public health is not giving sufficient priority to important global risk factors which are increasing over time, such as high blood pressure, high fasting glucose, high BMI, ambient particulate matter air pollution and drug and alcohol use.
- There are many challenges resulting from the change in global population pyramid structures, which have become inverted over recent decades and now pose many health, financial and political challenges (Fig. 6.3).



1. UN projection scenarios: The UN's World Population Prospects provides a range of projected scenarios of population change. These rely on different assumptions in fertility, mortality and/or migration patterns to explore different demographic futures.

Determinants of health

Health emerges from a highly complex interaction between a person's genetic background, environmental factors and the social and economic organisation of society (Fig. 6.4). Influences on health exist at many levels and extend beyond the individual to include the family, community, economy and both built and natural environments. Box 6.2 shows an example of this for determinants of coronary heart disease and demonstrates the importance of considering not only the disease process in a patient but also its context. Health-care provision is not the only determinant – and is not the major determinant – of health status in the population. The concept of 'global health' recognises the global dimension of health problems, whether these be, for example, emerging or pandemic infections or global economic influences on health internationally.

Health inequalities

The adverse health and social consequences of poverty are well documented. Typically, with industrialisation, disease patterns change: instead of infections, long-term conditions such as heart disease dominate in an older population. Many countries are now experiencing a 'double burden'. They have large populations still living in poverty that are suffering from problems such as diarrhoea and malnutrition, alongside affluent populations (often in cities) that suffer from chronic illness such as diabetes and heart disease.

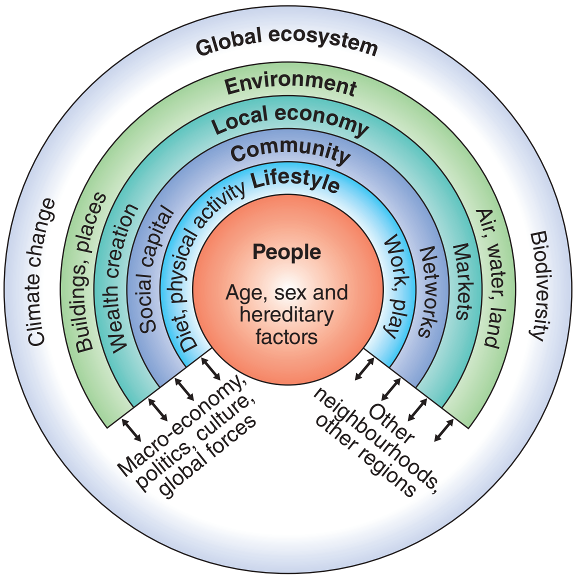

Fig. 6.4 Hierarchy of systems that influence population health. *Adapted from an original model by Whitehead M, Dahlgren G. What can be done about inequalities in health? Lancet 1991;338:1059–1063.*

i 6.2 'Hierarchy of systems' applied to ischaemic heart disease

Level in the hierarchy	Example of effect
Molecular	ApoB mutation causing hypercholesterolaemia
Cellular	Foam cells accumulate in vessel wall
Tissue	Atheroma and thrombosis of coronary artery
Organ	Ischaemia and infarction of myocardium
System	Cardiac failure
Person	Limited exercise capacity, impact on employment
Family	Passive smoking, diet
Community	Shops and leisure opportunities
Population	Prevalence of obesity
Society	Policies on smoking, screening for risk factors
Ecology	Agriculture influencing fat content in diet

Despite experiencing sustained economic growth for much of the last 50 years, health inequalities persist even within the populations of high-income countries. This is reflected in both life expectancy and the proportion of life spent in ill health varying across the socioeconomic gradient and by ethnicity, sex, disability and other characteristics. Whilst global events, such as the global financial crisis of 2007–2008 or the COVID-19 pandemic, have an impact on the health and well-being of populations, government policies have an important role in determining the relative impact across the socioeconomic gradient and within specific groups in society. For example, improvements in life expectancy stalled in the UK during the period 2011–2018 for the first time in over a century, with the slowdown more marked in the UK than other European countries.

Climate change

Climate change is the world's most important environmental health issue. A combination of increased production of carbon dioxide and habitat destruction, both caused primarily by human activity, is the main cause. The temperature of the globe is rising, the climate is being affected, and if the trend is not reversed, sea levels will rise and rainfall patterns will be altered so that severe weather events, droughts and floods will become more common. These have already claimed millions of lives during the past 20 years and have adversely affected the lives of many more. The economic costs of property damage and the impact on agriculture, food supplies and prosperity have also been substantial. The health impacts of global warming will also include changes in the geographical range of some vector-borne infectious diseases. Currently, politicians cannot agree on or implement an effective framework of actions to tackle the problem. Meanwhile, countries with the least resilient health systems are likely to be most severely affected by climate change.

The life course

The determinants of health operate over the whole lifespan. Exposure to adverse socioeconomic and built environments, along with values and behaviours acquired during childhood and adolescence, can have a profound influence on educational outcomes, job prospects and risk of disease. These can have a strong influence, for example, on whether a young person takes up a damaging behaviour like smoking, develops severe mental health problems or is the victim of violence or trauma. Influences on health can even operate before birth. Low birth weight can lead to higher risk of hypertension and type 2 diabetes in young adults and of cardiovascular disease in middle age. It has been suggested that under-nutrition during middle to late gestation permanently 'programmes' cardiovascular and metabolic responses.

This 'life course' perspective highlights the cumulative effect (through each stage of life) of exposures to illness, adverse environmental conditions and behaviours that damage health.

Health improvement

The complexity of the interactions between physical, social and economic determinants of health means that preventing ill health and promoting wellbeing is often difficult. Moreover, the life course perspective illustrates that it may be necessary to intervene early in life or even before birth, to prevent important disease in later life. Successful prevention is likely to require many interventions across the life course and at several levels in the hierarchy of systems. The examples below illustrate this principle.

Alcohol

Alcohol use is an increasingly important risk factor underlying global burden of disease (see Fig. 6.2). Reasons for increasing rates of alcohol-related harm vary by place and time but include the falling price of alcohol (in real terms), increased availability and cultural change fostering higher levels of consumption. Public, professional and governmental concern has now led to a range of policy interventions, including a minimum price being charged for a unit of alcohol, tightening of licensing regulations and curtailment of promotional activity in some countries. However, even more aggressive public health and policy measures will be needed to reverse the levels of harm in the population. The approach for individual patients suffering adverse effects of alcohol is described on pages 912 and 1273.

Smoking

Smoking is one of the top three risk factors underlying global burden of disease (see Fig. 6.2). It is responsible for the substantial majority of cases of lung cancer and chronic obstructive pulmonary disease (COPD), and most smokers die either from these respiratory diseases or from cardiovascular disease. Smoking also causes cancers of other organs, and increases the risk of peripheral vascular disease, stroke and peptic ulceration. Maternal smoking is an important cause of fetal growth restriction. Moreover, passive ('second hand') smoking also has adverse effects on cardiovascular and respiratory health.

The role of the tobacco industry in influencing uptake of cigarette smoking is well established, with the advertising budget of the tobacco industry being much greater than that of health services.

The decline in smoking rates in many high-income countries has been achieved by strategies to help individuals quit smoking (such as nicotine replacement therapy, anti-smoking advice and behavioural support), which are cost-effective and form an important part of the overall anti-tobacco strategy. In addition, interventions at a population level have been instrumental in reducing the prevalence of smoking, through policies aimed at increasing taxation of tobacco, banning of advertising, banning of smoking in public places and increasing support for smoking cessation. The widespread availability and rapid growth of e-cigarettes ('vaping') has also impacted on tobacco smoking rates, with the greatest reduction seen in age groups with the highest uptake of e-cigarettes. However, whilst e-cigarettes are considered to be less harmful than tobacco smoking, the longer-term effects of exposure to e-cigarettes are unclear.

Obesity

Obesity is an increasingly important risk factor underlying global burden of disease (see Fig. 6.2). The weight distribution of almost the whole population is shifting upwards – the slim are becoming less slim while the overweight and obese are becoming more so. In the UK, this translates into a 1-kilogram increase in weight per adult per year (on average over the adult population). The current obesity epidemic cannot be explained simply by individual behaviour and poor choice but also requires an understanding of the obesogenic environment that encourages people to eat more and exercise less. This includes the availability of cheap and heavily marketed energy-rich foods, the increase in labour-saving devices (e.g. elevators and remote controls) and the increase in passive transport (cars as opposed to walking, cycling, or walking to public transport hubs). Whilst drugs and surgical interventions have been developed to aid weight loss for individuals, the primary focus of interventions to combat the health impact of obesity must be at a societal level. Therefore, policies that impact on the whole population and reverse the obesogenic environment are urgently required, including tackling the barriers to healthy eating, promoting a healthier food environment, restricting advertising which targets children and redesigning the physical environment to promote physical activity and active travel choices.

Principles of screening and immunisation

Screening

Screening is the application of a screening test to a large number of asymptomatic people with the aim of reducing morbidity or mortality from a disease. WHO have identified a set of (Wilson and Jungner) criteria to guide health systems in deciding when it is appropriate to implement screening programmes. The essential criteria are:

- Is the disease an important public health problem?
- Is there a suitable screening test available?
- Is there a recognisable latent or early stage?
- Is there effective treatment for the disease at this stage which improves prognosis?

A suitable screening test is one that is cheap, acceptable, easy to perform, safe and gives a valid result in terms of sensitivity and specificity. Screening programmes should always be evaluated in trials so that robust evidence is provided in favour of their adoption. These evaluations are prone to several biases – self-selection bias, lead-time bias and length bias – and these need to be accounted for in the analysis. Examples of large-scale screening programmes in the UK include breast, colorectal and cervical cancer national screening programmes (https://www.gov.uk/topic/population-screening-programmes) and a number of screening tests carried out in pregnancy and in the newborn, such as the:

- diabetic eye screening programme
- fetal anomaly screening programme
- infectious diseases in pregnancy screening programme
- newborn and infant physical examination screening programme
- newborn blood spot screening programme
- newborn hearing screening programme
- sickle-cell disorder and thalassaemia screening programme.

These are illustrated in Figure 6.5.

Problems with screening include:

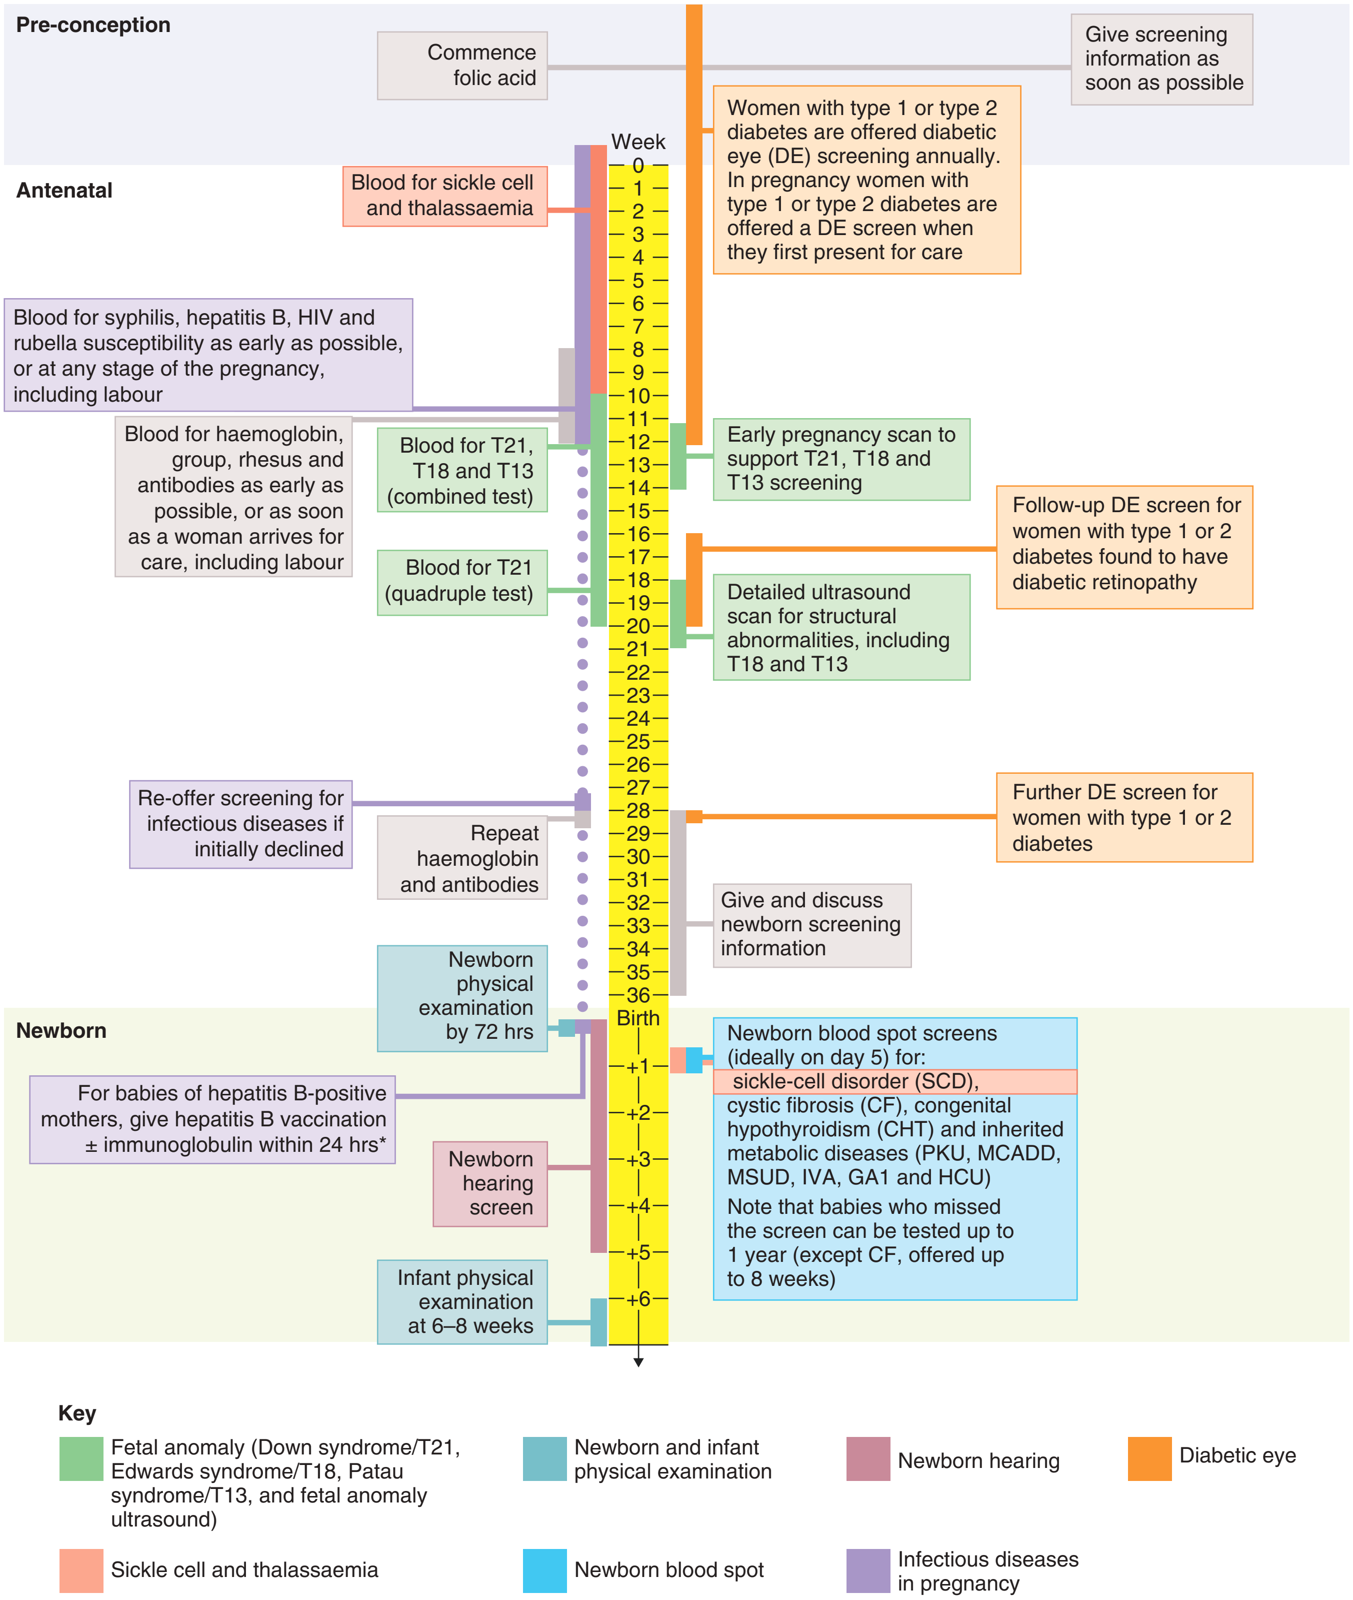
- over-diagnosis (of a disease that would not have come to clinical attention on its own or would not have led to death)
- false reassurance
- diversion of resources from investments that could control the disease more cost-effectively.

Immunisation

Immunisation can confer immunity to specific infectious diseases and be either passive (through injected antibodies, such as the monoclonal palivizumab against respiratory syncytial virus (RSV) infection given to premature infants) or active (through administration of a vaccine). Immunisation invokes antibody and/or cell-mediated immunity and can lead to both short- and longer-term protection in the person who is vaccinated. Immunisation has also been used to eradicate a disease, such as occurred in the smallpox eradication programme and is currently being targeted in the polio eradication programme. As well as direct effects of vaccination, a number of indirect effects can occur, such as protection of individuals who are vaccinated through altering disease transmission leading to 'herd immunity'; or reduction of antibiotic resistance through selective reduction of pneumococcal serogroups that are associated with antibiotic resistance. The UK immunisation schedule is described in detail and regularly updated in the UK government publication 'Immunisation against infectious disease' (Green Book).

Epidemiology

Epidemiologists study disease in free-living humans, seeking to describe patterns of health and disease and to understand how different exposures cause or prevent disease (Box 6.3). Measuring the frequency of diseases or events is an important principle in epidemiology. Long-term conditions and risk factors (e.g. smoking, obesity) are often described in terms of their prevalence. A prevalence is simply a proportion, for example the prevalence of diabetes among people aged 80 and older in high-income countries is around 10%.



Pre-conception
Commence folic acid
Give screening information as soon as possible
Women with type 1 or type 2 diabetes are offered diabetic eye (DE) screening annually. In pregnancy women with type 1 or type 2 diabetes are offered a DE screen when they first present for care

Antenatal
Blood for sickle cell and thalassaemia
Blood for syphilis, hepatitis B, HIV and rubella susceptibility as early as possible, or at any stage of the pregnancy, including labour
Blood for haemoglobin, group, rhesus and antibodies as early as possible, or as soon as a woman arrives for care, including labour
Blood for T21, T18 and T13 (combined test)
Early pregnancy scan to support T21, T18 and T13 screening
Follow-up DE screen for women with type 1 or 2 diabetes found to have diabetic retinopathy
Blood for T21 (quadruple test)
Detailed ultrasound scan for structural abnormalities, including T18 and T13
Re-offer screening for infectious diseases if initially declined
Further DE screen for women with type 1 or 2 diabetes
Repeat haemoglobin and antibodies
Give and discuss newborn screening information
Newborn
Newborn physical examination by 72 hrs
Newborn blood spot screens (ideally on day 5) for:
sickle-cell disorder (SCD),
cystic fibrosis (CF), congenital hypothyroidism (CHT) and inherited metabolic diseases (PKU, MCADD, MSUD, IVA, GA1 and HCU)
Note that babies who missed the screen can be tested up to 1 year (except CF, offered up to 8 weeks)
For babies of hepatitis B-positive mothers, give hepatitis B vaccination ± immunoglobulin within 24 hrs*
Newborn hearing screen
Infant physical examination at 6–8 weeks
Key
Fetal anomaly (Down syndrome/T21, Edwards syndrome/T18, Patau syndrome/T13, and fetal anomaly ultrasound)
Newborn and infant physical examination
Newborn hearing
Diabetic eye
Sickle cell and thalassaemia
Newborn blood spot
Infectious diseases in pregnancy

Fig. 6.5 UK NHS pregnancy and newborn screening programmes. Antenatal and newborn screening timeline. *To stop mother-to-baby transmission of infection follow up all infection screens in pregnancy that are positive: carry out paediatric assessment and follow-up of mothers who are found to be HIV-positive or had syphilis treatment in pregnancy; and if mothers are found to be susceptible to rubella then offer the mother MMR vaccination postnatally and refer to GP for second dose. (GA1 = glutaric aciduria type 1; HCU = homocystinuria; IVA = isovaleric acidaemia; MCADD = medium-chain acyl-CoA dehydrogenase deficiency; MSUD = maple syrup urine deficiency; PKU = phenylketonuria). *Based on Version 8.4, January 2019. Gateway Ref: 20144696. www.gov.uk/phe/screening.*

Events such as deaths, hospitalisations and first occurrences of a disease are described using incidence measures, which differ from prevalence measures by counting only new cases of a disease/event. The cumulative incidence or risk is the number of new cases as a proportion of the total people at risk at the beginning of the exposure time. For example, if there are 100 new cases of a disease in a population of 1000 people during a one-year period (i.e. with no one joining or leaving the group) then the one-year risk is 10% (100/1000). The time period should always be specified for measures of incidence.

6.3 Measures of frequency and risk used in epidemiology

Prevalence

- The number of people with a longer-term disease or condition at a specified time divided by the number of people in the population who are at risk

Incidence

- The number of events (new cases or episodes) occurring in the population at risk during a defined period of time

Attributable risk

- Also known as the absolute risk difference. The difference between the risk (or incidence) of disease in exposed and non-exposed populations

Population attributable fraction

- The proportion by which the incidence rate in the population would be reduced if the exposure was removed. It can be used to assess the impact of an exposure in the population

Relative risk or risk ratio

- The ratio of the risk (or incidence) in the exposed population to the risk (or incidence) in the non-exposed population

Odds ratio

- The ratio of the odds of the outcome in the exposed population to the odds of the outcome in the non-exposed population

These measures of frequency are used to describe how diseases (and risk factors) vary according to time, person and place. Temporal variation may occur seasonally, (e.g., malaria occurs in the wet season but not the dry) or as longer-term 'secular' trends (e.g. malaria may re-emerge due to drug resistance). 'Person' comparisons include age, sex, socioeconomic status, employment, and lifestyle characteristics. 'Place' comparisons include the local environment (e.g. urban versus rural) and international comparisons.

Effect measures are used to quantify the magnitude of the effect that an intervention or risk factor (exposure) has on the frequency of the outcome. Effect measures can be reported on an absolute scale (by subtraction) or on a relative scale (by division). For example, the ratio in the risk/rate of the outcome between groups is calculated by dividing the outcome frequency in exposed by non-exposed groups. This generates the relative risk/risk ratio (or rate ratio, if the outcome is an incidence rate). The odds ratio is frequently reported in studies rather than the risk ratio, despite it being a less intuitive measure to interpret. The odds ratio is calculated by dividing the odds of the outcome in exposed by odds of the outcome in non-exposed groups. Odds are not the same as measures of prevalence or incidence; the odds in the exposed group are calculated by dividing the number with the outcome by the number without the outcome. The number needed to treat (or numbers needed to harm) is an effect measure which can be more easily understood by the public when communicating risk. It is calculated by taking the reciprocal of the absolute risk difference. It is interpreted as number of people that would need to be treated (or exposed) to prevent one outcome event occurring when absolute risk difference demonstrates a reduction in the outcome in the exposed group. If the absolute risk difference demonstrates an increase in the outcome in the exposed group, the same measure is reported as the number needed to harm.

Understanding causes and effect

Epidemiological research complements that based on animal, cell and tissue models, the findings of which do not always translate to humans. For example, only a minority of drug discoveries from laboratory research are found to be effective when tested in people.

However, differentiating causes from mere non-causal associations is a considerable challenge for epidemiology. This is because while laboratory researchers can directly manipulate conditions to isolate and understand causes, such approaches are impossible in free-living populations.

6.4 Epidemiological study designs

Design	Description	Example
Clinical trial	Enrols a sample from a population and compares outcomes after randomly allocating patients to an intervention	The Medical Research Council (MRC) streptomycin trial – demonstrated effectiveness of streptomycin in tuberculosis
Cohort	Enrols a sample from a population and compares outcomes according to exposures	The Framingham Study – identified risk factors for cardiovascular disease
Case–control	Enrols cases with an outcome of interest and controls without that outcome, and compares exposures between the groups	Doll and Hill's study on smoking and carcinoma of the lung (BMJ 1950;2:739–748) demonstrated that smoking caused lung cancer
Cross-sectional	Enrols a cross-section (sample) of people from the population of interest. Obtains data on exposures and outcomes	World Health Organization Demographic and Health Survey – captures risk factor data in a uniform way across many countries

Epidemiologists have developed a different approach, based around a number of study designs (Box 6.4). Of these, the clinical trial is closest to the laboratory experiment. An early example of a clinical trial is shown in Figure 6.6, along with effect measures which can be calculated from the study.

In clinical trials, patients are usually randomly allocated to treatments so that, on average, groups are similar apart from the intervention of interest. Nevertheless, for any particular trial, especially a small trial, the laws of probability mean that differences may occur by chance. Poorly designed or executed trials can also limit comparability between groups. Allocation may not truly be random (e.g. because of inadequate concealment of the randomisation sequence), and there may be systematic differences (biases) in the way people allocated to different groups are treated or studied.

Such biases also occur in observational epidemiological study designs, such as cohort, case–control and cross-sectional studies (see Box 6.4). These designs are also much more subject to the problem of confounding and bias than are well-conducted randomised trials.

Confounding is where the relationship between an exposure and outcome of interest is confused by the presence of some other causal factor. For example, coffee consumption may be associated with lung cancer because smoking is commoner among coffee-drinkers. Here, smoking is said to confound the association between coffee and lung cancer. For these reasons, well-conducted randomised controlled trials are considered to provide higher quality evidence to understand causal relationships.

Most causes of diseases cannot be investigated using randomised controlled trials because of ethical, or more often practical, considerations. Epidemiologists therefore seek to minimise bias and confounding by careful study design and analysis. Once an association is observed in a study, epidemiologists subsequently evaluate whether the association could be affected by chance, error, bias and/or confounding, and weigh this up against the alternative probability that the relationship is causal. This weighing-up requires an understanding of the frequency and importance of different sources of bias and confounding as well as the scientific rationale of the putative causal relationship. It was this approach using observational study designs, collectively and over a number of years, that settled the fact that smoking causes lung cancer and, subsequently, heart disease.

Odds and risks of the outcome for each arm and the total population are reported alongside.

Health informatics and health information systems

As patients pass through health and social care systems, data are recorded concerning their family background, lifestyle and disease states, which is of potential interest to health-care organisations seeking to deliver services, policy-makers concerned with improving health, scientific researchers seeking to understand health, and also to pharmaceutical and other commercial organisations seeking to identify markets.

There is a long tradition of maintaining health information systems. In most countries, the registration of births and deaths is required by law, and in the majority, the cause of death is also recorded (Fig. 6.7). There are numerous challenges in ensuring such vital registrations data are useful, especially for making comparisons across time and place. First, a system of standard terminologies is needed, such as the World Health Organization International Classification of Diseases, which provides a list of diagnostic codes attempting to cover every diagnostic entity. Secondly, these terms must be understood to refer to the same, or at least similar, diseases in different places. Thirdly, access to diagnostic skill and facilities is required; fourthly, standard protocols for assigning clinical diagnoses to ICD-10 codes are needed; and fifthly, robust quality control processes are needed to maintain some level of data completeness and accuracy.

Many countries employ similar systems for hospitalisations, either to allow recovery of health-care utilisation costs, or to manage and plan services. Similar data are, however, rarely collected for community-based health care. Nor are detailed data on health-care processes generally included in national data systems.

Consequently, there has been considerable interest in using data from information technology systems used to deliver care – such as electronic patient records, drug-dispensing databases, radiological software, and clinical laboratory information systems.

Data from such systems are, of course, much less structured than those obtained from vital registrations. Moreover, the completeness of such data depends greatly on local patterns of health-care utilisation as well as how clinicians and others use IT systems within different settings. As such, deriving useful unbiased information from such data is a considerable challenge.

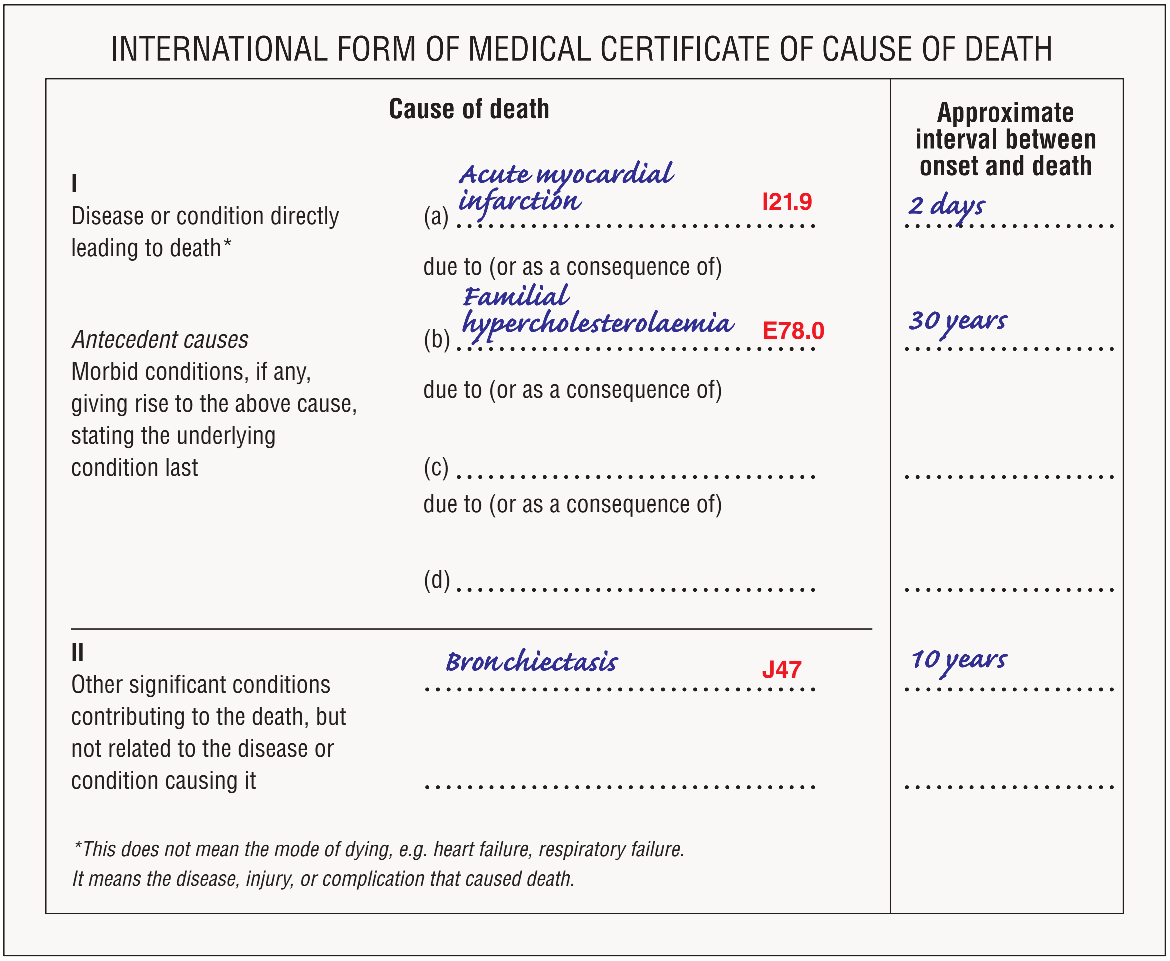
Much of the discipline of health informatics is concerned with addressing this challenge. One approach has been to develop comprehensive standard classification systems such as SNOMED-CT, 'a standardised, multilingual vocabulary of terms relating to the care of the individual', which has been designed for electronic health-care records. An alternative has been to use methods such as natural language processing to automatically derive information from free text (such as deriving diagnoses from radiological reports), or to employ 'machine learning', in which software algorithms are applied to data in order to derive useful insights. Such approaches are suited to large, messy data where the costs of systematisation would be prohibitive. It is likely that such innovations will over the coming years provide useful information to complement that obtained from more traditional health information systems.

Management of epidemics

An epidemic, as defined by the World Health Organization, occurs when 'in a community or region [the] cases of an illness, specific health-related behaviour, or other health-related events [are] clearly in excess of normal expectancy'. Epidemics that are small-scale or confined to a small geographic area are informally referred to as 'outbreaks'.

Epidemics are regularly caused where preventative measures break down; examples include breaches of food safety procedures in restaurants resulting in outbreaks of enteropathogenic *E. coli* infection, failure to adequately maintain cooling towers causing *Legionella* infections and falls in vaccination coverage resulting in measles epidemics.

Epidemics can also arise from novel infectious agents such as the SARS-CoV-1, MERS, SARS-CoV-2 and H1N1 viruses, for which new



INTERNATIONAL FORM OF MEDICAL CERTIFICATE OF CAUSE OF DEATH

Cause of death			Approximate interval between onset and death
I Disease or condition directly leading to death*	(a) Acute myocardial infarction	I21.9	2 days
	due to (or as a consequence of)		
Antecedent causes Morbid conditions, if any, giving rise to the above cause, stating the underlying condition last	(b) Familial hypercholesterolaemia	E78.0	30 years
	due to (or as a consequence of)		
	(c)		
	due to (or as a consequence of)		
	(d)		
II Other significant conditions contributing to the death, but not related to the disease or condition causing it	Bronchiectasis	J47	10 years

**This does not mean the mode of dying, e.g. heart failure, respiratory failure.*
It means the disease, injury, or complication that caused death.

Fig. 6.7 Completed death certificate. International Classification of Diseases 10 (ICD-10) codes are appended in red. *Based on World Health Organization, ICD-10, vol. 2. Geneva: WHO; 1990. Form retrieved from https://commons.m.wikimedia.org/wiki/File:International_form_of_medical_certificate_of_cause_of_death.png.*

preventative measures require to be developed. Where epidemics from novel agents are not controlled locally, but instead spread beyond international borders, these are termed pandemics, of which SARS-CoV-2 and H1N1 are examples.

To detect epidemics early, public health agencies undertake surveillance. Surveillance involves the collection and review of cases that have been identified via statutory notifications, or health information systems (such as microbiology reporting systems). For some infections such as *E. coli* and *Legionella*, one challenge for public health agencies is to distinguish epidemics from 'sporadic' cases at an early stage. This is done using human judgement, for example, if a large number of cases of *E. coli* occur in individuals who ate a specific food, although this task is sometimes supported using computer algorithms.

Epidemics require an incident management team, some of whose members have legal powers to impose measures to control infection. The team establish a formal case definition for confirmed, probable and possible cases (based on epidemiological features as well as clinical and/or microbiological findings), interview individuals with whom cases have had significant contact (termed contact tracing), test potential sources of infections (e.g. foodstuffs or industrial cooling towers), and implement control measures. The latter might include requiring infected individuals to isolate for a time period (e.g. until they are asymptomatic or until they test negative, depending on the infectious agent), and/or ordering temporary closure of businesses thought to be sources of infection (e.g. a restaurant with poor food hygiene practices).

Epidemic curves are crucial to the monitoring and management of epidemics. Figure 6.8 shows a notional epidemic curve for an epidemic caused by a single source, which is eliminated after 31 days. However, they are also used in more complex epidemics where there is person-to-person spread. In the latter, epidemic curves are used to estimate key statistics such as the basic reproduction number (R0) (an indicator of how contagious and transmissible a pathogen is) in the population as well as to make projections about future infections. Where the source of an epidemic is not apparent, comparative epidemiological methods can be used to identify the likely source; for example, a case–control design may identify a higher than expected consumption of a given food – for example,

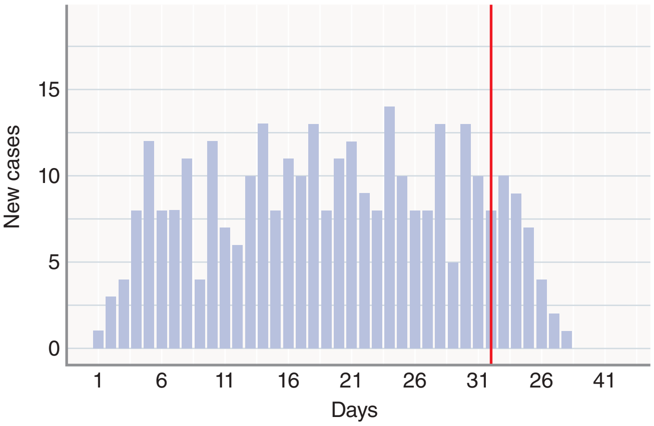


Fig. 6.8 Epidemic curve for a notional outbreak within a single ongoing source. Red line indicates time point where source of infection was removed (e.g. closure of a restaurant).

uncooked legumes – among cases compared to controls, prompting testing of foods, an education campaign and/or product recalls.

The principles for managing pandemics are similar to those for managing epidemics but operate on a national or international scale. The universality of pandemics, however, means that they pose special problems. Firstly, they pose risks to the society-wide infrastructure needed to deal with diseases, including, but not limited to, health-care facilities. Secondly, pandemics, unlike local and regional epidemics, are rare, so agencies have little direct experience with their management. For this reason, most settings develop pandemic plans and undertake regular table-top simulations to test and improve their preparedness. The COVID-19 pandemic, caused by SARS-CoV-2, is a key example and is discussed in Chapter 14.

Multiple Choice Questions

6.1. Which of the following are examples of large-scale screening programmes across all of the UK in 2021?

A. Cervical cancer national screening programme in women
B. Prostate cancer national screening programme in men
C. Diabetic eye screening programme in both men and women
D. Newborn hearing screening programme
E. Abdominal aortic aneurysm screening programme in both men and women

Answer: A, C and D.

Prostate cancer screening has not proven to be cost-effective and thus is not approved by the UK National Screening Committee. An abdominal aortic aneurysm screening programme operates only in men 65 years of age or over but not in women.

6.2. Which of the following statements describe the current newborn blood spot screening programme in the UK?

A. Ideally, blood spots should be collected on day 14
B. Babies who missed the screen can be tested up to 1 month of age
C. Blood spots are screened for sickle-cell disorder
D. Blood spots are screened for cystic fibrosis
E. Blood spots are screened for congenital hypothyroidism

Answer: C, D and E.

Ideally, blood spots should be collected on day 5. Babies who missed the screen can be tested up to 1 year of age. Newborn blood spot screens for: sickle-cell disorder, cystic fibrosis, congenital hypothyroidism and inherited metabolic diseases (PKU, MCADD, MSUD, IVA, GA1 and HCU – see Fig. 6.5).

6.3. Which of the following are examples of upstream determinants of health?

A. High blood pressure
B. Age
C. Access to quality education
D. Obesity
E. Ambient air pollution

Answer: C and E.

Upstream determinants of health refer to the broader social, economic and environmental factors that influence health outcomes before individual behaviours or clinical conditions manifest. These determinants shape the context in which people live and make health-related choices. Access to quality education is an upstream determinant because it affects employment opportunities, income, health literacy and long-term health outcomes. Ambient air pollution is an upstream determinant of health as an environmental risk factor. High blood pressure, age and obesity are considered downstream determinants or proximal factors – they are more immediate causes of disease and are influenced by upstream factors.

6.4. Which of the following are commonly used measures of risk in epidemiology?

A. Odds ratio
B. Relative risk
C. Prevalence
D. Incidence
E. Disability-adjusted life years (DALYs)

Answer: A and B.

In epidemiology, measures of risk quantify the likelihood of an outcome (usually disease) occurring in one group compared to another. The two most commonly used measures are:

- Odds ratio (OR): Used primarily in case–control studies, it compares the odds of exposure among cases to the odds among controls.
- Relative risk (RR): Used in cohort studies, it compares the probability of an outcome in the exposed group to the probability in the unexposed group.

The other options are not measures of risk. Prevalence measures the proportion of a population with a disease at a specific point in time. It reflects disease burden, not risk. Incidence measures the number of new cases over a period of time. It is a rate, not a comparative measure of risk. DALYs quantify overall disease burden by combining years of life lost due to premature death and years lived with disability. They are a population health metric, not a risk measure.

'Infection' in its strict sense describes the situation where microorganisms or other infectious agents become established in the host organism's cells or tissues, replicate, induce a host response, and result in pathologic changes in tissues. If a microorganism survives and replicates on an epithelial surface without causing pathological change, the host is said to be 'colonised' by that organism. If a microorganism survives and lies dormant after invading host cells or tissues, infection is said to be 'latent'. When a microorganism, or the host response to it, is sufficient to cause illness or harm, then the process is said to have caused infectious disease, which manifests with symptoms or signs. In milder cases there can be asymptomatic infection that may be identified by detection of a pathogen or the host response to the pathogen. Most pathogens (agents that can cause infection) are microorganisms but some are multicellular organisms. The manifestations of disease may aid pathogen dissemination (e.g. diarrhoea or coughing).

The term 'infection' is often used interchangeably with 'infectious disease' but not all infections are 'infectious', i.e. transmissible from person to person, and not all infections result in symptomatic disease. Infectious diseases caused by pathogens that are transmitted between hosts can also be called 'communicable diseases', whereas infection caused by organisms that are already colonising the host are described as 'endogenous'. The distinction is blurred in some situations, including health care–associated infections such as methicillin-resistant *Staphylococcus aureus* (MRSA) or *Clostridioides* (formerly *Clostridium*) *difficile* infection (CDI), in which colonisation precedes infection but the colonising bacteria may have been recently transmitted between patients. The chain of infection (Fig. 7.1) describes elements for communicable disease transmission.

Despite dramatic advances in hygiene, immunisation and antimicrobial therapy, infections still cause a massive burden of disease worldwide. Key challenges remain in tackling infection in resource-poor countries. Microorganisms are continually mutating and evolving; the emergence of new infectious agents (e.g. SARS-CoV-2, see Ch. 14) and antimicrobial-resistant microorganisms is therefore inevitable. This chapter describes the biological and epidemiological principles of infectious diseases and the general approach to their prevention, diagnosis and treatment. Specific infectious diseases are described in Chapters 14 and 15, and many of the organ-based chapters.

Agents causing infection

The concept of an infectious agent was established by Robert Koch in the 19th century (Box 7.1). Although fulfilment of 'Koch's postulates' became the standard for confirming the cause of an infection, many infectious agents do not fulfil Koch's postulates (e.g. uncultivable organisms and the causes of endogenous infections), and the postulates are now of mainly historical interest. The groups of infectious agents that are now recognised are described in the following sections.

7.1 Definition of an infectious agent – Koch's postulates

1. The same organism must be present in every case of the disease.
2. The organism must be isolated from the diseased host and grown in pure culture.
3. The isolate must cause the disease, when inoculated into a healthy, susceptible animal.
4. The organism must be re-isolated from the inoculated, diseased animal.

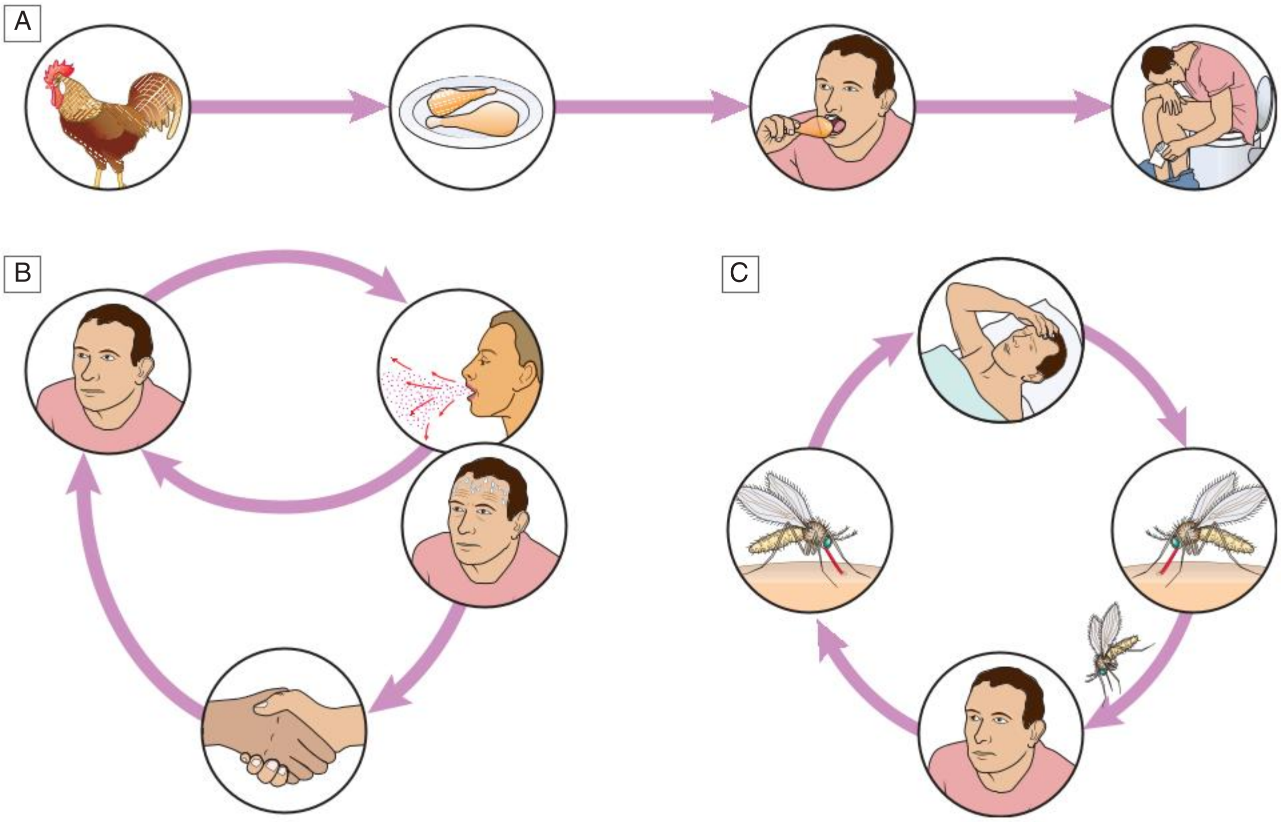

Fig. 7.1 The chain of infection can be linear (A) or cyclical (B and C). **A** Infections with an animal reservoir (e.g. *Campylobacter* enteritis) require a portal of exit from the reservoir and a vehicle for transmission to a susceptible human host (often water or a contaminated item of food). **B** Infections with person-to-person transmission (e.g. respiratory virus infection) require a mode of exit from the infected person, a mode of transmission (e.g. contaminated respiratory droplets or transmission via the surface of an intermediate fomite) and a portal of entry to a susceptible host. **C** Infections with an insect vector (e.g. malaria) require a mode of transmission from the insect reservoir to a susceptible human host and a mode of transmission back to the insect vector. Many infections involve a combination of these modes of transmission (e.g. Lyme disease, which has both an animal host and an insect vector) or several different modes of transmission.

Viruses

Viruses are incapable of independent replication. Instead, they subvert host cellular processes to ensure synthesis of their nucleic acids and proteins. Viruses' genetic material (the genome) consists of single- or double-stranded DNA or RNA. Retroviruses transcribe their RNA into DNA in the host cell by reverse transcription. An antigenically unique protein coat (capsid) encloses the genome, and together these form the nucleocapsid. In many viruses, the nucleocapsid is packaged within a lipid envelope. Enveloped viruses are less able to survive in the environment and are spread by respiratory, sexual or blood-borne routes, including arthropod-based transmission. Non-enveloped viruses survive better in the environment and are predominantly transmitted by faecal–oral or, less often, respiratory routes. A generic virus life cycle is shown in Figure 7.2. A virus that infects a bacterium is a bacteriophage (phage).

Prokaryotes: bacteria (including mycobacteria and actinomycetes)

Prokaryotic cells can synthesise their own proteins and nucleic acids, and are able to reproduce autonomously, although they lack a nucleus. The bacterial cell membrane is bounded by a peptidoglycan cell wall, which is thick (20–80 nm) in gram-positive organisms and thin (5–10 nm) in gram-negative ones. The gram-negative cell wall is surrounded by an outer membrane containing lipopolysaccharide. Genetic information is contained within a chromosome but bacteria may also contain rings of extrachromosomal DNA, known as plasmids, which can be transferred between organisms, without cells having to divide. Bacteria may be embedded in a polysaccharide capsule, and motile bacteria are equipped with flagella. Although many prokaryotes are capable of independent existence, some (e.g. *Chlamydia trachomatis*, *Coxiella burnetii*) are obligate intracellular organisms. Bacteria that can grow in artificial culture media are classified and identified using a range of characteristics (Box 7.2); examples are shown in Figures 7.3 and 7.4.

Eukaryotes: fungi, protozoa and helminths

Eukaryotic cells contain membrane-bound organelles, including nuclei, mitochondria and Golgi apparatus. Pathogenic eukaryotes are unicellular (e.g. yeasts, protozoa) or complex multicellular organisms (e.g. nematodes, trematodes and cestodes).

Fungi exist as either moulds (filamentous fungi) or yeasts. Dimorphic fungi exist in either form, depending on environmental conditions (see Fig. 14.75). The fungal plasma membrane differs from the human cell membrane in that it contains the sterol, ergosterol. Fungi have a cell wall made up of polysaccharides, chitin and mannoproteins. In most fungi, the main structural component of the cell wall is β-1,3-D-glucan, a polysaccharide. These differences from mammalian cells are important because they offer useful therapeutic targets.

Protozoa and helminths are often referred to as parasites. Many parasites have complex multistage life cycles, which involve animal and/or plant hosts in addition to humans.

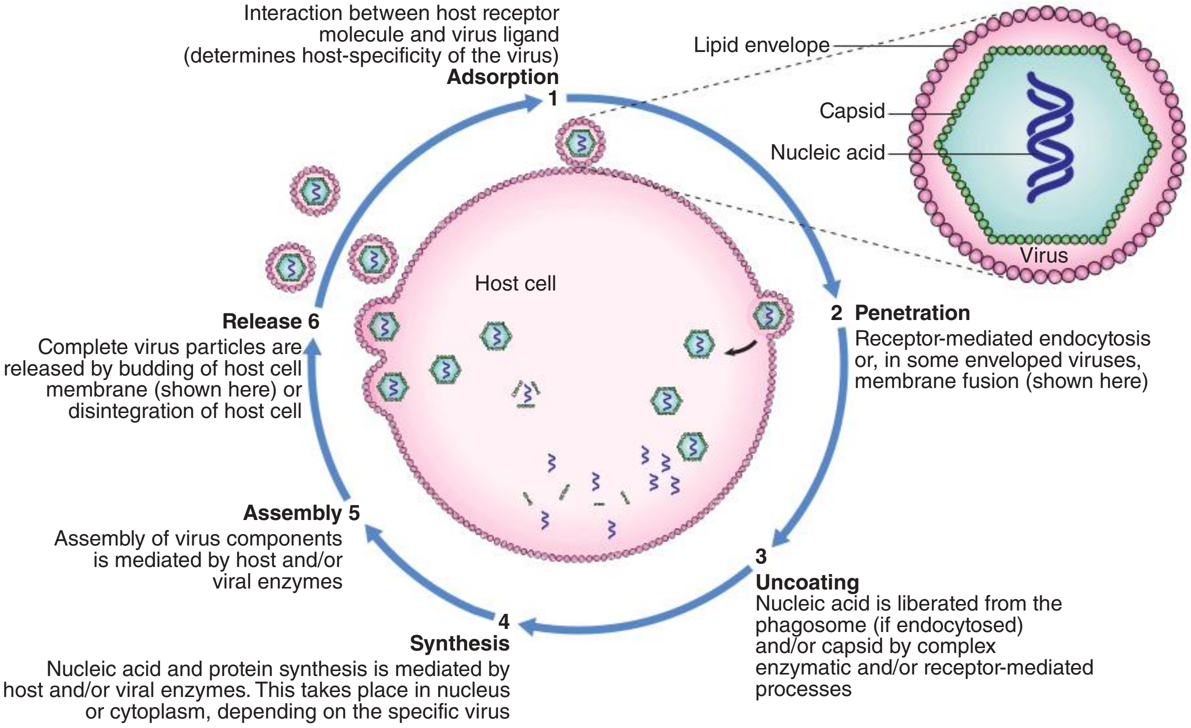
Prions

Although prions are transmissible and have some of the characteristics of infectious agents, they are not microorganisms, and are discussed on page 1225.

Normal microbial flora

The human body is colonised by large numbers of microorganisms (collectively termed the human microbiota). Colonising bacteria, also referred to as the 'normal bacterial flora', are able to survive and replicate on epithelial surfaces, e.g. skin and mucosal surfaces. The gastrointestinal tract and the mouth are the two most heavily colonised sites in the body and they have distinct microbiota, in both composition and function. Knowledge of non-sterile body sites and their normal bacterial flora is required to inform microbiological sampling strategies and interpret culture results (Fig. 7.5).

The microbiota is the total burden of microorganisms, their genes and their environmental interactions, and is now recognised to have a profound influence on human health and disease. Maintenance of the normal flora is beneficial to normal immune function. Other functions include: lower gastrointestinal tract bacteria synthesise and excrete vitamins (e.g. vitamins K and B_{12}); colonisation with normal flora confers



Interaction between host receptor molecule and virus ligand (determines host-specificity of the virus)
Adsorption
1
Lipid envelope
Capsid
Nucleic acid
Virus
Host cell
2 Penetration
Receptor-mediated endocytosis or, in some enveloped viruses, membrane fusion (shown here)
3
Uncoating
Nucleic acid is liberated from the phagosome (if endocytosed) and/or capsid by complex enzymatic and/or receptor-mediated processes
4
Synthesis
Nucleic acid and protein synthesis is mediated by host and/or viral enzymes. This takes place in nucleus or cytoplasm, depending on the specific virus
Assembly 5
Assembly of virus components is mediated by host and/or viral enzymes
Release 6
Complete virus particles are released by budding of host cell membrane (shown here) or disintegration of host cell

Fig. 7.2 A generic virus life cycle. Life cycle components common to most viruses are host cell attachment and penetration, virus uncoating, nucleic acid and protein synthesis, virus assembly and release. Virus release is achieved either by budding, as illustrated, or by lysis of the cell membrane. Life cycles vary between viruses.

i 7.2 How bacteria are identified

Gram stain reaction (see Fig. 7.3)

- Gram-positive bacteria (thick peptidoglycan layer), gram-negative bacteria (thin peptidoglycan) or unstainable

Microscopic morphology

- Cocci (round cells) or bacilli (elongated cells)
- Presence or absence of capsule

Cell association

- Association in clusters, chains or pairs

Colonial characteristics

- Colony size, shape or colour
- Effect on culture media (e.g. β-haemolysis of blood agar in haemolytic streptococci; see Fig. 7.4)

Atmospheric requirements

- Strictly aerobic (requires O_2), strictly anaerobic (requires absence of O_2), facultatively aerobic (grows with or without O_2) or micro-aerophilic (requires reduced O_2)

Biochemical reactions

- Expression of enzymes (oxidase, catalase, coagulase)
- Ability to ferment or hydrolyse various biochemical substrates

Motility

- Motile or non-motile

Antibiotic susceptibility

- Identifies organisms with invariable susceptibility (e.g. to optochin in *Streptococcus pneumoniae* or metronidazole in obligate anaerobes)

Matrix-assisted laser desorption/ionisation time-of-flight mass spectrometry (MALDI-TOF-MS)

- A rapid technique that identifies bacteria and some fungi from their specific molecular composition

Sequencing bacterial 16S ribosomal RNA gene

- A highly specific test for identification of organisms in pure culture and in samples from normally sterile sites

Whole-genome sequencing

- Although not yet in routine use, whole-genome sequencing (WGS) offers the potential to provide rapid and simultaneous identification, sensitivity testing and typing of organisms from pure culture and/or directly from clinical samples. As such, WGS is likely to replace many of the technologies described above over the next few years

'colonisation resistance' to infection with pathogenic organisms by altering the local environment (e.g. lowering pH), producing antibacterial agents (e.g. bacteriocins (small antimicrobial peptides/proteins), fatty acids and metabolic waste products or restriction of metabolites used by pathogens), and inducing host antibodies that cross-react with pathogenic organisms.

Conversely, some body sites are either sterile or contain very low numbers of colonising bacteria. For example, the submucosal tissues, blood stream, peritoneal and pleural cavities are maintained as sterile by physical separation from the external environment; and the lower airways and bladder, sites that were formerly believed to be sterile but are now known to support limited microbiota, are protected from excessive contamination by the mucociliary escalator and urethral sphincter respectively, as well as local immune responses.

Members of the normal flora can cause (endogenous) infection by 'translocation' from their normal location to other body sites or by excessive growth at the 'normal' site (overgrowth). Overgrowth is exemplified by dental caries and 'blind loop' syndrome (p. 839). Translocation results from spread along a surface or penetration through a colonised surface, e.g. urinary tract infection caused by perineal/enteric flora, and surgical site infections, particularly of prosthetic materials, caused by skin flora such as staphylococci. Normal flora also contribute to disease by cross-infection; organisms colonising one individual can cause disease when transferred to another more susceptible individual or can transmit multidrug-resistant strains, e.g. carbapenemase-producing Enterobacterales (CPE).

The importance of limiting antimicrobial-induced perturbations of microbiota is increasingly recognised. 'Probiotics' are proprietary microbes or mixtures of microbes administered with the aim of restoring a beneficial profile of gastrointestinal normal flora. Faecal microflora transplantation (FMT) has the same aim, by giving gastrointestinal microbiota from healthy people (filtered extract of faeces) to a patient. Although the clinical effectiveness of probiotics remains a subject of debate, FMT has proven benefit in recurrent *C. difficile* infection.

Host–pathogen interactions

A 'pathogen' is a microorganism that can cause infection. The manifestations of infection, including a pathogen's ability to cause severe disease in a previously healthy host, are affected by its 'virulence'. Virulence is determined by the number and type of disease-causing proteins and other factors that it can produce ('virulence factors').

- *Primary pathogens* cause disease in a proportion of individuals to whom they are exposed, regardless of the host's immunological status.
- *Opportunistic pathogens* cause disease only in individuals whose host defenses are compromised, e.g. by an intravascular catheter, or when the immune system is compromised, by genetic susceptibility, infection or immunosuppressive therapy.

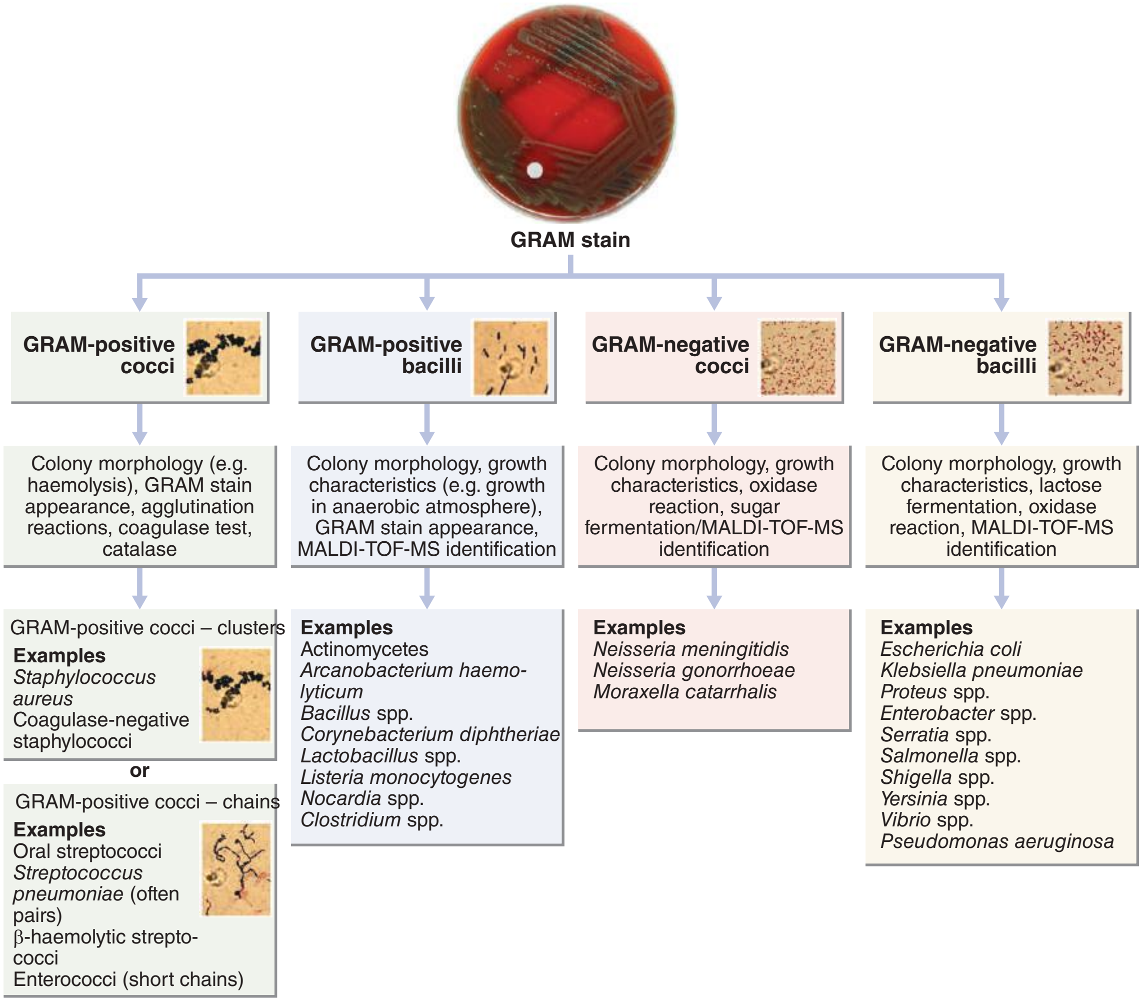
Determinants of virulence

For a primary pathogen to cause infection in a healthy host it must compete with colonising flora to reach target host cells or anatomic locations. It can do this in various ways, including sequestration of nutrients, adapting metabolism to exploit metabolites not used by commensal flora, production of bacteriocins, and using motility to 'swim' to the site of infection. Many microorganisms, including viruses, use 'adhesins' to initiate their attachment to host cells. Some pathogens can invade through tissues. Many bacteria and fungi multiply after initial adhesion to a host surface to form 'biofilms'. These are complex three-dimensional structures surrounded by a matrix of host and bacterial products, which afford protection to the colony and limit the effectiveness of antimicrobials. Biofilm-related infections on man-made medical devices such as vascular catheters or grafts can be particularly difficult to treat.

Pathogens may produce toxins, microbial molecules that cause adverse effects on host cells, either at the site of infection, or remotely following carriage through the blood stream. Endotoxin is the lipid component of gram-negative bacterial outer membrane lipopolysaccharide. It is released when bacterial cells are damaged and has generalised inflammatory effects. Exotoxins are proteins released by living bacteria, which often have specific effects on target organs (Box 7.3).

Intracellular pathogens, including viruses, bacteria (e.g. *Salmonella* spp., *Listeria monocytogenes* and *Mycobacterium tuberculosis*), parasites (e.g. *Leishmania* spp.) and fungi (e.g. *Histoplasma capsulatum*), are able to survive in intracellular environments, including after phagocytosis by macrophages. Pathogenic bacteria express different genes, depending on environmental stress (pH, iron starvation, O_2 level etc.) and anatomical location.

Genetic diversity enhances the pathogenic capacity of bacteria. Some virulence factor genes are found on plasmids or in phages and are exchanged between different strains or species. The ability to acquire genes from the gene pool of all strains of the species increases diversity and the potential for pathogenicity. Viruses exploit their rapid reproduction and potential to exchange nucleic acid with other strains of the virus to enhance diversity. Some micro-organisms use strategies such as mutagenesis (e.g. influenza A virus) or gene recombination (e.g. African trypanosomiasis) to increase antigenic diversity to escape the selective



GRAM stain
GRAM-positive cocci
GRAM-positive bacilli
GRAM-negative cocci
GRAM-negative bacilli
Colony morphology (e.g. haemolysis), GRAM stain appearance, agglutination reactions, coagulase test, catalase
Colony morphology, growth characteristics (e.g. growth in anaerobic atmosphere), GRAM stain appearance, MALDI-TOF-MS identification
Colony morphology, growth characteristics, oxidase reaction, sugar fermentation/MALDI-TOF-MS identification
Colony morphology, growth characteristics, lactose fermentation, oxidase reaction, MALDI-TOF-MS identification
GRAM-positive cocci – clusters
Examples

pressure of the host immune system. Once a new strain acquires sufficient virulence genes, including those enhancing infectivity and enabling immune evasion, it may become an epidemic or pandemic strain, resulting in regional or global transmission, respectively. This phenomenon accounts for influenza and COVID-19 pandemics (see Box 7.10 and Ch. 14).

The host response

Innate and adaptive immune and inflammatory responses, which humans use to control the normal flora and respond to pathogens, are reviewed in Chapter 4.

Pathogenesis of infectious disease

The severity of an infection is determined by the virulence of the pathogen and the host response. The host must balance pathogen clearance ('immune resistance') with preservation of host tissue function ('tolerance'). Optimal responses achieve pathogen clearance with minimal tissue injury but sometimes tolerance is achieved with preservation of function over pathogen clearance, e.g. malaria in immune individuals from endemic regions. Whilst an intact host response protects against infection or reduces its severity, an excessive response can be damaging. Both the host immune response and pathogen-produced factors can contribute to tissue injury and systemic manifestations of infection (see 'Sepsis', p. 235). The contribution of the immune response to disease

i 7.3 Exotoxin-mediated bacterial diseases

Disease	Organism
Antibiotic-associated diarrhoea/ pseudomembranous colitis	*Clostridioides difficile*
Botulism	*Clostridium botulinum*
Cholera	*Vibrio cholerae*
Diphtheria	*Corynebacterium diphtheriae*
Haemolytic uraemic syndrome	Enterohaemorrhagic *Escherichia coli* (*E. coli* 0157 and other strains)
Necrotising pneumonia	*Staphylococcus aureus*
Tetanus	*Clostridium tetani*
Toxic shock syndrome	*Staphylococcus aureus* *Streptococcus pyogenes*

manifestations is exemplified by the immune reconstitution inflammatory syndrome (IRIS), which can be seen in human immunodeficiency virus (HIV) infection, post-transplantation neutropenia or tuberculosis (which causes suppression of T-cell function): there is a paradoxical worsening of the clinical condition as the immune dysfunction is corrected, caused by an exuberant but dysregulated inflammatory response.

Clinical manifestations of infection

The clinical manifestations of infection can be localised to the site of infection or generalised. Examples of local manifestations include the inflammation of cellulitis, facial pain of sinusitis or neck stiffness of meningitis (Ch. 14). Generalised manifestations include sweats, chills (feeling very cold, even with extra clothes/blankets), rigors, fevers, anorexia, lethargy and generalised aches, and many of these result from the immune response to infection. While the presence of infection may be clinically clear in some settings, often it is not. Identifying the responsible pathogen in patients with infection is usually not possible on clinical grounds, neither is prediction of pathogen susceptibility and resistance to antimicrobial agents. Hence there is a need to carefully investigate suspected infections to optimise, or avoid unnecessary, antimicrobial therapy. Rigors are a clinical symptom (or sign if they are witnessed) characterised by feeling very cold (‘chills’) and uncontrollable shivering, usually followed by fever and sweating. Rigors occur when the thermoregulatory centre attempts to correct a core temperature to a higher level by stimulating skeletal muscle activity and shaking.

Thermoregulation can be altered during infection, causing both hyperthermia (fever) and hypothermia. Fever is mediated mainly by ‘pyrogenic cytokines’ (e.g. interleukins IL-1 and IL-6, and tumour necrosis factor [TNF]), which are released in response to various stimuli, including activation of pattern recognition receptors (PRRs) by microbial products (e.g. lipopolysaccharide) and factors released by injured cells (Ch. 4). This induces prostaglandin E_2 production, which binds to specific receptors in the preoptic nucleus of the hypothalamus (thermoregulatory centre), causing the core temperature to rise.

Investigation of infection

The aims of investigating a patient with suspected infection are: to confirm the presence of infection; identify the specific pathogen(s); and, where appropriate, identify its susceptibility to specific antimicrobial agents in order to optimise therapy. Pathogens may be detected directly (e.g. by culturing a normally sterile body site) or their presence may be inferred by identifying the host response to the organism ('indirect detection', Box 7.4), e.g. C-reactive protein or procalcitonin as part of the acute phase response (p. 66), although these are activated to varying extents by other inflammatory stimuli. Careful sampling increases the likelihood of diagnosis (Box 7.5). Culture results must be interpreted in the context of the normal flora at the sampled site (see Fig. 7.5). The extent to which a microbiological test result supports or excludes a particular diagnosis depends on its statistical performance (e.g. sensitivity, specificity, positive and negative predictive value). Sensitivity and specificity vary according to the type of test, sampling and processing techniques, and time between infection and testing. Positive and negative predictive values depend on the prevalence of the condition in the test population. The complexity of test interpretation is illustrated in Figure 7.9 below, which shows the 'windows of opportunity' afforded by various testing methods. Given this complexity, coordinated thought and action ensure appropriate test application and timing; effective communication between clinicians and the microbiologists facilitates optimal results and interpretation.

Direct detection of pathogens

Some direct detection methods provide rapid results and enable detection of organisms that cannot be grown easily on artificial culture media, such as *Chlamydia* spp.; they can also provide information on antimicrobial susceptibility, e.g. *M. tuberculosis*.

Detection of whole organisms

Whole organisms are detected by examination of biological fluids or tissue using a microscope.

- *Bright field microscopy* (in which the test sample is interposed between the light source and the objective lens) uses stains to enhance visual contrast between the organism and its background. Examples include Gram staining of bacteria and Ziehl–Neelsen or auramine staining of acid- and alcohol-fast bacilli (AAFB) in tuberculosis (the latter requires an ultraviolet light source). Another commonly used example is Giemsa staining of blood films to diagnose malaria. Thick films are used to enhance sensitivity of detecting the blood stages of *Plasmodium* spp. and thin films are examined to help with speciation and quantifying the percentage of red blood cells that are parasitised. In histopathological examination of tissue samples, stains are used to demonstrate not only the presence of microorganisms but also features of disease pathology.
- *Dark field microscopy* (in which light is scattered to make organisms appear bright on a dark background) is used, for example, to examine genital chancre fluid in suspected syphilis.
- *Electron microscopy* may be used to examine stool and vesicle fluid to detect enteric and herpesviruses, respectively, but its use has largely been supplanted by nucleic acid detection (see below).
- *Flow cytometry* can be used to analyse liquid samples (e.g. urine) for the presence of particles based on properties such as size, impedance and light scatter. This technique can detect bacteria but may misidentify other particles as bacteria too.

Detection of components of organisms

Components of microorganisms detected for diagnostic purposes include nucleic acids, cell wall molecules, toxins and other antigens. Commonly used examples include *Legionella pneumophila* serogroup 1 and *Streptococcus pneumoniae* antigens both in urine and cryptococcal polysaccharide antigen in cerebrospinal fluid (CSF) and blood. Lateral flow (LF) immunochromatography is mainly used to detect antigens in both blood and other fluids (e.g. respiratory secretions, urine). These have been developed into useful point-of-care tests (POCTs) so results can be obtained rapidly outside of laboratory environments. The system consists of a porous test strip (e.g. a nitrocellulose membrane), at one end of which there is target-specific antibody, complexed with coloured microparticles. Further specific antibody is immobilised in a transverse narrow line some distance along the strip. Test material is added to the antibody–particle complexes, which then migrate along the strip by capillary action. If these are complexed with antigen, they will be immobilised by the specific antibody and visualised as a transverse line across the strip. If the test is negative, the antibody–particle complexes will bind to a line of immobilised

7.4 Tests used to diagnose infection

Non-specific markers of inflammation/infection

- e.g. White cell count in blood sample (WCC), plasma C-reactive protein (CRP), procalcitonin (PCT)*, serum lactate, cell counts in urine or cerebrospinal fluid (CSF), CSF protein and glucose

Direct detection of organisms or organism components

- Microscopy
- Detection of organism components (e.g. antigen, toxin)
- Nucleic acid amplification tests (e.g. polymerase chain reaction)

Culture of organisms

- Antimicrobial susceptibility testing

Tests of the host's specific immune response

- Antibody detection
- Interferon-gamma release assays (IGRA)

*Although PCT is used increasingly in clinical practice, further evidence is required to establish its precise role in distinguishing bacterial infections from other causes of inflammation.

7.5 How to provide samples for microbiological sampling

Communicate with the laboratory

- Discuss samples that require processing urgently or that may contain hazardous or unusual pathogens with laboratory staff *before* collection
- Communication is key to optimising microbiological diagnosis. If there is doubt about any aspect of sampling, it is far better to discuss it with laboratory staff beforehand than to risk diagnostic delay by inappropriate sampling or sample handling

Take samples based on a clinical diagnosis

- Sampling in the absence of clinical evidence of infection is rarely appropriate (e.g. collecting urine, or sputum for culture)

Use the correct container

- Certain tests (e.g. nucleic acid and antigen detection tests) require proprietary sample collection equipment

Follow sample collection procedures

- Failure to follow sample collection instructions precisely can result in false-positive (e.g. contamination of blood culture samples) or false-negative (e.g. collection of insufficient blood for culture) results

Label sample and request form correctly

- Label sample containers and request forms according to local policies, with demographic identifiers, specimen type and time/date collected
- Include clinical details on request forms
- Identify samples carrying a high risk of infection (e.g. blood liable to contain a blood-borne virus) with a hazard label

Use appropriate packaging

- Close sample containers tightly and package securely (usually in sealed plastic bags)
- Attach request forms to samples but not in the same compartment (to avoid contamination, should leakage occur)

Manage storage and transport

- Transport samples to the microbiology laboratory quickly
- Consider pre-transport storage, conditions (e.g. refrigeration, incubation, storage at room temperature) vary with sample type
- Notify the receiving laboratory prior to arrival of unusual or urgent samples, to ensure timely processing

anti-immunoglobulin antibody placed further along the strip, which acts as a negative control. Immunochromatographic tests are rapid and relatively cheap to perform, and are appropriate for point-of-care testing, e.g. in HIV-1, COVID-19 and malaria. Rapid diagnostic tests (RDTs) for malaria parasites are widely used on blood commonly obtained from a finger-prick. These RDTs rely on dye-labelled antibodies that capture specific parasite antigens in blood. A variety of other POCTs have been developed or are in development. Figure 7.6 depicts the mechanism of action of POCTs.

In reverse passive agglutination (an antigen detection test), a carrier particle is coated with specific antibody, which agglutinate when incubated with patient samples that contain the specific antigen from the pathogen of interest (see section on agglutination techniques below).

Other methods may be used, such as tissue culture cytotoxicity assay for *C. difficile* toxin. In toxin-mediated disease, detection of toxin may be of greater relevance than identification of the organism itself (e.g. stool *C. difficile* toxin).

Nucleic acid amplification tests

In a nucleic acid amplification test (NAAT), specific sequences of microbial DNA or RNA are identified using a nucleic acid primer that is amplified exponentially by enzymes to generate multiple copies of a target nucleotide sequence. The most commonly used NAAT is the polymerase chain reaction (PCR; see Fig. 3.12). Reverse transcription PCR (RT-PCR) is used to detect RNA from RNA viruses. The use of fluorescent labels in the reaction enables 'real-time' detection of amplified DNA; quantification is based on the principle that the time taken to reach the detection threshold is proportional to the initial number of copies of the target nucleic acid sequence. In multiplex PCR, multiple primer pairs are used to enable detection of several different organisms in a single reaction. Genes that are relevant to virulence (such as toxin genes) or antimicrobial resistance can also be detected; for example, the *mecA* gene can be used to screen for MRSA.

NAATs are the most sensitive direct detection methods and are also relatively rapid. They are used widely in virology, where the possibility of false-positive results from colonising or contaminating organisms is remote, and are applied to blood, respiratory samples, stool and urine. Many NAATs have been developed as POCTs where results can be obtained rapidly within a clinical environment without needing to process samples in a laboratory (e.g. for influenza A virus and SARS-CoV-2). In bacteriology, PCR is used to examine CSF, blood, tissue and genital samples, and multiplex PCR is used in multiple sample types including faeces and respiratory samples. PCR is particularly helpful for microorganisms that cannot be readily cultured, e.g. *Tropheryma whipplei*, and is being used increasingly in mycology and parasitology.

Genome sequence-based diagnostics

Diagnostic assays based on comparing the genome sequences of organisms in a clinical sample with large databases are increasingly used. These can be divided into targeted approaches where pathogen genes are amplified or enriched prior to sequencing, and unbiased approaches where all material in a sample is sequenced (e.g. metagenomic sequencing). One common amplicon-based approach is where PCR is undertaken using primers targeting parts of the bacterial gene that encode the 16S ribosomal RNA (rRNA) that have shared DNA sequences across most bacteria. Between these shared DNA sequences, the 16S rRNA gene varies between species; so, using PCR and nucleotide sequencing of the product, then comparing the DNA sequence information with large databases, allows bacterial detection and species identification. Similar approaches can be used to detect fungi (e.g. targeting the 18S rRNA gene or internal transcribed spacer 2 (ITS2) region). Metagenomic sequencing has the advantage of being able to detect any organism that is present in a sample, but interpretation of results can be challenging and sensitivity may be lower than with amplicon-based approaches.

Determination of nucleotide sequences in a target gene(s) can also be used to assign microorganisms to specific strains, which may be relevant to treatment and/or prognosis (e.g. in hepatitis C infection).

Culture

Microorganisms may be both detected and further characterised by culture from clinical samples (e.g. tissue, swabs and body fluids).

- *Ex vivo culture* (tissue or cell culture) was widely used in the isolation of viruses but has been largely supplanted by NAATs.
- *In vitro culture* (in artificial culture media) of bacteria and fungi is used to confirm the presence of pathogens, allow identification, test antimicrobial susceptibility and subtype the organism for epidemiological purposes.

Culture has its limitations: results are not immediate, even for organisms that are easy to grow, and negative cultures rarely exclude infection. Organisms such as *M. tuberculosis* are slow-growing, typically taking at least 2 weeks, even in rapid-culture systems. Certain organisms, such as *Mycobacterium leprae* and *Tropheryma whipplei*, cannot be cultivated

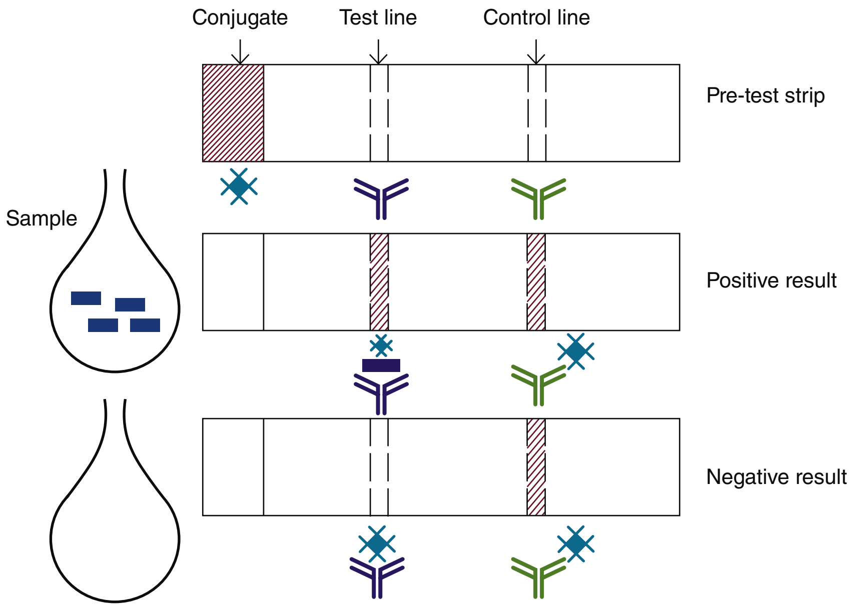

Fig. 7.6 Point-of-care test illustrating mechanism of action.

on artificial media, and others (e.g. *Chlamydia* spp. and viruses) grow only in culture systems, which are slow and labour-intensive.

Blood culture

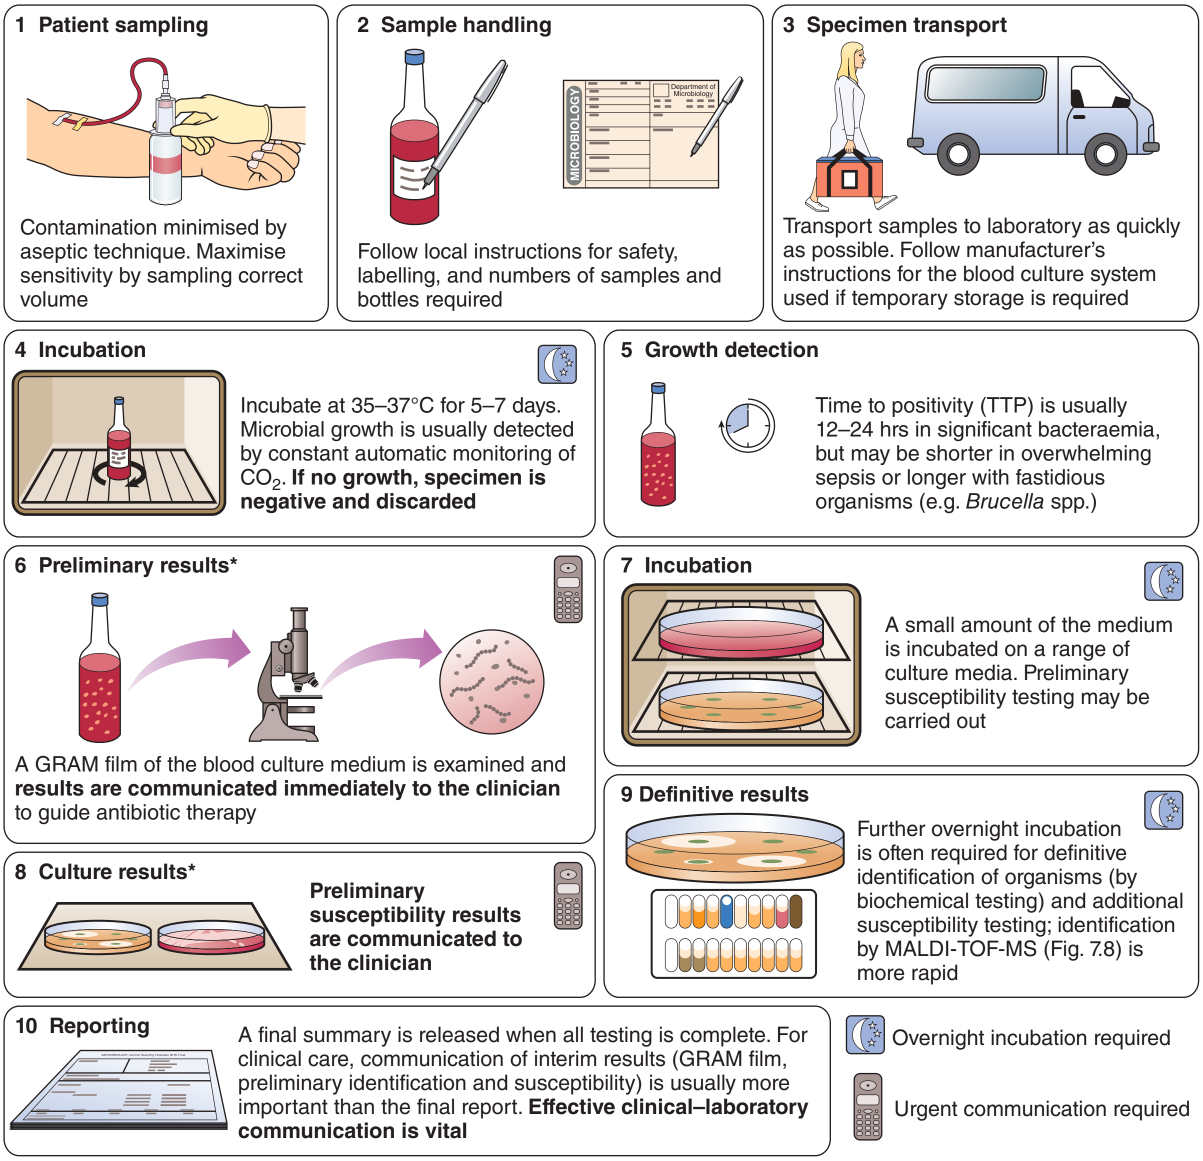
The terms 'bacteraemia' and 'fungaemia' describe the presence of bacteria and fungi in the blood without implication of clinical significance, while the term 'blood stream infection' means that bacteraemia or fungaemia are present together with symptoms or signs infection; this is discussed on p. 304. Bacteraemia/fungaemia is identified by inoculating a liquid culture medium with freshly drawn blood, which is then incubated in a system that monitors it constantly for growth of microorganisms (e.g. by detecting products of microbial respiration using fluorescence; Fig. 7.7). If growth is detected, organisms are identified and sensitivity testing is performed. Traditionally, identification has been achieved by Gram stain appearance and biochemical reactions. However, matrix-assisted laser desorption/ionisation time-of-flight mass spectrometry (MALDI-TOF-MS; see Box 7.2) is being used increasingly to identify organisms. MALDI-TOF-MS produces a profile of proteins of different sizes from the target microorganism and uses databases of such profiles to identify the organism (Fig. 7.8). It is rapid and accurate. Taking multiple blood samples for culture at different times allows differentiation of transient (one positive sample) and persistent (majority are positive) bacteraemia. This can be clinically important in identifying the source of infection.

Indirect detection of pathogens

Tests may be used to detect the host's immune (e.g. antibody or T-cell) response to a specific microorganism, enabling the diagnosis of infection with organisms that are difficult to detect by other methods or are no longer present in the host. The term 'serology' describes tests carried out on serum and includes both antigen (direct) and antibody (indirect) detection. Detection of antigen is described above in the section on detection of components of organisms.

Antibody detection

Organism-specific antibody detection is applied mainly to blood (Fig. 7.9). Results are typically expressed as titres: that is, the reciprocal of the highest dilution of the serum at which antibody is detectable (e.g. detection at serum dilution of 1:64 gives a titre of 64). 'Seroconversion' is defined as either a change from negative to positive detection or a fourfold rise in



1 Patient sampling

Contamination minimised by aseptic technique. Maximise sensitivity by sampling correct volume

2 Sample handling

Follow local instructions for safety, labelling, and numbers of samples and bottles required

3 Specimen transport

Transport samples to laboratory as quickly as possible. Follow manufacturer's instructions for the blood culture system used if temporary storage is required

4 Incubation

Incubate at 35–37°C for 5–7 days. Microbial growth is usually detected by constant automatic monitoring of CO_2. **If no growth, specimen is negative and discarded**

5 Growth detection

Time to positivity (TTP) is usually 12–24 hrs in significant bacteraemia, but may be shorter in overwhelming sepsis or longer with fastidious organisms (e.g. *Brucella* spp.)

6 Preliminary results*

A GRAM film of the blood culture medium is examined and **results are communicated immediately to the clinician** to guide antibiotic therapy

7 Incubation

A small amount of the medium is incubated on a range of culture media. Preliminary susceptibility testing may be carried out

8 Culture results*

Preliminary susceptibility results are communicated to the clinician

9 Definitive results

Further overnight incubation is often required for definitive identification of organisms (by biochemical testing) and additional susceptibility testing; identification by MALDI-TOF-MS (Fig. 7.8) is more rapid

10 Reporting

A final summary is released when all testing is complete. For clinical care, communication of interim results (GRAM film, preliminary identification and susceptibility) is usually more important than the final report. **Effective clinical–laboratory communication is vital**

Overnight incubation required

Urgent communication required

Fig. 7.7 An overview of the processing of blood cultures. *In laboratories equipped with MALDI-TOF-MS (see Fig. 7.8), rapid definitive organism identification may be achieved at stage 6 and/or stage 8.

titre between acute and convalescent serum samples. An acute sample is usually taken during the first week of disease and the convalescent sample 2–4 weeks later. Earlier diagnosis can be achieved by detection of immunoglobulin M (IgM) antibodies, which are produced early in infection. A limitation of these tests is that antibody production requires a fully functional host immune system, so there may be false-negative results in immunocompromised patients. Also, antibody tests usually provide a retrospective diagnosis. False-positive results can occur when there is cross-reactivity of the test reagents with other molecules or when patients have been given blood products containing other people's antibodies. Serological testing methods are described below.

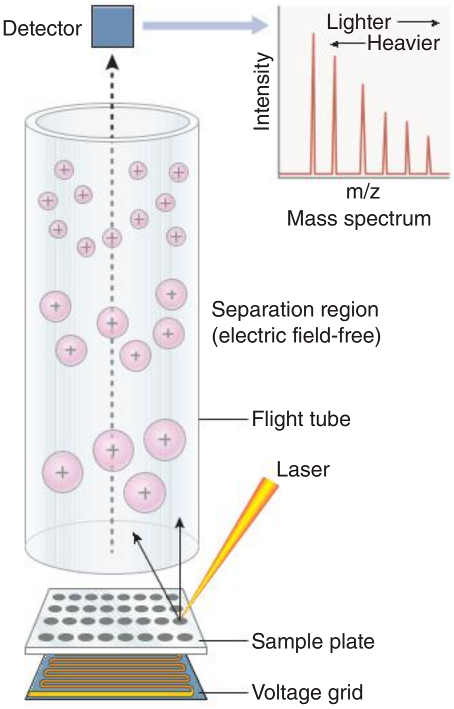


Fig. 7.8 **The workings of matrix-assisted laser desorption/ionisation time-of-flight mass spectrometry (MALDI-TOF MS).** *Adapted from Sobin K, Hameer D, Ruparel T. Digital genotyping using molecular affinity and mass spectrometry. Nature Rev Genet 2003;4:1001–1008.*

Enzyme-linked immunosorbent assay

The principles of the enzyme-linked immunosorbent assay (ELISA, EIA) are illustrated in Figure 7.10. These assays rely on linking an antibody with an enzyme that generates a colour change on exposure to a chromogenic substrate. Various configurations allow detection of antigens or specific subclasses of immunoglobulin (e.g. IgG, IgM, IgA). ELISA may also be adapted to detect PCR products, using immobilised oligonucleotide hybridisation probes and various detection systems.

Immunoblot (Western blot)

Microbial proteins are separated according to molecular weight by polyacrylamide gel electrophoresis (PAGE) and transferred (blotted) on to a nitrocellulose membrane, which is incubated with patient serum. Binding of specific antibody is detected with an enzyme–anti-immunoglobulin conjugate similar to that used in ELISA, and specificity is confirmed by its location on the membrane. Immunoblotting is a highly specific test, which may be used to confirm the results of less specific tests such as ELISA (e.g. in Lyme disease).

Immunofluorescence assays

Indirect immunofluorescence assays (IFAs) detect antibodies by incubating a serum sample with immobilised antigen (e.g. virus-infected cells on a glass slide); any virus-specific antibody present in the serum binds to antigen and is then detected by fluorescence microscopy using a fluorescent-labelled anti-human immunoglobulin ('secondary' antibody). This method can also detect organisms in clinical samples (usually tissue or centrifuged cells) using a specific antibody in place of immobilised antigen to achieve capture.

Complement fixation test (CFT)

In a CFT, patient serum is heat-treated to inactivate complement and mixed with test antigen. Any specific antibody in the serum will complex with the antigen. Complement is then added to the reaction. If antigen–antibody complexes are present, the complement will be 'fixed' (consumed). Sheep erythrocytes, coated with an anti-erythrocyte antibody, are added. The degree of erythrocyte lysis reflects the remaining complement and is inversely proportional to the quantity of the specific antigen–antibody complex present.

Agglutination tests

When antigens are present on the surface of particles (e.g. cells, latex particles or microorganisms) and cross-linked with antibodies, visible clumping (or 'agglutination') occurs.

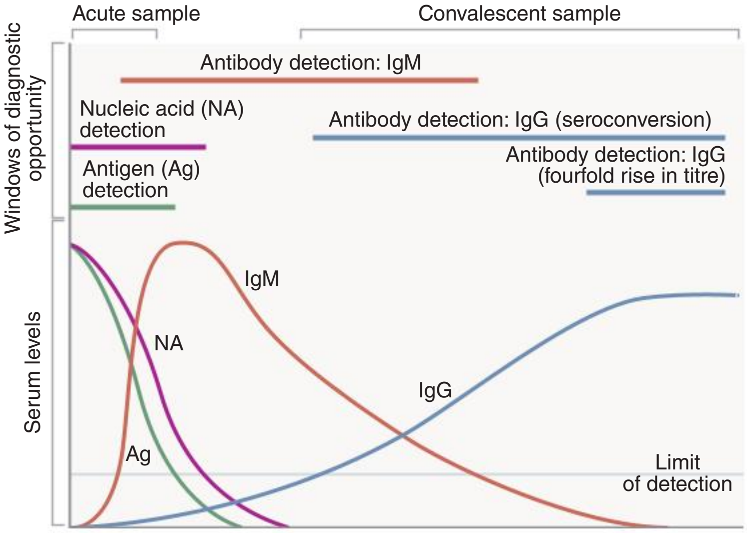

Fig. 7.9 **Detection of antigen, nucleic acid and antibody in infectious disease.** The acute sample is usually taken during the first week of illness, and the convalescent sample 2–4 weeks later. Detection limits and duration of detectability vary between tests and diseases, although in most diseases immunoglobulin M (IgM) is detectable within the first 1–2 weeks.

Patient Ab
Antibody–enzyme conjugate
Ig subclass-specific Ab
Specific Ag
Chromogenic substrate
Ab specific to Ag from the disease-causing organism

Fig. 7.10 Antibody (Ab) and antigen (Ag) detection by enzyme-linked immunosorbent assay (ELISA). This can be configured in various ways. **A** Patient Ab binds to immobilised specific Ag and is detected by addition of anti-immunoglobulin–enzyme conjugate and chromogenic substrate. **B** Patient Ab binds to immobilised Ig subclass-specific Ab and is detected by addition of specific Ag, followed by antibody–enzyme conjugate and chromogenic substrate. **C** Patient Ab and antibody–enzyme conjugate bind to immobilised specific Ag. Magnitude of colour change reaction is inversely proportional to concentration of patient Ab. **D** Patient Ag binds to immobilised Ab and is detected by addition of antibody–enzyme conjugate and chromogenic substrate. In **A**, the conjugate Ab is specific for human immunoglobulin. In **B**–**D**, it is specific for Ag from the disease-causing organism.

- In *direct agglutination*, patient serum is added to a suspension of organisms that express the test antigen. A widely used example is the use of *Leishmania* direct agglutination test (DAT). The Widal agglutination test uses a suspension of *Salmonella* Typhi and *S.* Paratyphi ‘A’ and ‘B’, treated to retain only ‘O’ and ‘H’ antigens. These antigens are kept to detect corresponding antibodies in serum from a patient suspected of having typhoid fever. Although no longer used in many parts of the world, it retains importance in some regions.
- In *indirect (passive) agglutination*, specific antigen is attached to the surface of carrier particles, which agglutinate when incubated with patient samples that contain specific antibodies.

Immunodiffusion

Immunodiffusion involves antibodies and antigen migrating through gels and forming insoluble complexes where they meet. The complexes are seen on staining as ‘precipitin bands’. Immunodiffusion is used in the diagnosis of dimorphic fungi and some forms of aspergillosis.

Tests based on cellular immune responses

Interferon-gamma release assays (IGRAs) are used to diagnose latent tuberculosis infection. The principle behind IGRA is illustrated in Figure 17.42. IGRA cannot distinguish between latent and active tuberculosis infection.

Antimicrobial susceptibility testing

If growth of microorganisms in culture is inhibited by the addition of an antimicrobial agent, the organism is considered to be susceptible to that antimicrobial. The lowest concentration of the antimicrobial agent at which growth is inhibited is the minimum inhibitory concentration (MIC), and the lowest concentration that causes cell death is the minimum bactericidal concentration (MBC). If the MIC is less than or equal to a predetermined breakpoint threshold, the organism is considered susceptible, and if the MIC is greater than the breakpoint, it is resistant. Breakpoints are determined for antimicrobial agents using a combination of pharmacokinetic and clinical data. The relationship between *in vitro* antimicrobial susceptibility and clinical response is complex, as response also depends on severity of illness, site of infection, pharmacokinetics, pharmacodynamics, immune status, comorbidities and antibiotic dosing. Thus, although treating a patient according to the results of susceptibility testing increases the likelihood of recovery, it does not guarantee therapeutic success.

Susceptibility testing is often carried out by disc diffusion (Fig. 7.11). Antibiotic-impregnated filter paper discs are placed on agar plates containing bacteria; antibiotic diffuses into the agar, resulting in a concentration gradient centred on the disc. Bacteria are unable to grow where the antibiotic concentration exceeds the MIC, which may therefore be inferred from the size of the zone of inhibition. The MIC is commonly measured in diagnostic laboratories using ‘diffusion strips’.

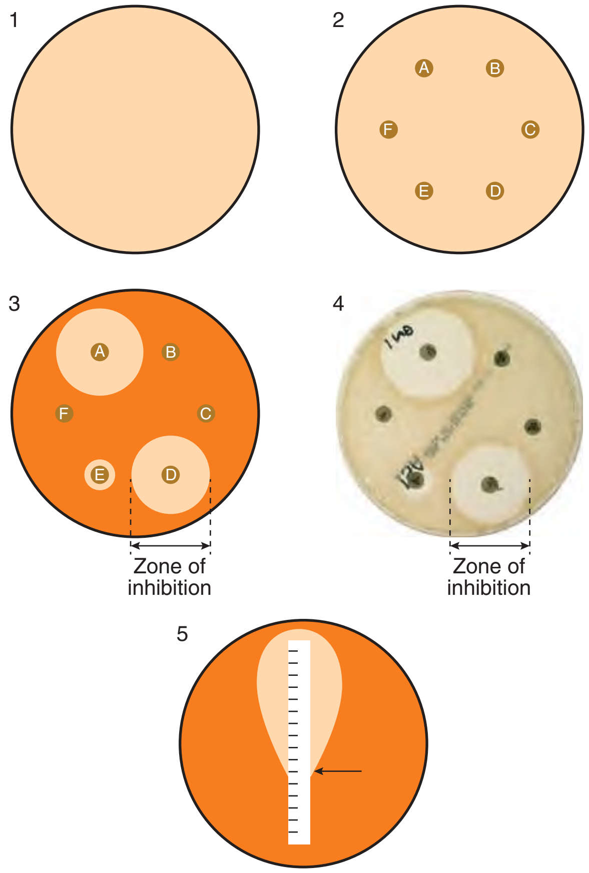

Fig. 7.11 Antimicrobial susceptibility testing by disc diffusion (panels 1–4) and minimum inhibitory concentration (MIC, panel 5). (1) The test organism is spread over the surface of an agar plate. (2) Antimicrobial-impregnated discs (A–F) are placed on the surface and the plate is incubated (e.g. overnight). (3–4) After incubation, zones of growth inhibition may be seen. The organism is considered susceptible if the diameter of the zone of inhibition exceeds a predetermined threshold. (5) In a ‘diffusion strip’ test, the strip is impregnated with antimicrobial at a concentration gradient that decreases steadily from top to bottom. The system is designed so that the MIC value is the point at which the ellipse cuts a scale on the strip (arrow). *(4) Courtesy of Charlotte Symes.*

Epidemiology of infection

The communicability of many infections means that, once a clinician has diagnosed an infectious disease, potential exposure of other patients must also be considered. Measures to control spread may be required at a patient level (e.g. separation from other patients ('isolation')), at organisation or institutional levels (e.g. in a nursing home or hospital), at a national level, or, in the case of a pandemic, at an international level (Ch. 6). The approach will be specific to the microorganism involved (Chs. 14 and 15) but the principles are outlined below.

Geographical and temporal patterns of infection

Endemic disease

Endemic disease has a constant presence within a given geographical area or population. The infectious agent may have a reservoir, vector or intermediate host that is geographically restricted, or may itself have restrictive environmental requirements (e.g. temperature range, humidity). The population affected may be geographically isolated or the disease may be limited to unvaccinated populations. Factors that alter geographical restriction include:

- expansion of an animal reservoir (e.g. Lyme disease from reforestation)
- vector escape (e.g. airport malaria)
- extension of host range (e.g. schistosomiasis from dam construction)
- importation of foods
- human migration (e.g. carbapenemase-producing *Klebsiella pneumoniae*)
- public health service breakdown (e.g. diphtheria in unvaccinated areas)
- climate change (e.g. dengue virus and Rift Valley fever)

Emerging and re-emerging disease

An emerging infectious disease is one that has newly appeared in a population, or has been known for some time but is increasing in incidence or geographical range. If the disease was previously known and thought to have been controlled or eradicated, it is considered to be re-emerging. Many emerging diseases are caused by organisms that infect animals and have undergone adaptations that enable them to infect humans. This is exemplified by HIV-1, which originated in higher primates in Africa (Ch. 14), and SARS-CoV-2, from bats potentially via intermediate hosts. The geographical pattern of some recent emerging and re-emerging infections is shown in Figure 7.12.

Reservoirs of infection

The US Centers for Disease Control (CDC) define a reservoir of infection as any person, other living organism, environment or combination of these in which the infectious agent lives and replicates and on which the infectious agent is dependent for its survival. The infectious agent is transmitted from this reservoir to a susceptible host.

Human reservoirs

Both colonised and infected individuals can act as human reservoirs, and infected human reservoirs may be asymptomatic. The organism must be long-lasting in at least a proportion of those affected, to facilitate onward transmission. Infections in which humans act as reservoirs include tuberculosis, MRSA, HIV and COVID-19. For some infections (e.g. measles) humans are the only known reservoir.

Animal reservoirs

The World Health Organization (WHO) defines a zoonosis as 'a disease or infection that is naturally transmissible from vertebrate animals to humans'. Infected animals may be asymptomatic. Zoonotic agents may be transmitted via any of the routes described below. Primary infection with zoonoses may be transmitted onward between humans, causing secondary disease (e.g. Q fever, brucellosis, Ebola virus disease).

Environmental reservoirs

Some pathogens are acquired from an environmental source (e.g. *Pseudomonas aeruginosa* from hospital water supplies). However, some of these are maintained in human or animal reservoirs, with the environment acting only as a conduit for infection.

Transmission of infection

Communicable diseases may be transmitted by one or more of the following routes:

- Respiratory route: airborne/droplet spread (see p. 349).
- Faecal–oral route: ingestion of material originating from faeces.
- Sexually transmitted infections: direct contact between mucous membranes.
- Blood-borne infections: direct inoculation of blood.
- Direct contact: very few organisms are capable of causing infection by direct contact with intact skin. Most infection by this route requires contact with damaged skin (e.g. surgical wound).
- Via a vector or fomite: the vector/fomite bridges the gap between the infected host or reservoir and the uninfected host. Vectors are animate, and include mosquitoes in malaria and dengue virus

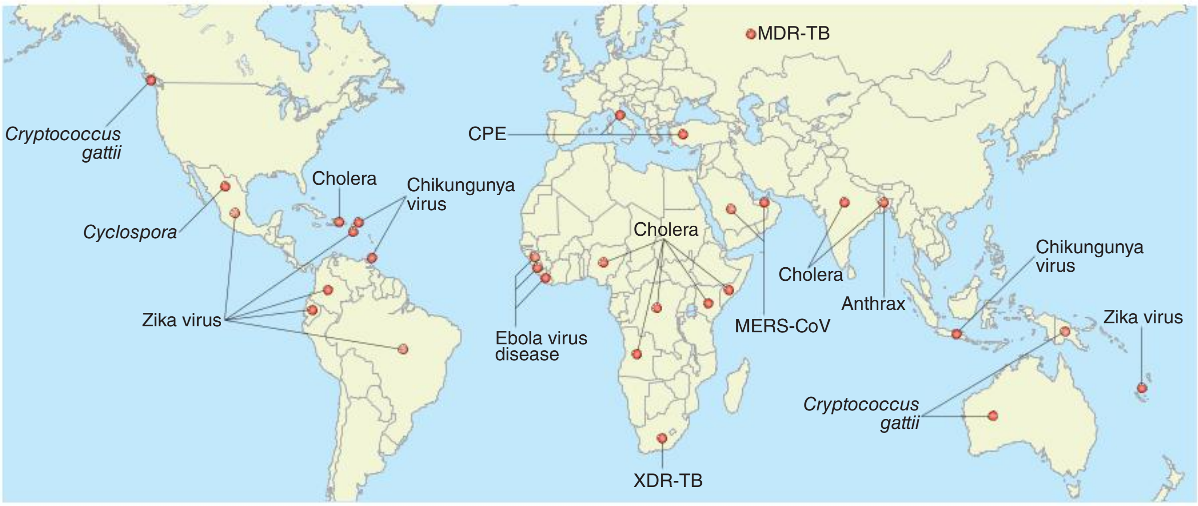

Fig. 7.12 Geographical locations of some infectious disease outbreaks, with examples of emerging and re-emerging diseases. Map lines delineate study areas and do not necessarily depict accepted national boundaries. (CPE = carbapenemase-producing Enterobacterales; MDR-TB = multidrug-resistant tuberculosis; MERS-CoV = Middle East respiratory syndrome coronavirus; XDR-TB = extensively drug-resistant tuberculosis)

infection and humans in MRSA. Fomites are inanimate objects such as door handles, water taps and ultrasound probes, which are particularly associated with health care–associated infection (HCAI).

The basic reproduction number (R_0) is a measure of the propensity for a communicable disease to spread between people; it is the average number of people one person with an infection is likely to pass on infection to. R_0 is calculated by mathematical models that take into account infection rates, the period of infectivity (known or estimated), opportunities for transmission and susceptibility to infection. R_0 assumes everyone is susceptible, whereas 'effective R' (R_e) takes into account the development of herd immunity within the population (e.g. from infection or vaccination) and therefore varies with time. R_0 and R_e are calculated for whole populations, so will hide local variations in transmission.

The likelihood of infection following transmission of a pathogen depends on the virulence of the organism and the susceptibility of the host. The incubation period is the time between exposure and development of symptoms, and the period of infectivity is the period after exposure during which the patient is infectious to others. Knowledge of incubation periods and periods of infectivity is important in controlling the spread of disease, although for many diseases these estimates are imprecise (Boxes 7.6 and 7.7).

7.6 Incubation periods of important infections[1]

Infection	Incubation period
Short incubation periods	
Anthrax, cutaneous[2]	9 hours to 2 weeks
Anthrax, inhalational[2]	2 days[3]
Bacillary dysentery[4]	1–6 days
Cholera[2]	2 hours to 5 days
Dengue haemorrhagic fever[5]	3–14 days
Diphtheria[5]	1–10 days
Gonorrhoea[6]	2–10 days
Influenza[4]	1–3 days
Meningococcaemia[2]	2–10 days
Norovirus[1]	1–3 days
SARS[2]	2–7 days[3]
SARS-CoV-2 (COVID-19)	3–6 days[7]
Scarlet fever[4]	2–4 days
Intermediate incubation periods	
Amoebiasis[5]	1–4 weeks
Brucellosis[6]	5–30 days
Chickenpox[4]	11–20 days
Lassa fever[2]	3–21 days
Malaria[2]	10–15 days
Measles[4]	6–19 days
Mumps[4]	15–24 days
Poliomyelitis[5]	3–35 days
Psittacosis[6]	1–4 weeks
Rubella[4]	15–20 days
Typhoid[4]	5–31 days
Whooping cough[4]	5–21 days
Long incubation periods	
Hepatitis A[4]	3–7 weeks
Hepatitis B[6]	6 weeks to 6 months
Leishmaniasis, cutaneous[5]	Weeks to months
Leishmaniasis, visceral[5]	Months to years
Leprosy (Hansen disease)[2]	5–20 years
Rabies[6]	3–12 weeks[3]
Trypanosoma brucei gambiense infection[5]	Months to years
Tuberculosis[4]	1–12 months

[1] Incubation periods are approximate and may differ from local or national guidance.

(SARS = severe acute respiratory syndrome)

Deliberate release

Deliberate release of pathogens with the intention of causing disease is known as biological warfare or bioterrorism. Deliberate release incidents have included a 750-person outbreak of *Salmonella* Typhimurium caused by contamination of salads in 1984 (Oregon, USA) and 22 cases of anthrax (five fatal) from the mailing of finely powdered (weaponised) anthrax (*Bacillus anthracis*) spores in 2001 (New Jersey, USA). Diseases with high potential for deliberate release include anthrax, plague, tularaemia, smallpox and botulism (through toxin release).

Infection prevention and control

Infection prevention and control (IPC) describes the measures applied to populations with the aim of breaking the chain of infection (see Fig. 7.1).

Health care–associated infection

The risk of developing infection following admission to a health-care facility (health care–associated infection, HCAI) in the developed world is about 10%. Many nosocomial bacterial infections are caused by organisms that are resistant to numerous antibiotics (multi-resistant bacteria), including MRSA, extended-spectrum β-lactamases (ESBLs) and CPE, and glycopeptide-resistant enterococci (GRE). Other infections of particular concern in hospitals include *C. difficile* and norovirus. Some examples are shown in Figure 7.13.

IPC measures are described in Box 7.8. The most important is maintenance of good hand hygiene (Fig. 7.14). Hand decontamination (e.g. using alcohol gel or washing) is mandatory before and after every patient contact. Decontamination with alcohol gel is usually adequate but hand-washing (with hot water, liquid soap and complete drying) is required after any procedure that involves more than casual physical contact, or if hands are visibly soiled. In situations where the prevalence of *C. difficile* is high (e.g. a local outbreak), alcohol gel decontamination between patient contacts is inadequate as it does not kill *C. difficile* spores, and hands must be washed.

7.7 Periods of infectivity in common childhood infectious diseases

Disease	Infectious period
Chickenpox[1]	From 4 days before until 5 days after appearance of the rash (transmission before 48 hours prior to the onset of rash is rare)[4]
Measles[2]	From 4 days before onset to 4 days after onset of the rash
Mumps[3]	From 2–3 days before to 5 days after disease onset[5]
Rubella[3]	From 10 days before until 15 days after the onset of the rash, but most infectious during prodromal illness[4]
Scarlet fever[1]	Unknown[6]
Whooping cough[1]	Unknown[7]

Fig. 7.13 Commonly encountered health care–associated infections (HCAIs) and the factors that predispose to them.

Some infections necessitate additional measures to prevent cross-infection (Box 7.9) and sometimes these are combined, e.g. both droplet and contact precautions in the case of SARS-CoV-2. To minimise risk of infection, invasive procedures must be performed using strict aseptic technique.

Outbreaks of infection

Descriptive terms for infectious disease outbreaks are defined in Box 7.10. Confirmation of an infectious disease outbreak usually requires evidence from 'typing' that the causal organisms have identical phenotypic and/or genotypic characteristics. When an outbreak of infection is suspected, a case definition is agreed. The number of cases that meet the case definition is then assessed by case-finding, using methods ranging from administration of questionnaires to national reporting systems. Case-finding usually includes microbiological testing, at least in the early stages of an outbreak. Temporal changes in cases are noted in order to plot an outbreak curve, and demographic details are collected to identify possible sources of infection. A case–control study, in which recent activities (potential exposures) of affected 'cases' are compared to those of unaffected 'controls', may be undertaken to establish the outbreak source, and measures are taken to manage the outbreak and control its spread. Good communication between relevant personnel during and after the outbreak is important to inform practice in future outbreaks.

Surveillance ensures that disease outbreaks are either prevented or identified early. In hospitals, staff are made aware of the isolation of 'alert organisms', which have the propensity to cause outbreaks, and 'alert conditions', which are likely to be caused by such organisms. Analogous systems are used nationally; many countries publish lists of organisms and diseases, which, if detected (or suspected), must be reported to public health authorities. Reasons why a disease might be reportable are shown in Box 7.11.

A pandemic is the most extensive form of outbreak, in which the disease spreads over a wide area and may affect a large proportion of the population. The most recent major global pandemic was the COVID-19 pandemic. The measures that may be put in place in an attempt to control a pandemic are shown in Box 7.12.

Immunisation

Immunisation may be passive or active. Passive immunisation is achieved by administering antibodies targeting a specific pathogen. Antibodies are obtained from blood, so confer some of the infection risks associated with blood products. The protection afforded by passive immunisation is immediate but of short duration (a few weeks or months); it is used to prevent or attenuate infection before or after exposure (Box 7.13).

Vaccination

Active immunisation is achieved by vaccination with whole organisms, organism components or nucleic acids (DNA/RNA) (Box 7.14).

Types of vaccine

Whole-cell vaccines consist of live or inactivated (killed) microorganisms. Component vaccines contain only extracted or synthesised components of microorganisms (e.g. polysaccharides or proteins). Live vaccines contain organisms with attenuated (reduced) virulence, which cause only mild symptoms but induce T-lymphocyte and humoral responses and are therefore more immunogenic than inactivated whole-cell vaccines. The use of live vaccines in immunocompromised individuals is not generally recommended, but they may be used by specialists following a risk/benefit assessment, e.g. in people with HIV and on antiretroviral therapy with undetectable HIV viral load and CD4 T-cell levels above certain thresholds, depending on the vaccine.

Component vaccines consisting only of polysaccharides, such as the pneumococcal polysaccharide vaccine (PPV), are poor activators of T lymphocytes and produce a short-lived antibody response without long-lasting memory. Conjugation of polysaccharide to a protein, as in the *Haemophilus influenzae* type B (Hib) vaccine and the protein conjugate pneumococcal vaccine (PCV), activates T lymphocytes, which results in a sustained response and immunological memory. Toxoids are bacterial toxins that have been modified to reduce toxicity but maintain antigenicity. Vaccine response can be improved by co-administration with mildly pro-inflammatory adjuvants, such as aluminium hydroxide.

i 7.8 Measures used in infection prevention and control (IPC)

Organisational measures

- Handling, storage and disposal of clinical waste
- Containment and safe removal of spilled blood and body fluids
- Cleanliness of environment and medical equipment
- Specialised ventilation (e.g. laminar flow, air filtration, controlled pressure gradients)
- Sterilisation and disinfection of instruments and equipment
- Food hygiene
- Laundry management

Health-care staff interventions

- Education
- Hand hygiene, including hand-washing (see Fig. 7.14)
- Sharps management and disposal
- Use of personal protective equipment (PPE, e.g. masks, sterile and non-sterile gloves, gowns and aprons)
- Screening health workers for disease (e.g. tuberculosis, hepatitis B virus, MRSA)
- Immunisation and post-exposure prophylaxis

Clinical practice

- Antibiotic stewardship
- Aseptic technique
- Perioperative antimicrobial prophylaxis
- Screening patients for colonisation or infection (e.g. MRSA, GRE, CPE)

Response to infections

- Surveillance to detect alert organism (see text) outbreaks and antimicrobial resistance
- Antibiotic chemoprophylaxis in infectious disease contacts, if indicated (see Box 7.20)
- Isolation (see Box 7.9)
- Reservoir control
- Vector control

Population measures

- See Box 7.12 and p. 349

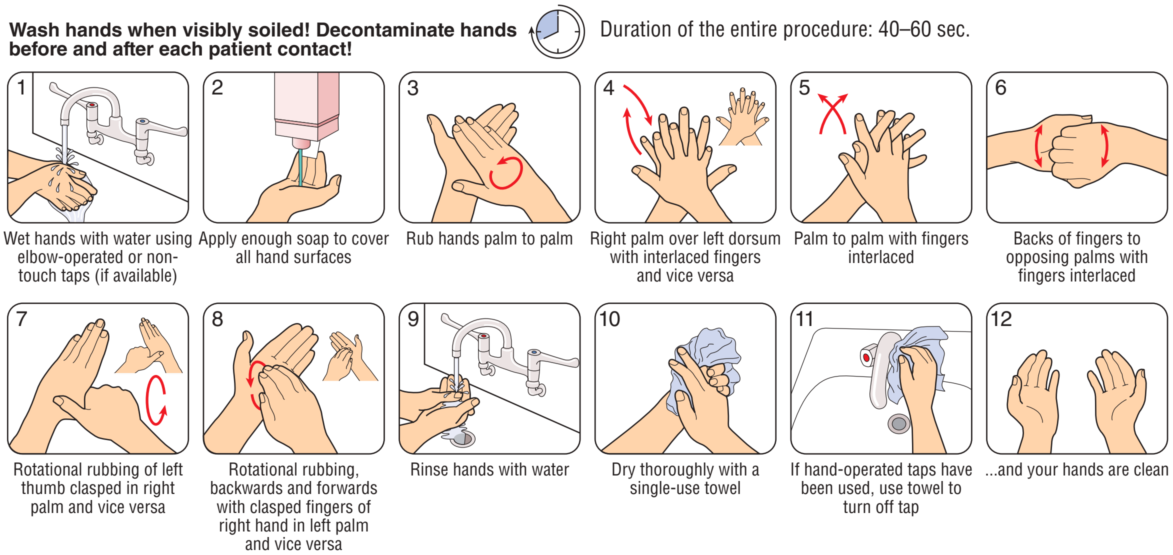
(CPE = carbapenemase-producing Enterobacterales; GRE = glycopeptide-resistant enterococci; MRSA = methicillin-resistant *Staphylococcus aureus*)

Recent and emerging vaccine approaches include nucleic acid (DNA or RNA)-based vaccines, in which the vaccine nucleic acid encodes the microbial component of interest; when the vaccine enters the vaccinee's cells they are induced to express viral antigens. They have several advantages over component vaccines: antigen is expressed for a period of time and with the modifications that the host cell would normally produce; antigen is presented by both major histocompatibility class I and II and induces broad B- and T-lymphocyte responses; vaccines are stable and cost-effective; production can be at large scale. DNA and RNA vaccines can be administered directly or may be added with other components to aid cell entry, e.g. liposomes for DNA vaccines or lipid nanoparticles for RNA vaccines. Long-term persistence and chromosomal integration with the potential for mutagenesis remain theoretical concerns for DNA vaccines.

Another approach is to use viral vectors in which an unrelated and modified virus expresses the antigen of interest. These vectors include poxviruses (e.g. modified vaccinia virus Ankara or canarypox virus), adenovirus or adeno-associated viruses. The vector may replicate or be non-replicating. These vaccines work on the same basis as DNA vaccines and are safe and stable. Pre-existing immunity to the vector can influence efficacy but use of rare human or related animal strains or a strategy of priming with a non-viral DNA vaccine can help overcome this ('prime-boost' strategy). Nucleic acid vaccines are administered intramuscularly or intradermally while viral vector vaccines can be given by these routes but also intranasally or orally. The first viral vector vaccine to receive clinical approval was for dengue virus, while to date DNA vaccines have only been used in veterinary settings. However, both strategies are employed in studies investigating a range of approaches against Ebola virus and pandemic infections. For COVID-19, vaccine approaches have included viral vectored, RNA, DNA, live attenuated, inactivated (killed) virus, subunit and virus-like particle (lacking genetic material) vaccines. The mRNA approaches allow frequent updates of vaccines to reflect the genetic makeup of currently circulating strains.

Use of vaccines

Vaccination may be applied to entire populations or to subpopulations at specific risk through travel, occupation or other activities. In ring vaccination, the population immediately surrounding a case or outbreak of infectious disease is vaccinated to curtail further spread. This strategy has been used for Ebola in West Africa. Vaccination is aimed mainly at preventing infectious disease. However, vaccination against human



Wash hands when visibly soiled! Decontaminate hands before and after each patient contact!

Duration of the entire procedure: 40–60 sec.

1 Wet hands with water using elbow-operated or non-touch taps (if available)

2 Apply enough soap to cover all hand surfaces

3 Rub hands palm to palm

4 Right palm over left dorsum with interlaced fingers and vice versa

5 Palm to palm with fingers interlaced

6 Backs of fingers to opposing palms with fingers interlaced

7 Rotational rubbing of left thumb clasped in right palm and vice versa

8 Rotational rubbing, backwards and forwards with clasped fingers of right hand in left palm and vice versa

9 Rinse hands with water

10 Dry thoroughly with a single-use towel

11 If hand-operated taps have been used, use towel to turn off tap

12 ...and your hands are clean

Fig. 7.14 Hand-washing. Good hand hygiene, whether with soap/water or alcohol handrub, includes areas that are often missed, such as fingertips, web spaces, palmar creases and the backs of hands. *Adapted from 'How to Handwash': who.int/publications/m/item/how-to-handwash © World Health Organization 2009. All rights reserved.*

7.9 Types of isolation precaution in health-care settings[1]

Contact transmission[2]	Droplet transmission[2,3]	Airborne transmission[2,3]	High consequence infectious diseases (HCID)[2,4]
Precautions			
Private room preferred (otherwise, inter-patient spacing ≥ 1 m, consider cohorting approaches) PPE: Gloves and gown for staff in contact with patient or contaminated areas	Private room preferred (otherwise, inter-patient spacing ≥ 1 m, consider cohorting approaches) PPE: Surgical masks for staff prior to entry into patient room. Cover eyes with visor or goggles if splash risk is high.	Negative pressure private room with air exhausted externally or filtered[1] PPE: N95 masks or personal respirators for staff Avoid using non-immune staff (e.g. in care of patients with chickenpox)	Single patient room, with negative pressure if airborne HCID PPE: N95 masks or personal respirators, goggles or visor, fluid-resistant or impermeable gowns, multiple layers of gloves (e.g. two or three), leg and shoe covering/boots. Appropriate training in donning and doffing of PPE with a buddy is essential[5] Special handling of waste
Examples of infections managed with these precautions			
Enteroviral infections in young children (diapered or incontinent) Norovirus *Clostridioides difficile* infection Multidrug-resistant organisms (e.g. MRSA, ESBL, GRE, VRSA, penicillin-resistant *Streptococcus pneumoniae*) Parainfluenza in infants and young children Rotavirus RSV in infants, children and immunocompromised[2] Viral conjunctivitis, acute SARS-CoV-2[2] VZV (chickenpox or disseminated disease)[2]	Diphtheria, pharyngeal *Haemophilus influenzae* type b infection Herpes simplex infection, disseminated or severe Influenza[2] SARS-CoV-2[2] Meningococcal infection Mumps *Mycoplasma pneumoniae* Parvovirus (erythrovirus) B19 (erythema infectiosum, fifth disease) Pertussis Plague, pneumonic Rubella *Streptococcus pyogenes* (group A), pharyngeal	Measles Tuberculosis, pulmonary or laryngeal, suspected VZV (chickenpox or disseminated disease)[2] SARS-CoV-2[2]	Viral haemorrhagic fevers due to Lassa, Ebola, Marburg, Crimean–Congo fever viruses Avian influenza viruses (e.g. H5N1)

[1] Recommendations based on 2007 CDC guideline for isolation precautions, revised in July 2023. May differ from local or national recommendations.
[2] In addition to standard infection prevention precautions such as good hand hygiene and safe injection practices, which apply in all cases.
[3] In many cases gloves and gown are worn for primarily droplet and airborne transmitted pathogens as contact transmission can also occur.
[4] High consequence infectious diseases (HCIDs) are acute infectious diseases that typically have high case-fatality rate, may not have effective prophylaxis or treatment, and have the ability to spread in the community and within health-care settings. They can often be difficult to recognise and detect rapidly. HCIDs can be airborne HCIDs and/or contact HCIDs (see Ch. 14). https://www.gov.uk/guidance/high-consequence-infectious-diseases-hcid#infection-prevention-and-control-in-healthcare-settings.
[5] Based on 2007 CDC guideline for isolation precautions, revised in July 2023; and NHS England addendum on high consequence infectious disease (HCID) personal protective equipment (PPE): england.nhs.uk/national-infection-prevention-and-control-manual-nipcm-for-england/addendum-on-hcid-ppe; 2025.
(ESBL = extended-spectrum β-lactamase; GRE = glycopeptide-resistant enterococci; MRSA = methicillin-resistant *Staphylococcus aureus*; RSV = respiratory syncytial virus; SARS = severe acute respiratory syndrome; VRSA = vancomycin-resistant *Staphylococcus aureus*; VZV = varicella zoster virus)

papillomavirus (HPV) was successfully introduced to prevent cervical and other cancers that complicate HPV infection. Vaccination guidelines for individuals are shown in Box 7.15.

Vaccination becomes successful for a population once the number of susceptible hosts falls below the level required to sustain continued transmission of the target organism, i.e. when R_e is less than 1 ('herd immunity'). Naturally acquired smallpox was declared to have been eradicated worldwide in 1980 through mass vaccination. In 1988, the WHO resolved to eradicate poliomyelitis by vaccination; the number of cases of wild poliovirus infection worldwide has since fallen from approximately 350 000 per annum to 6 in 2021. Recommended vaccination schedules, including catch-up schedules for people who join vaccination programmes late, vary between countries.

Antimicrobial stewardship

Antimicrobial stewardship (AMS) refers to the systems and processes applied to a population to optimise the use of antimicrobial agents. The populations referred to here may be a nation, region, hospital, or a unit within a health-care organisation (e.g. ward or clinic). AMS aims to improve patient outcomes and reduce antimicrobial resistance (AMR). IPC and AMS complement each other (Fig. 7.15). Elements of AMS include treatment guidelines, antimicrobial formularies and ward rounds by infection specialists.

Treatment of infectious diseases

Key components of treating infection are:

- prompt initiation of antimicrobial therapy in severe infections, e.g. sepsis, meningitis
- optimising antimicrobial therapy while minimising selection for antimicrobial resistance and the impact on the normal microbial flora
- addressing predisposing factors, e.g. glycaemic control in diabetes; viral load control in HIV-1 infection
- achieving source control, e.g. removal of an infected medical device, pus or necrotic tissue
- managing complications, e.g. sepsis and acute kidney injury.

For communicable disease, treatment must also take into account contacts of the infected patient, and may include IPC interventions such as isolation, antimicrobial prophylaxis, vaccination and contact tracing.

Principles of antimicrobial therapy

In some situations (e.g. pneumonia, meningitis, sepsis) it is important to start appropriate antimicrobial therapy promptly, whereas in others prior confirmation of the diagnosis and pathogen is preferred. The principles underlying the choice of antimicrobial agent(s) are discussed below. The WHO 'World Antibiotic Awareness Week' campaign is a yearly event

i 7.10 Terminology in outbreaks of infection

Term	Definition
Classification of related cases of infectious disease*	
Cluster	An aggregation of cases of a disease that are closely grouped in time and place, and may or may not exceed the expected number
Epidemic	The occurrence of more cases of disease than expected in a given area or among a specific group of people over a particular period of time
Outbreak	Synonymous with epidemic. Alternatively, a localised, as opposed to generalised, epidemic
Pandemic	An epidemic occurring over a very wide area (several countries or continents) and usually affecting a large proportion of the population
Classification of affected patients (cases)	
Index case	The first case identified in an outbreak
Primary cases	Cases acquired from a specific source of infection
Secondary cases	Cases acquired from primary cases
Types of outbreak	
Common source outbreak	Exposure to a common source of infection (e.g. water-cooling tower, medical staff member shedding MRSA). New primary cases will arise until the source is no longer present
Point source outbreak	Exposure to a single source of infection at a specific point in time (e.g. contaminated food at a party). Primary cases will develop disease synchronously
Person-to-person spread	Outbreak with both primary and secondary cases. May complicate point source or common source outbreak

*Adapted from cdc.gov.
(MRSA = methicillin-resistant *Staphylococcus aureus*)

aimed at highlighting the importance of prudent antimicrobial prescribing (see ‘Further information’).

Antimicrobial action and spectrum

Antimicrobial agents may kill or inhibit microorganisms by targeting essential and non-essential cellular processes, respectively. The range, or spectrum, of microorganisms that is killed or inhibited by a particular antimicrobial agent needs consideration when selecting therapy. Mechanisms of action of the major classes of antibacterial agent are listed in Box 7.16 and appropriate agents for some common infecting organisms are shown in Box 7.17.

Empiric versus targeted therapy

Empiric antimicrobial therapy is selected to treat a suspected infection (e.g. meningitis) before the microbiological cause is known. Targeted or ‘directed’ therapy can be prescribed when the pathogen(s) is known. Empirical antimicrobial regimens need to have activity against the range of pathogens potentially causing the infection; because broad-spectrum agents affect a wide range of bacteria they select for antimicrobial resistance. ‘Start Smart – Then Focus’ (Fig. 7.16) describes the principle of converting from empiric therapy to narrow-spectrum targeted therapy. Optimum empiric therapy depends on the site of infection, patient characteristics and local antimicrobial resistance patterns. National or local guidelines should inform antimicrobial prescribing decisions.

i 7.11 Reasons for including an infectious disease on a regional/national list of reportable diseases*

Reason for inclusion	Examples
Endemic/local disease with the potential to spread and/or cause outbreaks	Influenza, *Salmonella*, tuberculosis
Imported disease with the propensity to spread and/or cause outbreaks	Typhoid, cholera (depending on local epidemiology)
Evidence of a possible breakdown in health protection/public health functions	*Legionella*, *Cryptosporidium*
Evidence of a possible breakdown in food safety practices	Botulism, verotoxigenic *Escherichia coli*
Evidence of a possible failure of a vaccination programme	Measles, poliomyelitis, pertussis
Disease with the potential to be a novel or increasing threat to human health	COVID-19, MERS-CoV, multi-resistant bacteria
Evidence of expansion of the range of a reservoir/vector	Lyme disease, rabies, West Nile encephalitis
Evidence of possible deliberate release	Anthrax, tularaemia, plague, smallpox, botulism

*Given the different geographical ranges of individual diseases and wide national variations in public health services, vaccination programmes and availability of resources, reporting regulations vary between regions, states and countries. Many diseases are reportable for more than one reason.
(MERS-CoV = Middle East respiratory syndrome)

i 7.12 Pandemic response*

- International travel restrictions
- National entry screening (e.g. testing for fever or pathogen) and quarantining new arrivals from areas with high infection rates
- Isolation of disease contacts
- Social isolation
- Shielding (strict separation of the vulnerable)
- Social distancing (maintaining physical separation between people and restricting public gatherings)
- Encouraging home working
- Restricting commuting and work-related travel to ‘key workers’ (workers required to maintain a functioning society)
- Home education
- Curfews
- Closure or reduction in public transport
- Requirement for PPE use in public areas (e.g. face coverings, eye protection)
- Litigation and imposition of legal sanctions to enforce the above responses

*Pandemic control measures vary widely by jurisdiction and depend on the stage and extent of the outbreak and political considerations such as the acceptability of restriction of personal freedoms and the economic consequences of the interventions.

Combination therapy

It is sometimes appropriate to combine antimicrobial agents:

- when there is a need to increase clinical effectiveness (e.g. biofilm infections)
- when no single agent’s spectrum covers all potential pathogens (e.g. polymicrobial infection)
- when there is a need to reduce development of antimicrobial resistance in the target pathogen, as the organism would need to develop resistance to multiple agents simultaneously (e.g. antituberculous chemotherapy and antiretroviral therapy (ART) for HIV; p. 334).

7.13 Indications for post-exposure prophylaxis with immunoglobulins*

Human normal immunoglobulin (pooled immunoglobulin)

- Hepatitis A (unvaccinated contacts)
- Measles (exposed child with heart or lung disease)

Human specific immunoglobulin

- Hepatitis B (sexual partners, inoculation injuries, infants born to infected mothers)
- Tetanus (high-risk wounds or incomplete or unknown immunisation status)
- Rabies
- Chickenpox (immunosuppressed children and adults, pregnant women)

*Active immunisation is preferred if contact is with a patient who is within 1 week of onset of jaundice.

7.14 Vaccines in current clinical use

Live attenuated vaccines

- Dengue virus (TAK-003)
- Measles, mumps, rubella (MMR)
- Oral poliomyelitis (OPV, not used in UK)
- Live attenuated influenza vaccine (intranasal)
- Rotavirus (oral)
- Tuberculosis (bacille Calmette–Guérin, BCG)
- Typhoid (oral typhoid vaccine)
- Varicella zoster virus (e.g. Varivax, Zostavax)

Inactivated (killed) whole-cell vaccines

- Cholera
- Hepatitis A
- Influenza
- Poliomyelitis (inactivated polio virus, IPV)
- Rabies
- COVID-19

Component vaccines

- Anthrax (adsorbed extracted antigens)
- COVID-19
- Diphtheria (adsorbed toxoid)
- Hepatitis B (adsorbed recombinant hepatitis B surface antigen, HBsAg)
- *Haemophilus influenzae* type B (conjugated capsular polysaccharide)
- Human papillomavirus (recombinant capsid proteins)
- Influenza (containing hemagglutinin component only)
- Meningococcal, quadrivalent A, C, Y, W135 (conjugated capsular polysaccharide)
- Meningococcal, serogroup B combining specific protein components and outer membrane vesicles from serogroup B strains
- Pertussis (adsorbed extracted antigens)
- Pneumococcal conjugate (PCV; conjugated capsular polysaccharide, 13 or more serotypes)
- Pneumococcal polysaccharide (PPV; purified capsular polysaccharide, 23 serotypes)
- Tetanus (adsorbed toxoid)
- Typhoid (purified Vi capsular polysaccharide; typhoid conjugate vaccine (TCV))
- Varicella zoster virus (Shingrix; glycoprotein E with ASO1$_{B}$ adjuvant)

Viral vector vaccines

- Dengue virus (CYD-TDV; containing yellow fever 17D vaccine strain with dengue virus genes)
- Ebola virus (vesicular stomatitis virus expressing Ebola virus glycoproteins)
- COVID-19

Virus-like particles (VLP)

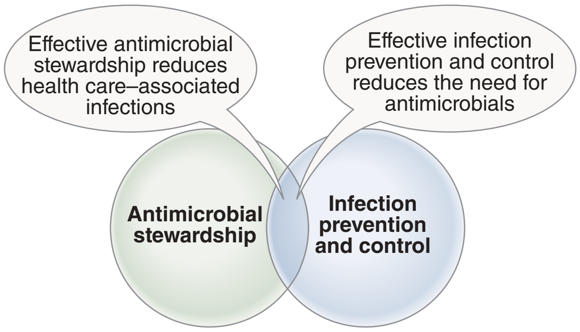
- Human papillomavirus (HPV)

Nucleic acid vaccines

- COVID-19 (RNA vaccines)
- Ebola virus (DNA in clinical trials)

7.15 Guidelines for vaccination against infectious disease

- The principal contraindication to inactivated vaccines is an anaphylactic reaction to a previous dose or a vaccine component
- Live vaccines should not be given during an acute infection, to pregnant women or to the immunosuppressed, unless the immunosuppression is mild and the benefits outweigh the risks
- If two live vaccines are required, they should be given either simultaneously in opposite arms or 4 weeks apart
- Live vaccines should not be given for 3 months after an injection of human normal immunoglobulin (HNI)
- HNI should not be given for 2 weeks after a live vaccine
- Hay fever, asthma, eczema, sickle-cell disorder, topical glucocorticoid therapy, antibiotic therapy, prematurity and chronic heart and lung diseases, including tuberculosis, are not contraindications to vaccination



Effective antimicrobial stewardship reduces health care–associated infections
Effective infection prevention and control reduces the need for antimicrobials
Antimicrobial stewardship
Infection prevention and control

Fig. 7.15 The relationship between infection prevention and control (IPC) and antimicrobial stewardship (AMS).

7.16 Target and mechanism of action of common antibacterial agents

Aminoglycosides, chloramphenicol, macrolides, lincosamides, oxazolidinones

- Inhibition of bacterial protein synthesis by binding to subunits of bacterial ribosomes

Tetracyclines

- Inhibition of protein synthesis by preventing transfer RNA binding to ribosomes

β-lactams

- Inhibition of cell wall peptidoglycan synthesis by competitive inhibition of transpeptidases ('penicillin-binding proteins')

Glycopeptides

- Inhibition of cell wall peptidoglycan synthesis by forming complexes with D-alanine residues on peptidoglycan precursors

Cyclic lipopeptide (daptomycin)

- Insertion of lipophilic tail into plasma membrane causing depolarisation and cell death

Fluoroquinolones

- Inhibition of DNA replication by binding to DNA topoisomerases (DNA gyrase and topoisomerase IV), preventing supercoiling and uncoiling of DNA

Nitroimidazoles

- The reduced form of the drug causes strand breaks in DNA

Rifamycins

- Inhibition of RNA synthesis by inhibiting DNA-dependent RNA polymerase

Sulphonamides and trimethoprim

- Inhibition of folate synthesis by dihydropteroate synthase (sulphonamides) and dihydrofolate reductase (trimethoprim) inhibition

7.17 Antimicrobial options for common infecting bacteria

Organism	Antimicrobial options*
Gram-positive organisms	
Enterococcus faecalis	Ampicillin, vancomycin/teicoplanin
Enterococcus faecium	Vancomycin/teicoplanin, linezolid
Glycopeptide-resistant enterococci	Linezolid, tigecycline, daptomycin
MRSA	Clindamycin, vancomycin, rifampicin (never used as monotherapy), linezolid, daptomycin, tetracyclines, tigecycline, co-trimoxazole
Staphylococcus aureus (methicillin sensitive)	Flucloxacillin, clindamycin
Streptococcus pyogenes	Penicillin, clindamycin, vancomycin
Streptococcus pneumoniae	Penicillin, cephalosporins, levofloxacin, vancomycin
Gram-negative organisms	
E. coli, 'coliforms' (enteric gram-negative bacilli)	Amoxicillin, trimethoprim, cefuroxime, ciprofloxacin, co-amoxiclav
Enterobacter spp., *Citrobacter* spp.	Ciprofloxacin, meropenem, ertapenem, aminoglycosides
ESBL-producing Enterobacterales	Ciprofloxacin, meropenem, ertapenem (if sensitive), temocillin, aminoglycosides
Carbapenemase-producing Enterobacterales	Ciprofloxacin, aminoglycosides, tigecycline, colistin
Haemophilus influenzae	Amoxicillin, co-amoxiclav, macrolides, cefuroxime, cefotaxime, ciprofloxacin
Legionella pneumophila	Azithromycin, levofloxacin, doxycycline
Neisseria gonorrhoeae	Ceftriaxone/cefixime, spectinomycin
Neisseria meningitidis	Penicillin, cefotaxime/ceftriaxone, chloramphenicol
Pseudomonas aeruginosa	Ciprofloxacin, piperacillin–tazobactam, aztreonam, meropenem, aminoglycosides, ceftazidime/cefepime
Salmonella Typhi	Ceftriaxone, azithromycin (uncomplicated typhoid), chloramphenicol (resistance common)
Strict anaerobes	
Bacteroides spp.	Metronidazole, clindamycin, co-amoxiclav, piperacillin–tazobactam, meropenem
Clostridioides difficile	Metronidazole, vancomycin (oral), fidaxomicin
Clostridium spp.	Penicillin, metronidazole, clindamycin
Fusobacterium spp.	Penicillin, metronidazole, clindamycin
Other organisms	
Chlamydia trachomatis	Azithromycin, doxycycline
Treponema pallidum	Penicillin, doxycycline

*Antibiotic selection depends on multiple factors, including local susceptibility patterns, which vary enormously between geographical areas. There are many appropriate alternatives to those listed.
(ESBL= extended-spectrum β-lactamase; MRSA = methicillin-resistant *Staphylococcus aureus*)

Antimicrobial resistance

Microorganisms have evolved in the presence of naturally occurring antibiotics and have therefore developed resistance mechanisms to all classes of antimicrobial agent (antibiotics and their derivatives) (Fig. 7.17). Intrinsic resistance is an innate property of a microorganism, whereas acquired resistance arises by spontaneous mutation or horizontal transfer of genetic material from another organism, usually via a plasmid. Plasmids can be easily transferred between bacteria (especially Enterobacterales) and often encode resistance to multiple antibiotics.

Penicillin-binding proteins (PBP) are enzymes involved in bacterial cell wall synthesis. The *mecA* gene encodes a PBP, which has a low affinity for penicillins and therefore confers resistance to β-lactam antibiotics in staphylococci. Extended-spectrum β-lactamases (ESBLs) are bacterial-produced enzymes that break down β-lactam antibiotics, and are frequently encoded on plasmids in Enterobacterales. Plasmid-encoded carbapenemases have been detected in strains of *Klebsiella pneumoniae* (e.g. New Delhi metallo-β-lactamase 1, NDM-1). Strains of MRSA have been described that also have reduced susceptibility to glycopeptides through the development of a relatively impermeable cell wall.

Factors promoting antimicrobial resistance include the inappropriate use of antibiotics (e.g. to treat viral infections), inadequate dosage or unnecessarily prolonged treatment, and use of antimicrobials as growth promoters in agriculture. However, *any* antimicrobial use exerts a selection pressure that favours the development of resistance. Combination antimicrobial therapy may reduce the emergence of resistance in the target pathogen but not in the normal flora that it also affects. Despite use of combination therapy for *M. tuberculosis*, multidrug-resistant tuberculosis (MDR-TB) and extremely drug-resistant tuberculosis (XDR-TB) have been reported worldwide and are increasing in incidence (see p. 563).

The term 'post-antibiotic era' was coined to describe a future in which widespread antimicrobial resistance will render antimicrobials useless. At present there is a gradual but inexorable progression of resistance globally, necessitating the use of more expensive antimicrobials or older antimicrobials with significant toxicity.

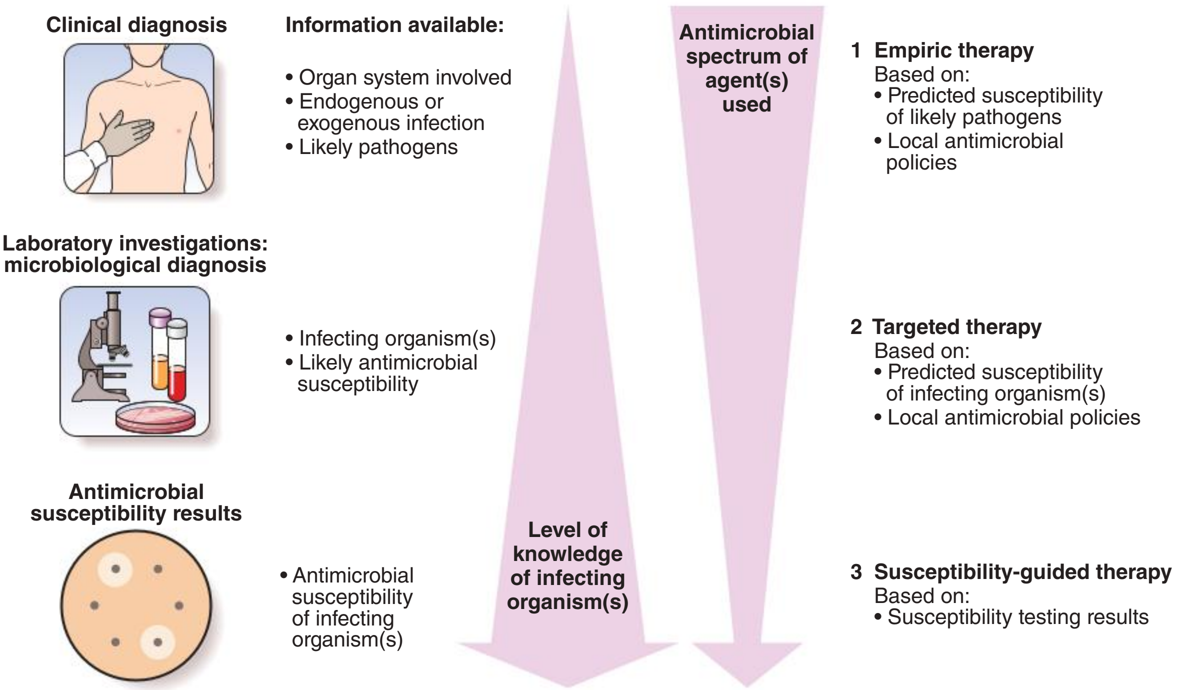
Duration of therapy

Treatment duration reflects the severity of infection and accessibility of the infected site to antimicrobial agents. For most infections, there is limited evidence available to support a specific duration of treatment (Box 7.18). Depending on the indication, initial intravenous therapy can often be switched to oral as soon as the patient is apyrexial and improving. In the absence of specific guidance, antimicrobial therapy should be stopped when there is no longer any clinical evidence of infection and increasingly trial data supports shorter durations (Box 7.19).

Pharmacokinetics and pharmacodynamics

Pharmacokinetics of antimicrobial agents is the study of how antibiotics are absorbed, distributed and excreted from the body. Septic patients often have poor gastrointestinal absorption, so the preferred initial route of therapy is intravenous. Knowledge of anticipated antimicrobial drug concentrations at sites of infection is critical. For example, achieving a 'therapeutic' blood level of gentamicin is of little practical use in treating meningitis, as CSF penetration of the drug is poor. Knowledge of routes of antimicrobial elimination is also critical; for instance, urinary tract infection is ideally treated with a drug that is excreted unchanged in the urine.

Pharmacodynamics describes the complex relationship between antimicrobial concentrations and microbial killing in the body. For many agents, antimicrobial effect can be categorised as 'concentration-dependent' or for many others as 'time-dependent'. The concentration of antimicrobial achieved after a single dose is illustrated in Figure 7.18. The maximum concentration achieved is C_{max} and the measure of overall exposure is the area under the curve (AUC). The efficacy of antimicrobial agents whose killing is concentration-dependent (e.g. aminoglycosides) increases with the amount by which C_{max} exceeds the minimum inhibitory concentration (C_{max} : MIC ratio). For this reason, it has become customary to administer aminoglycosides (e.g. gentamicin) infrequently at high doses (e.g. 7 mg/kg) rather than frequently at low doses. This has the added advantage of minimising toxicity by reducing the likelihood of drug accumulation. Conversely, the β-lactam antibiotics and vancomycin exhibit time-dependent killing, and their efficacy depends on C_{max} exceeding the MIC for a certain time (which is different for each class of agent). This is reflected in the dosing interval of benzylpenicillin, which is



Clinical diagnosis

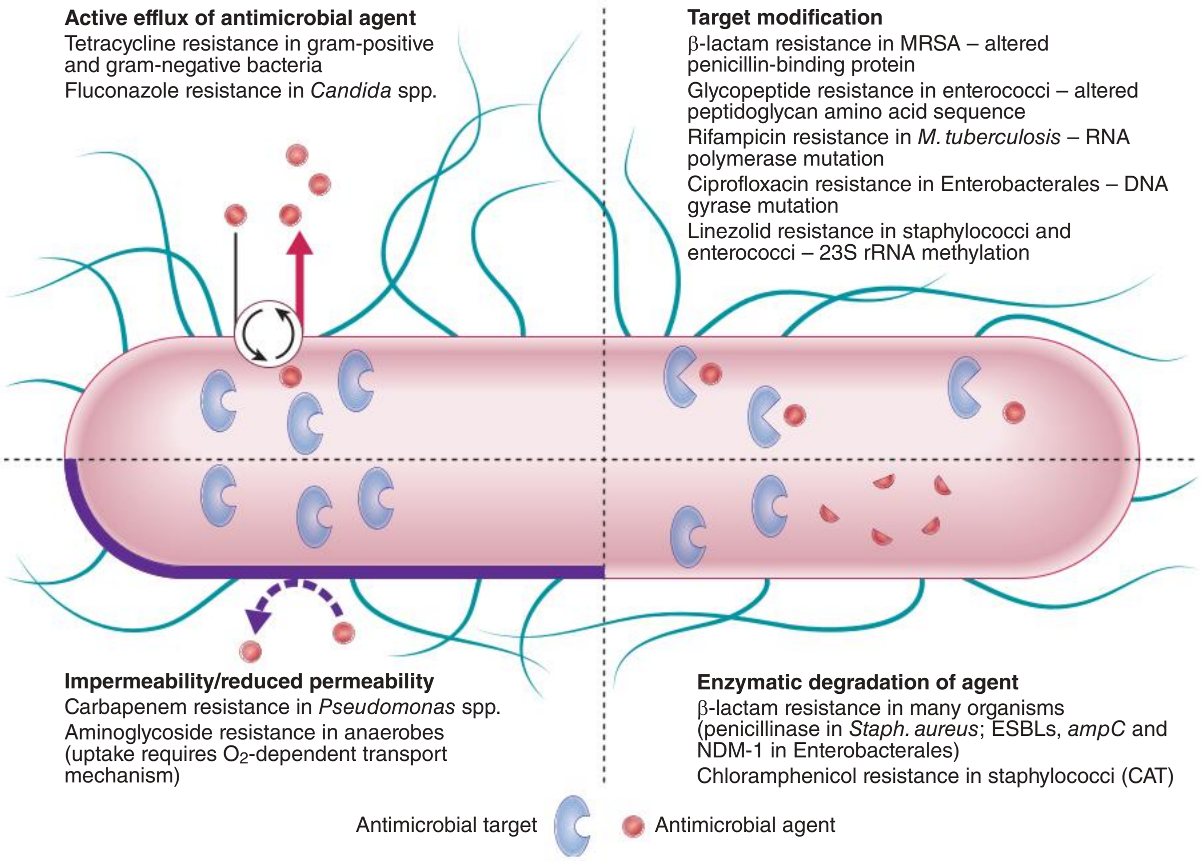
Fig. 7.16 **Stages in the selection and refinement of antimicrobial therapy: 'Start Smart – Then Focus'.**



Active efflux of antimicrobial agent
Tetracycline resistance in gram-positive and gram-negative bacteria
Fluconazole resistance in *Candida* spp.

Target modification
β-lactam resistance in MRSA – altered penicillin-binding protein
Glycopeptide resistance in enterococci – altered peptidoglycan amino acid sequence
Rifampicin resistance in *M. tuberculosis* – RNA polymerase mutation
Ciprofloxacin resistance in Enterobacterales – DNA gyrase mutation
Linezolid resistance in staphylococci and enterococci – 23S rRNA methylation

Impermeability/reduced permeability
Carbapenem resistance in *Pseudomonas* spp.
Aminoglycoside resistance in anaerobes (uptake requires O_2-dependent transport mechanism)

Enzymatic degradation of agent
β-lactam resistance in many organisms (penicillinase in *Staph. aureus*; ESBLs, *ampC* and NDM-1 in Enterobacterales)
Chloramphenicol resistance in staphylococci (CAT)

Antimicrobial target
Antimicrobial agent

Fig. 7.17 **Examples of mechanisms of antimicrobial resistance.** (CAT = chloramphenicol acetyltransferase; ESBLs = extended-spectrum β-lactamases; MRSA = methicillin-resistant *Staph. aureus*; NDM-1 = New Delhi metallo-β-lactamase 1)

7.18 Duration of antimicrobial therapy for some common infections*

Infection	Duration of therapy
Viral infections	
Herpes simplex encephalitis	2–3 weeks
Bacterial infections	
Gonorrhoea	Single dose
Infective endocarditis (streptococcal, native valve)	4 weeks ± gentamicin for first 2 weeks
Infective endocarditis (prosthetic valve)	6 weeks
Osteomyelitis	6 weeks
Pneumonia (community-acquired, severe)	3–5 days (no organism identified), 14–21 days (*Staphylococcus aureus* or *Legionella* spp.)
Septic arthritis	2–4 weeks
Urinary tract infection (male)	1–2 weeks depending on severity
Urinary tract infection, upper tract, uncomplicated (female)	7 days
Urinary tract infection, lower (female)	3 days
Intra-abdominal infection	4–5 days
Mycobacterial infections	
Tuberculosis (meningeal)	12 months
Tuberculosis (pulmonary)	6 months
Fungal infections	
Invasive pulmonary aspergillosis	Until clinical/radiological resolution and reversal of predisposition
Candidaemia (acute disseminated)	2 weeks after last positive blood culture and resolution of signs and symptoms

*All recommendations are indicative. Actual duration takes into account predisposing factors, specific organisms and antimicrobial susceptibility, source control, current guidelines and clinical response.

7.19 Examples of common bacterial infections where shorter antimicrobial durations have equivalent efficacy*

Syndrome	Shorter duration	Longer duration
Community-acquired pneumonia	3–5 days	5–14 days
Complicated urinary tract infection/pyelonephritis	5–7 days	10–14 days
Intra-abdominal infection	4 days	8–10 days
Bacterial meningitis (paediatrics)	4–7 days	7–14 days
Septic arthritis	14 days	28 days

*Examples from Shorter is Better (bradspellberg.com/shorter-is-better), but note caveats apply and shorter duration in many cases assumes lower severity scores and absence of certain criteria that may indicate longer durations.

usually given every 4 hours in severe infection (e.g. meningococcal meningitis), and may be administered by continuous infusion. For other antimicrobial agents, the pharmacodynamic relationships are more complex and often less well understood. With some agents, bacterial inhibition persists after antimicrobial exposure (post-antibiotic and post-antibiotic sub-MIC effects).

Therapeutic drug monitoring

Therapeutic drug monitoring is used to confirm that levels of antimicrobial agents with a low therapeutic index (e.g. aminoglycosides) are not excessive, and that levels of agents with marked pharmacokinetic variability (e.g. vancomycin) are adequate. Specific recommendations for monitoring depend on individual clinical circumstances; for instance, different pre- and post-dose levels of gentamicin are recommended, depending on whether it is being used in traditional divided doses, once daily or for synergy in infective endocarditis (p. 498).

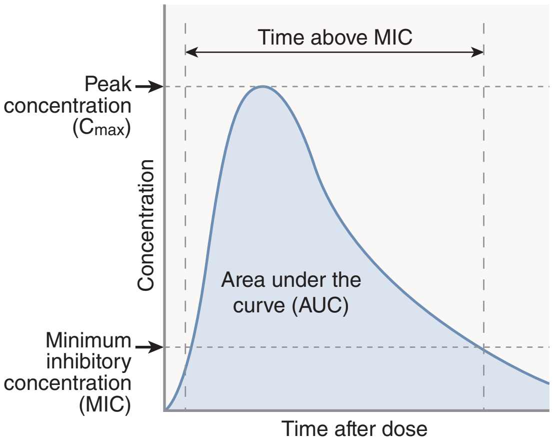


Fig. 7.18 **Antimicrobial pharmacodynamics.** The curve represents drug concentrations after a single dose of an antimicrobial agent. Factors that determine microbial killing are C_{max} : MIC ratio (concentration-dependent killing), time above MIC (time-dependent killing) and AUC : MIC ratio.

Antimicrobial prophylaxis

Antimicrobial prophylaxis is the use of antimicrobial agents to prevent infection. Primary prophylaxis is used to reduce the risk of infection following certain medical procedures (e.g. colonic resection or prosthetic hip insertion), following exposure to a specific pathogen (e.g. *Bordetella pertussis*) or in specific situations such as post-splenectomy (Box 7.20). Antimicrobial prophylaxis should be chosen to have minimal adverse effects and based on robust evidence. In the case of exposure, it may be combined with passive immunisation (see Box 7.13). Secondary prophylaxis is used in patients who have been treated successfully for an infection but remain predisposed to it. It is used in haemato-oncology patients in the context of fungal infection and in HIV-positive individuals with an opportunistic infection until a defined level of immune reconstitution is achieved.

Antibacterial agents

For details of antibacterial usage in pregnancy and old age, see Boxes 7.21 and 7.22.

Beta-lactam antibiotics

These antibiotics have a β-lactam ring structure and exert a bactericidal action by inhibiting PBPs and cell wall synthesis. They are classified in Box 7.23.

Pharmacokinetics

- Good drug levels are achieved in lung, kidney, bone, muscle and liver, and in pleural, synovial, pericardial and peritoneal fluids.
- CSF levels are low, except when meninges are inflamed.
- 'Inoculum effect': the activity of β-lactams is reduced in the presence of a high organism burden, although the clinical relevance of this effect is a subject of debate.
- Generally safe in pregnancy (except imipenem/cilastatin).

Adverse effects

Immediate (IgE-mediated) allergic reactions are rare but life-threatening. Approximately 90% of patients who report a penicillin allergy do not have a true IgE-mediated allergy, highlighting the importance of careful allergy histories, documentation of reactions and rechallenge of select patients without a clear history of a significant drug allergy.

7.20 Recommendations for antimicrobial prophylaxis in adults*

Infection risk	Recommended antimicrobial
Bacterial	
Diphtheria (prevention of secondary cases)	Erythromycin
Gas gangrene (after high amputation or major trauma)	Penicillin or metronidazole
Lower gastrointestinal tract surgery	Cefuroxime + metronidazole, gentamicin + metronidazole, or co-amoxiclav (single dose only)
Meningococcal disease (prevention of secondary cases)	Rifampicin or ciprofloxacin
Rheumatic fever (prevention of recurrence)	Phenoxymethylpenicillin or sulfadiazine
Tuberculosis (prevention of secondary cases)	Isoniazid ± rifampicin
Whooping cough (prevention of secondary cases)	Erythromycin
Viral	
HIV, occupational exposure (sharps injury)	Combination tenofovir/emtricitabine and raltegravir. Modified if index case's virus known to be resistant
Influenza A (prevention of secondary cases in adults with chronic respiratory, cardiovascular, renal disease, immunosuppression or diabetes mellitus)	Oseltamivir
Fungal	
Aspergillosis (in high-risk haematology patients)	Posaconazole (voriconazole or itraconazole alternatives if intolerant)
Pneumocystis pneumonia (prevention in HIV and other immunosuppressed states)	Co-trimoxazole, pentamidine or dapsone
Protozoal	
Malaria (prevention of travel-associated disease)	Specific antimalarials depend on travel itinerary. Specialist guidance should be consulted

*These are based on current UK practice. Recommendations may vary locally or nationally. Antimicrobial prophylaxis for infective endocarditis during dental procedures is not currently recommended in the UK.

7.21 Antimicrobial agents in pregnancy[1]

Contraindicated

- Chloramphenicol: neonatal 'grey baby' syndrome – collapse, hypotension and cyanosis
- Fluconazole: teratogenic in high doses
- Quinolones: arthropathy in animal studies
- Sulphonamides: neonatal haemolysis and methaemoglobinaemia
- Tetracyclines, glycylcyclines: skeletal abnormalities in animals in first trimester; fetal dental discoloration and maternal hepatotoxicity with large parenteral doses in second or third trimesters
- Trimethoprim: teratogenic in first trimester
- Macrolides[2]: major malformations in first trimester and genital malformations any trimester

Relatively contraindicated

- Aminoglycosides: potential damage to fetal auditory and vestibular nerves in second and third trimesters
- Metronidazole: avoidance of high dosages is recommended[3]

Not known to be harmful; use only when necessary

- Aciclovir
- Penicillins and cephalosporins
- Clindamycin
- Glycopeptides
- Linezolid
- Meropenem

[2] Fan H, Gilbert R, O'Callaghan F, Li L. Associations between macrolide antibiotics prescribing during pregnancy and adverse child outcomes in the UK: population based cohort study. BMJ 2020;368:m331

[3] Theoretical risk of teratogenicity, not supported by available clinical evidence

7.22 Problems with antimicrobial therapy in old age

- ***Clostridioides difficile* infection**: all antibiotics predispose to some extent, but second- and third-generation cephalosporins, co-amoxiclav and clindamycin especially so.
- **Hypersensitivity reactions**: rise in incidence due to increased previous exposure.
- **Renal impairment**: may be significant in old age, despite creatinine levels being within the reference range.
- **Nephrotoxicity**: more likely, e.g. aminoglycosides.
- **Accumulation of β-lactam antibiotics:** may result in myoclonus, seizures or coma.
- **Reduced gastric acid production**: gastric pH is higher, which causes increased penicillin absorption.
- **Reduced hepatic metabolism**: results in a higher risk of isoniazid-related hepatotoxicity.
- **Quinolones**: associated with delirium and may increase the risk of seizures.

Other reactions, such as rashes, fever and haematological effects (e.g. low white cell count), usually follow more prolonged therapy (more than 2 weeks). Patients with infectious mononucleosis may develop a rash if given aminopenicillins; this does not imply lasting allergy. The relationship between allergy to penicillin and allergy to cephalosporins depends on the specific cephalosporin used. Avoidance of cephalosporins, however, is recommended in patients who have IgE-mediated penicillin allergy (p. 77). Cross-reactivity between penicillin and carbapenems is rare (approximately 1% by skin testing) and carbapenems may be administered if there are no suitable alternatives and appropriate resuscitation facilities are available.

Gastrointestinal upset and diarrhoea are common, and a mild reversible hepatitis is recognised with many β-lactams. More severe forms of hepatitis can be observed with flucloxacillin and co-amoxiclav. Leucopenia, thrombocytopenia, coagulation deficiencies, interstitial nephritis and potentiation of aminoglycoside-mediated kidney damage are also recognised. Seizures and encephalopathy have been reported, particularly with high doses in the presence of renal insufficiency. Thrombophlebitis occurs in up to 5% of patients receiving parenteral β-lactams.

Drug interactions

Synergism occurs in combination with aminoglycosides in vitro. Ampicillin decreases the biological effect of oral contraceptives and the whole class is significantly affected by concurrent administration of probenecid, producing a 2- to 4-fold increase in the peak serum concentration.

Penicillins

Natural penicillins are primarily effective against gram-positive organisms (except staphylococci, most of which produce a penicillinase) and anaerobic organisms. *Streptococcus pyogenes* has remained sensitive to natural penicillins worldwide. According to the European Antimicrobial Resistance Surveillance Network (EARS-Net), the prevalence of non-susceptibility to penicillin in *Streptococcus pneumoniae* in Europe in 2018 varied widely from 0.1% (Belgium) to 40% (Romania).

Penicillinase-resistant penicillins (e.g. flucloxacillin) are the mainstay of treatment for infections with *Staphylococcus aureus*, other than MRSA. However, EARS-Net data from 2021 indicate that MRSA rates in Europe vary widely from 1.1% (Iceland) to 41% (Romania).

Aminopenicillins have the same spectrum of activity as the natural penicillins, with additional gram-negative cover against Enterobacterales. Amoxicillin has better oral absorption than ampicillin. Unfortunately, resistance to these

7.23 β-lactam antibiotics

Penicillins

- Natural penicillins: benzylpenicillin, phenoxymethylpenicillin
- Penicillinase-resistant penicillins: methicillin*, flucloxacillin, nafcillin, oxacillin
- Aminopenicillins: ampicillin, amoxicillin
- Carboxy- and ureido-penicillins: ticarcillin, piperacillin, temocillin

Cephalosporins

- See Box 7.24

Monobactams

- Aztreonam

Carbapenems

- Imipenem, meropenem, ertapenem, doripenem

*Not used for treatment.

7.24 Cephalosporins

First generation

- Cefalexin, cefradine (oral)
- Cefazolin (IV)

Second generation

- Cefuroxime (oral/IV)
- Cefaclor (oral)
- Cefoxitin (IV)

Third generation

- Cefixime (oral)
- Cefotaxime (IV)
- Ceftriaxone (IV)
- Ceftazidime (IV)

Fourth generation

- Cefepime (IV)

Fifth generation (also referred to as 'next generation')

- Ceftobiprole (IV)
- Ceftaroline (IV)

(IV = intravenous)

agents is widespread (*Escherichia coli* Europe-wide country-specific resistance rates in 2018, range 35.3%–67.6%), so they are no longer appropriate for empiric use in gram-negative infections. In many organisms, resistance is due to β-lactamase production, which can be overcome by the addition of β-lactamase inhibitors (clavulanic acid or sulbactam).

Carboxypenicillins (e.g. ticarcillin) and ureidopenicillins (e.g. piperacillin) are particularly active against gram-negative organisms, especially *Pseudomonas* spp., which are resistant to the aminopenicillins. Beta-lactamase inhibitors may be added to extend their spectrum of activity (e.g. piperacillin–tazobactam). Temocillin is derived from ticarcillin; it has good activity against Enterobacterales, including those that produce ESBL enzymes, but poor activity against *P. aeruginosa* and gram-positive bacteria.

Cephalosporins and cephamycins

Cephalosporins are broad-spectrum agents. Unfortunately, their use is associated with *C. difficile* infection. With the exception of ceftobiprole, the group has no activity against enterococci. Only the cephamycins have anti-anaerobic activity. All cephalosporins are inactivated by ESBL. Cephalosporins are arranged in 'generations' (Box 7.24).

- *First-generation compounds* have excellent activity against gram-positive organisms and some activity against gram-negatives.
- *Second-generation drugs* retain gram-positive activity but have extended gram-negative activity. Cephamycins (e.g. cefoxitin), included in this group, are active against anaerobic gram-negative bacilli.
- *Third-generation agents* have improved anti–gram-negative coverage. For some (e.g. ceftazidime), this is extended to include *Pseudomonas* spp. Cefotaxime and ceftriaxone have excellent gram-negative activity and retain good activity against *Strep. pneumoniae* and β-haemolytic streptococci. Ceftriaxone is administered once daily and is therefore a suitable agent for outpatient intravenous (parenteral) antimicrobial therapy (OPAT).
- *Fourth-generation agents*, e.g. cefepime, have a broad spectrum of activity, including streptococci and some gram-negatives, including *P. aeruginosa*.
- *Fifth-generation agents*, such as ceftobiprole and ceftaroline, have an enhanced spectrum of gram-positive activity that includes MRSA, and also have activity against gram-negative bacteria; some, such as ceftobiprole, are active against *P. aeruginosa*. These agents are inactivated by ESBLs.
- Cefiderocol is a novel siderophore cephalosporin, which is also active in the presence of ESBLs and carbapenemases.

The spectrum of cephalosporins has also been enhanced by adding β-lactamase inhibitors, e.g. ceftazidime/avibactam and ceftolozane/tazobactam.

Monobactams

Aztreonam is the only available monobactam. It is active against gram-negative bacteria, except ESBL-producing organisms, but inactive against gram-positive organisms or anaerobes. It is a parenteral-only agent and may be used safely in most penicillin-allergic patients other than those with an allergy to ceftazidime, which shares a common side chain.

Carbapenems

These intravenous agents have the broadest antibiotic activity of the β-lactam antibiotics, covering most clinically significant bacteria, including anaerobes (e.g. imipenem–cilastatin, meropenem, ertapenem). Carbapenems are also being combined with β-lactamase inhibitors in response to emergence of carbapenemase enzymes that inactivate this class (e.g. meropenem–vaborbactam and imipenem/cilastatin–relebactam).

Macrolide and lincosamide antibiotics

Macrolides (e.g. erythromycin, clarithromycin and azithromycin) and lincosamides (e.g. clindamycin) are bacteriostatic agents. Both classes bind to the same component of the ribosome, so they are not administered together. Macrolides are used for *Legionella*, *Mycoplasma*, *Chlamydia* and *Bordetella* infections. Azithromycin is employed for single-dose/short-course therapy for genitourinary *Chlamydia/Mycoplasma* spp. infections. Clindamycin is used primarily for skin, soft tissue, bone and joint infections.

Pharmacokinetics

Macrolides

- Variable bioavailability (intravenous and oral preparations available).
- Frequency of administration: erythromycin is administered 4 times daily, clarithromycin twice daily, azithromycin once daily.
- High protein binding.
- Excellent intracellular accumulation.

Lincosamides (e.g. clindamycin)

- Good oral bioavailability.
- Food has no effect on absorption.
- Good bone/joint penetration; limited CSF penetration.

Adverse effects

- Gastrointestinal upset, especially in young adults (erythromycin 30%).
- Cholestatic jaundice with erythromycin estolate.
- Prolongation of QT interval can cause torsades de pointes (p. 454).
- Clindamycin predisposes to CDI.

Aminoglycosides and spectinomycin

Aminoglycosides are effective mainly in gram-negative infections and are therefore commonly used in regimens for intra-abdominal infection. Some aminoglycosides, e.g. amikacin, are important components of therapy for MDR-TB. Because they act synergistically with β-lactam antibiotics they are used in combinations to treat biofilm infections, including infective endocarditis and orthopaedic implant infections. They cause very little local irritation at injection sites and negligible allergic responses. Oto- and nephrotoxicity must be avoided by monitoring of renal function and drug levels and by use of short treatment regimens. Aminoglycosides are not subject to an inoculum effect and they all exhibit a post-antibiotic effect. Resistance is mediated mainly through inactivation by aminoglycoside-modifying enzymes (AMEs). Plazomicin is a novel aminoglycoside that is not yet inactivated by AMEs.

Pharmacokinetics

- Negligible oral absorption.
- Hydrophilic, so excellent penetration to extracellular fluid in body cavities and serosal fluids, but poor penetration into adipose tissue.
- Very poor intracellular penetration (except hair cells in cochlea and renal cortical cells).
- Negligible CSF and corneal penetration.
- Peak plasma levels 30 minutes after infusion.
- Exhibit a post-antibiotic effect.
- Monitoring of therapeutic levels required.

Gentamicin dosing

- Gentamicin should be dosed according to actual body weight or ideal body weight if obese.
- Except in certain forms of endocarditis, pregnancy, severe burns, end-stage renal disease and paediatric patients, gentamicin can be administered at 7 mg/kg body weight. The appropriate dose interval depends on drug clearance and is determined by reference to the Hartford nomogram (Fig. 7.19).
- In most other situations, gentamicin is usually administered twice or 3 times daily at 3–5 mg/kg/day with target pre- and post-dose levels of < 1 mg/L and 5–10 mg/L.
- In streptococcal and enterococcal endocarditis, gentamicin is used with a cell wall active agent (usually a β-lactam), to provide synergy. Lower doses and target levels are used in this situation.
- For all aminoglycoside dosing, local guidance should be consulted.

Adverse effects

- Renal toxicity (usually reversible) accentuated by other nephrotoxic agents.
- Cochlear toxicity (permanent) more likely in older people and those with a predisposing mitochondrial gene mutation.
- Neuromuscular blockade after rapid intravenous infusion (potentiated by calcium channel blockers, myasthenia gravis and hypomagnesaemia).

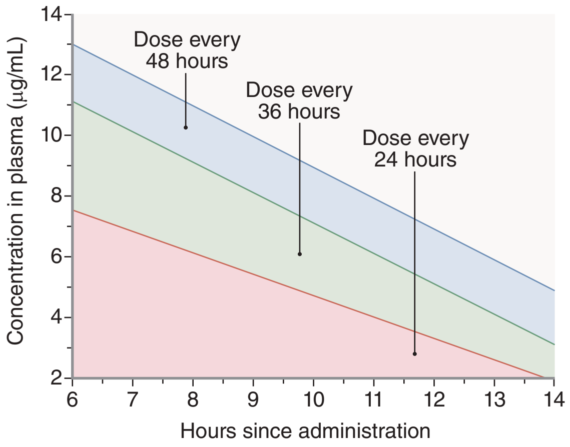

Fig. 7.19 Dosing of aminoglycosides using the Hartford nomogram. The nomogram is used to determine the dose interval for 7 mg/kg doses of gentamicin or tobramycin, using measurements of drug levels in plasma 6–14 hours after a single dose.

Spectinomycin

Chemically similar to the aminoglycosides and given intramuscularly, spectinomycin was developed to treat strains of *Neisseria gonorrhoeae* resistant to β-lactam antibiotics. Unfortunately, resistance to spectinomycin is very common. Its only indication is the treatment of gonococcal urethritis in pregnancy or in patients allergic to β-lactam antibiotics.

Plazomicin

Plazomicin is an aminoglycoside that has been designed to withstand aminoglycoside-modifying enzymes and is usually active against Enterobacterales expressing ESBLs or carbapenemases, which harbour resistance mechanisms to multiple classes of antibiotics. It has been used to treat complicated urinary tract infections caused by highly drug-resistant strains when other options are not available. It has also shown activity against multidrug-resistant *Acinetobacter baumannii* and can be used in combination with other agents against this microorganism.

Quinolones and fluoroquinolones

These are effective bactericidal agents. The quinolones have purely anti–gram-negative activity, whereas the fluoroquinolones are broad-spectrum agents (Box 7.25). Ciprofloxacin has anti-pseudomonal activity but resistance emerges rapidly. In 2021, European surveillance showed that resistance to fluoroquinolones in *E. coli* ranged between < 10% (Norway and Finland) and > 50% (Russia, Turkey, Northern Macedonia and Cyprus). Quinolones and fluoroquinolones are used for a variety of infections, including pyelonephritis, osteomyelitis and less common problems like MDR-TB. The possibility of disabling and potentially long-lasting musculoskeletal and CNS adverse events has been highlighted in recent years, with advice from regulatory bodies to use quinolones only when commonly recommended antimicrobials are not appropriate.

Pharmacokinetics

- Well absorbed after oral administration but delayed by food, antacids, ferrous sulphate and multivitamins.
- Wide volume of distribution; tissue concentrations twice those in serum.
- Good intracellular penetration, concentrating in phagocytes.

7.25 Quinolones and fluoroquinolones

Agent	Route of administration	Typical antimicrobial spectrum
Quinolones		
Nalidixic acid	Oral	Enteric gram-negative bacilli (not *Pseudomonas aeruginosa*)
Fluoroquinolones		
Ciprofloxacin Norfloxacin Ofloxacin	IV/oral Oral IV/oral/topical	Enteric gram-negative bacilli, *P. aeruginosa*, *Haemophilus* spp., ‘atypical’ respiratory pathogens*
Levofloxacin (L-isomer of ofloxacin)	IV/oral	*Haemophilus* spp., *Streptococcus pneumoniae*, ‘atypical’ respiratory pathogens*
Moxifloxacin	Oral	*Strep. pneumoniae*, *Staphylococcus aureus*, ‘atypical’ respiratory pathogens*, mycobacteria and anaerobes

*‘Atypical’ pathogens include *Mycoplasma pneumoniae* and *Legionella* spp. Fluoroquinolones have variable activity against *Mycobacterium tuberculosis* and other mycobacteria.

Adverse effects

- Gastrointestinal side-effects in 1%–5%.
- Rare skin reactions (phototoxicity).
- Tendonitis and Achilles tendon rupture, especially in older people, those with renal impairment, taking corticosteroids, and solid organ transplant recipients.
- Central nervous system effects (delirium, tremor, dizziness and occasional seizures in 5%–12%), especially in older people.
- Reduces clearance of xanthines and theophyllines, potentially inducing insomnia and increased seizure potential.
- Prolongation of QT interval on ECG, cardiac arrhythmias.
- Ciprofloxacin use is associated with acquisition of MRSA and strains of *C. difficile*.

Glycopeptides

Glycopeptides (vancomycin and teicoplanin) are effective against gram-positive organisms only, and are used mainly against staphylococci (including MRSA) and enterococci. Some staphylococci and enterococci are resistant, and glycopeptide use should be restricted to limit the emergence of resistance. Glycopeptides are not absorbed after oral administration but vancomycin is used orally to treat CDI.

Dalbavancin and telavancin are semisynthetic derivatives of glycopeptide (lipoglycopeptides). Dalbavancin is used primarily for skin and skin structure infections. Telavancin has a dual mechanism of action, inhibiting both cell wall synthesis and membrane polarisation; it is reserved for hospital-acquired pneumonia when other agents cannot be used.

Pharmacokinetics

- Vancomycin is administered by slow intravenous infusion. It has good tissue distribution and a short half-life, and enters the CSF only in the presence of inflammation. Therapeutic drug monitoring is recommended, to maintain pre-dose levels of > 10 mg/L (15–20 mg/L in serious staphylococcal infections).
- Teicoplanin is administered intravenously or intramuscularly. Its long half-life allows once-daily dosing.
- Telavancin and dalbavancin are lipoglycopeptides administered intravenously. Telavancin has a long half-life that allows once-daily dosing; dalbavancin has a very long half-life, allowing once-weekly dosing. Oritavancin, a further lipoglycopeptide, has a half-life up to 16 days allowing single-dose treatment.

Adverse effects

- Rapid infusion of vancomycin can cause histamine release ('red man' syndrome), although this is rare with modern preparations.
- Vancomycin and teicoplanin are associated with nephrotoxicity and ototoxicity.
- Vancomycin and teicoplanin can cause DRESS (drug reaction with eosinophilia and systemic symptoms, see Box 26.35).

Lipopeptides

Daptomycin is a cyclic lipopeptide with bactericidal activity against gram-positive organisms only, including MRSA and glycopeptide-resistant enterococci. It is not absorbed orally, and is used intravenously to treat gram-positive infections, such as soft tissue infections and *Staph. aureus* infective endocarditis. Daptomycin is inactivated by pulmonary surfactant and is not effective for pneumonia. Treatment can be associated with increased levels of creatine kinase and eosinophilic pneumonitis.

Polymyxins

Colistin is a polymyxin antibiotic that binds and disrupts the outer cell membrane of gram-negative bacteria, including *P. aeruginosa* and *Acinetobacter baumannii*. Its use has increased with the emergence and spread of multi-resistant gram-negative bacteria, including CPEs. It can be administered by oral, intravenous and nebulised routes. Significant adverse effects include neurotoxicity, including encephalopathy, and nephrotoxicity.

Folate antagonists

These are bacteriostatic antibacterials. A combination of a sulphonamide and either trimethoprim or pyrimethamine is most commonly used, which interferes with two consecutive steps in the folate metabolic pathway. Available combinations include trimethoprim/sulfamethoxazole (cotrimoxazole) and pyrimethamine with either sulfadoxine (used to treat malaria) or sulfadiazine (used in toxoplasmosis). Co-trimoxazole is the first-line drug for *Pneumocystis jirovecii* infection, the second-line drug for treatment and prevention of *B. pertussis* infection, and is also used for a variety of other infections, including *Staph. aureus*. Dapsone is used to treat leprosy (Hansen disease) and to prevent toxoplasmosis (where it is combined with pyrimethamine) and pneumocystis when patients are intolerant of other medications. Folinic acid should be given to prevent myelosuppression if these drugs are used long term or unavoidably in early pregnancy.

Pharmacokinetics

- Well absorbed orally.
- Sulphonamides are hydrophilic, distributing well to the extracellular fluid.
- Trimethoprim is lipophilic with high tissue concentrations.

Adverse effects

- Trimethoprim is generally well tolerated, with few adverse effects.
- Sulphonamides and dapsone may cause haemolysis in glucose-6-phosphate dehydrogenase deficiency.
- Sulphonamides and dapsone cause skin and mucocutaneous reactions, including Stevens–Johnson syndrome and 'dapsone syndrome' (rash, fever and lymphadenopathy).
- Dapsone causes methaemoglobinaemia and peripheral neuropathy.

Tetracyclines and glycylcyclines

Tetracyclines

Of this mainly bacteriostatic class, the newer drugs doxycycline and minocycline show better absorption and distribution than older ones. Resistance is common in streptococci and gram-negative bacteria. Tetracyclines are indicated for infections caused by *Mycoplasma* spp., *Chlamydia* spp., *Rickettsia* spp., *Coxiella* spp., *Bartonella* spp., *Borrelia* spp., *Helicobacter pylori*, *Treponema pallidum* and atypical mycobacteria. Tetracyclines can also be used for malaria prevention.

Pharmacokinetics

- Best oral absorption is in the fasting state (doxycycline is 100% absorbed unless gastric pH rises) and absorption is inhibited by cations, e.g. calcium or iron, which should not be administered at the same time.

Adverse effects

- All tetracyclines except doxycycline are contraindicated in renal failure.
- Dizziness with minocycline.
- Binding to metallic ions in bones and teeth causes discoloration (avoid in children and pregnancy) and enamel hypoplasia.
- Oesophagitis/oesophageal ulcers with doxycycline.
- Phototoxic skin reactions.

Glycylcyclines (tigecycline)

Chemical modification of tetracycline has produced tigecycline, a broad-spectrum, parenteral-only antibiotic with activity against resistant gram-positive and gram-negative pathogens, such as MRSA and ESBL (but excluding *Pseudomonas* spp.). Re-analysis of trial data has shown that there was excess mortality following tigecycline treatment as opposed to comparator antibiotics, so tigecycline should be used only when there has been adequate assessment of risk versus benefit.

Eravacycline and omadacycline

Eravacycline is a halogenated tetracycline administered parenterally. It is active against gram-positive and gram-negative bacteria including MRSA and carbapenemase producing Enterobacteriaceae. It has activity against *Acinetobacter baumannii* but not *Pseudomonas aeruginosa*. The initial license has been for complicated intra-abdominal infection. Thrombophlebitis is the main side-effect.

Omadacycline is an aminomethylcycline and like eravacycline is related to tigecycline. It is active against gram-positive and gram-negative bacteria, including MRSA and ESBL-producing Enterobacterales and has activity against *A. baumannii* but not *P. aeruginosa*. Licensing has supported indications for use in community-acquired pneumonia and skin and soft tissue infection. It is available in parenteral and oral formulations. Side-effects primarily involve gastrointestinal upset.

Nitroimidazoles

Nitroimidazoles (e.g. metronidazole) are highly active against strictly anaerobic bacteria, especially *Bacteroides fragilis*, *C. difficile* and *Clostridium* spp. Both metronidazole and tinidazole have significant antiprotozoal activity against amoebae and *Giardia lamblia*. Nitroimidazoles are almost completely absorbed after oral administration (60% after rectal administration) and well distributed, especially to brain and CSF. They can be used in pregnancy after a risk assessment.

Adverse effects include: metallic taste (dose-dependent), severe vomiting if taken with alcohol ('Antabuse effect') and peripheral neuropathy with prolonged use.

Phenicols (chloramphenicol)

Chloramphenicol use is best reserved for severe and life-threatening infections when other antibiotics are either unavailable or impractical, due to toxicity. It is bacteriostatic to most organisms and has a very broad spectrum of activity against aerobic and anaerobic organisms. It competes with macrolides and lincosamides for ribosomal binding sites, so should not be used in combination with these agents. Significant adverse effects are 'grey baby' syndrome in infants (cyanosis and circulatory collapse due to inability to conjugate drug and excrete the active form in urine); reversible dose-dependent bone marrow depression in adults receiving high cumulative doses; and severe aplastic anaemia in 1 in 25 000–40 000 exposures (unrelated to dose, duration of therapy or route of administration).

Oxazolidinones

Linezolid and tedizolid are examples and have good activity against gram-positive organisms. They are primarily used in infection caused by resistant gram-positive bacteria, including MRSA and GRE, but also for resistant *Mycobacterium tuberculosis*. Administration can be intravenous or oral. Common linezolid adverse effects include mild gastrointestinal upset and tongue discoloration. Myelodysplasia and peripheral and optic neuropathy can occur with prolonged use. Linezolid has monoamine oxidase inhibitor (MAOI) activity, and co-administration with other MAOIs or serotonin re-uptake inhibitors should be avoided, as this may precipitate a 'serotonin syndrome'.

Other antibacterial agents

Fusidic acid

This antibiotic, active against gram-positive bacteria, is available in intravenous, oral or topical formulations. It is lipid-soluble and distributes well to tissues. Its antibacterial activity is, however, unpredictable. Fusidic acid is used in combination, typically with antistaphylococcal penicillins, or for MRSA with clindamycin or rifampicin. It interacts with coumarin derivatives and oral contraceptives.

Nitrofurantoin

This drug has very rapid renal elimination and is active against aerobic gram-negative and gram-positive bacteria, including enterococci. It is used only for treatment of lower urinary tract infection, being generally safe in pregnancy and childhood. With prolonged treatment, however, it can cause eosinophilic lung infiltrates, fever, pulmonary fibrosis, peripheral neuropathy, hepatitis and haemolytic anaemia so its use must be carefully balanced against risks.

Fidaxomicin

Fidaxomicin is an RNA synthesis inhibitor, and was introduced for the treatment of CDI in 2012. The registration trial found fidaxomicin was non-inferior to oral vancomycin in non-severe CDI and was associated with a lower recurrence rate. Its effectiveness for severe CDI has not been assessed in trials.

Fosfomycin

Fosfomycin acts by inhibiting cell wall synthesis. It has activity against gram-negative and gram-positive bacteria and can demonstrate in vitro synergy against MRSA when combined with other antimicrobials. It is used for treatment of urinary tract infections but can be employed in other situations against multi-resistant bacteria.

Lefamulin

Lefamulin is a pleuromutilin antibiotic that inhibits the 50S ribosome and inhibits protein synthesis. It has recently been licensed for use in community-acquired pneumonia and is available orally and intravenously. It should not be used in pregnancy and prolongs the QT interval.

Antimycobacterial agents

Isoniazid

Isoniazid is bactericidal for replicating bacteria and bacteriostatic for non-replicating bacteria. It is activated by mycobacterial catalase-peroxidase (KatG) and inhibits the *InhA* gene product, a reductase involved in mycolic acid synthesis. Mutations in *KatG* or *InhA* result in isoniazid resistance, which was reported in 15% of cases of *M. tuberculosis* infection globally in 2013. Isoniazid is well absorbed orally and metabolised by acetylation in the liver. The major side-effects are hepatitis, neuropathy (ameliorated by co-administration of pyridoxine) and hypersensitivity reactions.

Rifampicin

Rifampicin inhibits DNA-dependent RNA polymerase and is bactericidal against replicating bacteria. It is also active in necrotic foci, where mycobacteria have low levels of replication, and is therefore important in sterilisation and sputum conversion. Resistance most often involves the β-subunit of RNA polymerase and most often occurs with isoniazid-resistant MDR-TB. Rifampicin is well absorbed orally. It is metabolised by the liver via the microsomal cytochrome P450 system and is one of the most potent inducers of multiple P450 isoenzymes, so is subject to extensive drug–drug interactions. Common side-effects include hepatitis, influenza-like symptoms and hypersensitivity reactions. Orange discoloration of urine and body secretions is expected.

Pyrazinamide

The mechanism of action of pyrazinamide is incompletely defined but includes inhibition of fatty acid synthase and ribosomal trans-translation, a quality control system for mRNA and protein synthesis. Pyrazinamide is often bacteriostatic but can be bactericidal and is active against semi-dormant bacteria in a low-pH environment. Primary resistance is rare but MDR-TB strains are frequently pyrazinamide-resistant and intrinsic resistance is a feature of *Mycobacterium bovis* strains. Pyrazinamide is well absorbed orally and metabolised by the liver. Side-effects include nausea, hepatitis, asymptomatic elevation of uric acid and myalgia.

Ethambutol

Ethambutol is a bacteriostatic agent. It inhibits arabinosyl transferase, which is involved in the synthesis of arabinogalactan, a component of the mycobacterial cell wall. Resistance is usually seen when resistance to other antimycobacterial agents is also present, e.g. in MDR-TB strains. It is orally absorbed but, in contrast to the first-line agents described above, it achieves poor CSF penetration and is renally excreted. The major side-effect is optic neuritis with loss of red–green colour discrimination and impaired visual acuity.

Streptomycin

Streptomycin is an aminoglycoside whose mechanism of action and side-effects are similar to those of other aminoglycosides. It is administered intramuscularly.

Other antituberculous agents

Second-line agents used in MDR or XDR strains (p. 563) include aminoglycosides (amikacin, capreomycin or kanamycin) and fluoroquinolones (moxifloxacin or levofloxacin), discussed above. Other established second-line agents administered orally are cycloserine (which causes neurological side-effects); ethionamide or prothionamide (which are not active with *InhA*-gene-mediated resistance but have reasonable CSF penetration; their side-effect profile includes gastrointestinal disturbance, hepatotoxicity and neurotoxicity); and paraminosalicylic acid (which causes rashes and gastrointestinal upset). Linezolid may also be used and has good CSF penetration, while meropenem with co-amoxiclav is occasionally chosen. Newer drugs developed for XDR-TB include delamanid (which targets cell wall arabinogalactan synthesis) and bedaquiline (which targets the ATP synthase); their adverse effects include QT prolongation and cardiac arrhythmias. Their co-administration with other agents with a similar side-effect profile (e.g. fluoroquinolones) therefore requires careful risk assessment. Pretomanid, which has a similar mechanism of action to delamanid, is used in combinations with bedaquiline for drug-resistant strains and improves the bactericidal activity of combination therapy which may enable shorter durations. Its side-effects include nerve damage, headaches, gastrointestinal upset, abnormal liver function tests, low glucose and skin rash. Treatment regimens for MDR-TB often lasted at least 18–24 months, although six month oral regimens using bedaquiline, pretomanid, linezolid and moxifloxacin (BPaLM) are now recommended.

Clofazimine

Clofazimine is used against *M. leprae* and resistant strains of *M. tuberculosis*. Its mode of action may involve induction of oxidative stress and it is weakly bactericidal. Oral absorption is variable and it is excreted in the bile. Side-effects include gastrointestinal upset, dry eyes and skin, and skin pigmentation, especially in those with pigmented skin.

Antifungal agents

See Box 7.26.

Azole antifungals

The azoles (imidazoles and triazoles) inhibit synthesis of ergosterol, a constituent of the fungal cell membrane. Side-effects vary but include gastrointestinal upset, hepatitis and rash. Azoles are inhibitors of cytochrome P450 enzymes, so they tend to increase exposure to cytochrome P450-metabolised drugs.

Imidazoles

Miconazole, econazole, clotrimazole and ketoconazole are relatively toxic and therefore administered topically. Clotrimazole is used extensively to treat superficial fungal infections. Triazoles are used for systemic treatment because they are less toxic.

Triazoles

Fluconazole is effective against yeasts (*Candida* and *Cryptococcus* spp.) and has a long half-life (approximately 30 hours) and an excellent safety profile. The drug is highly water-soluble and distributes widely to all body sites and tissues, including CSF. Itraconazole is lipophilic and distributes extensively, including to toenails and fingernails. Its CSF penetration is poor. Because oral absorption of itraconazole is erratic, therapeutic drug monitoring is required. Voriconazole is well absorbed orally but variability in levels requires therapeutic drug monitoring. It is used mainly in aspergillosis. Side-effects include photosensitivity, hepatitis and transient retinal toxicity. Posaconazole and isavuconazole are broad-spectrum azoles, with activity against *Candida* spp., *Aspergillus* spp. and some mucoraceous moulds. Isavuconazole is non-inferior to voriconazole in the management of invasive aspergillosis and may be considered as an alternative when voriconazole cannot be used. Fosravuconazole is a prodrug of ravuconazole and is used to treat onychomycosis and mycetoma. It has been found to be safe and well tolerated.

i 7.26 Antifungal agents

Agent	Usual route(s) of administration	Clinically relevant antifungal spectrum
Imidazoles		
Miconazole Econazole Clotrimazole	Topical	*Candida* spp., dermatophytes
Ketoconazole	Topical, oral	*Malassezia* spp., dermatophytes, agents of eumycetoma
Triazoles		
Fluconazole	Oral, IV	Yeasts (*Candida* and *Cryptococcus* spp.)
Itraconazole	Oral, IV	Yeasts, dermatophytes, dimorphic fungi (p. 398), *Aspergillus* spp.
Voriconazole	Oral, IV	Yeasts and most filamentous fungi (excluding mucoraceous moulds)
Posaconazole	Oral, IV	Yeasts and many filamentous fungi (including most mucoraceous moulds)
Isavuconazole	Oral, IV	Yeasts and many filamentous fungi (variable activity against mucoraceous moulds)
Echinocandins		
Anidulafungin Caspofungin Micafungin	IV only	*Candida* spp., *Aspergillus* spp. (no activity against *Cryptococcus* spp. or mucoraceous moulds)
Polyenes		
Amphotericin B	IV	Yeasts and most dimorphic and filamentous fungi (including mucoraceous moulds)
Nystatin	Topical	
Others		
5-fluorocytosine	Oral, IV	Yeasts
Griseofulvin	Oral	Dermatophytes
Terbinafine	Topical, oral	Dermatophytes

(IV = intravenous)

Echinocandins

The echinocandins inhibit β-1,3-glucan synthesis in the fungal cell wall. They have few significant adverse effects. Caspofungin, anidulafungin and micafungin are used to treat systemic candidosis, and caspofungin is also used in aspergillosis.

Polyenes

Amphotericin B (AmB) deoxycholate causes cell death by binding to ergosterol and damaging the fungal cytoplasmic membrane. Its use in resource-rich countries has been largely supplanted by less toxic agents. Its long half-life enables once-daily administration. CSF penetration is poor.

Adverse effects include immediate anaphylaxis, other infusion-related reactions and nephrotoxicity. Nephrotoxicity may be sufficient to require dialysis and occurs in most patients who are adequately dosed. It may be ameliorated by concomitant infusion of normal saline. Irreversible nephrotoxicity occurs with large cumulative doses of AmB.

Nystatin has a similar spectrum of antifungal activity to AmB. Its toxicity limits it to topical use, e.g. in oral and vaginal candidiasis.

Lipid formulations of amphotericin B

Lipid formulations of AmB have been developed to reduce AmB toxicity and have replaced AmB deoxycholate in many regions. They consist of AmB encapsulated in liposomes (liposomal AmB, L-AmB) or complexed with phospholipids (AmB lipid complex, ABLC). The drug becomes active on dissociating from its lipid component. Adverse effects are similar to, but considerably less frequent than, those with AmB deoxycholate, and efficacy is similar. Lipid formulations of AmB are used in invasive fungal disease, as empirical therapy in patients with neutropenic fever and also in visceral leishmaniasis.

Other antifungal agents

Flucytosine

Flucytosine (5-fluorocytosine) has particular activity against yeasts. When it is used as monotherapy, acquired resistance develops rapidly, so it should be given in combination with another antifungal agent. Adverse effects include myelosuppression, gastrointestinal upset and hepatitis.

Griseofulvin

Griseofulvin has been largely superseded by terbinafine and itraconazole for treatment of dermatophyte infections, except in children, for whom these agents remain largely unlicensed. It is deposited in keratin precursor cells, which become resistant to fungal invasion.

Terbinafine

Terbinafine distributes with high concentration to sebum and skin, with a half-life of more than 1 week. It is used topically for dermatophyte skin infections and orally for onychomycosis. The major adverse reaction is hepatic toxicity (approximately 1:50 000 cases). Terbinafine is not recommended for breastfeeding mothers.

Antiviral agents

Most viral infections in immunocompetent individuals resolve without intervention. Antiviral therapy is available for a limited number of infections only (Box 7.27).

7.27 Antiviral agents

Drug	Route(s) of administration	Indications	Significant side-effects
Antiretroviral therapy			
(ART, p. 333)	Oral	HIV infection (including AIDS)	CNS symptoms, anaemia, lipodystrophy
Anti-herpesvirus agents			
Aciclovir	Topical/oral/IV	Herpes zoster Chickenpox (esp. in immunosuppressed) Herpes simplex infections: encephalitis (IV only), genital tract, oral, ophthalmic	Significant side-effects rare Hepatitis, renal impairment and neurotoxicity reported rarely
Valaciclovir	Oral	Herpes zoster, herpes simplex	As for aciclovir
Famciclovir	Oral	Herpes zoster, herpes simplex (genital)	As for aciclovir
Penciclovir	Topical	Labial herpes simplex	Local irritation
Ganciclovir	IV	Treatment and prevention of CMV infection in immunosuppressed	Gastrointestinal symptoms, liver dysfunction, neurotoxicity, myelosuppression, renal impairment, fever, rash, phlebitis at infusion sites Potential teratogenicity
Valganciclovir	Oral	Treatment and prevention of CMV infection in immunosuppressed	As for ganciclovir but neutropenia is predominant
Cidofovir	IV/topical	HIV-associated CMV infections and occasionally other viruses (see text)	Renal impairment, neutropenia
Foscarnet	IV	CMV and aciclovir-resistant HSV and VZV infections in immunosuppressed	Gastrointestinal symptoms, renal impairment, electrolyte disturbances, genital ulceration, neurotoxicity
Anti-influenza agents			
Zanamivir	Inhalation/IV	Influenza A and B	Allergic reactions (very rare)
Oseltamivir	Oral	Influenza A and B	Gastrointestinal side-effects, rash, hepatitis (very rare)
Peramivir	IV, IM	Influenza A and B	Allergic reactions, CNS side effects, renal impairment
Amantadine, rimantadine	Oral	Influenza A (but see text)	CNS symptoms, nausea
Agents used in other virus infections*			
Ribavirin	Oral/IV/inhalation	Lassa fever (IV) RSV infection in infants (inhalation)	Haemolytic anaemia, cough, dyspnoea, bronchospasm and ocular irritation (when given by inhalation)
Remdesivir	IV	COVID-19	Significant side-effects rare

*Antiviral agents used in viral hepatitis are discussed on pages 903–910.

(AIDS = acquired immunodeficiency syndrome; CMV = cytomegalovirus; CNS = central nervous system; HIV = human immunodeficiency virus; HSV = herpes simplex virus; IM = intramuscular; IV = intravenous; RSV = respiratory syncytial virus; VZV = varicella zoster virus)

Anti-herpesvirus agents

Aciclovir, valaciclovir, penciclovir and famciclovir

These antivirals are acyclic analogues of guanosine, which inhibit viral DNA polymerase after being phosphorylated by virus-derived thymidine kinase (TK). Aciclovir is poorly absorbed after oral dosing; better levels are achieved intravenously or by use of the prodrug valaciclovir. Famciclovir is the prodrug of penciclovir. Resistance is mediated by viral TK or polymerase mutations.

Ganciclovir

Chemical modification of the aciclovir molecule allows preferential phosphorylation by protein kinases of cytomegalovirus (CMV) and other β-herpesviruses (e.g. human herpesvirus (HHV)-6/7) and hence greater inhibition of the DNA polymerase, but at the expense of increased toxicity. Ganciclovir is administered intravenously or as a prodrug (valganciclovir) orally.

Cidofovir and brincidofovir

Cidofovir inhibits viral DNA polymerases with potent activity against CMV, including most ganciclovir-resistant CMV. It also has activity against aciclovir-resistant herpes simplex virus (HSV) and varicella zoster virus (VZV), HHV-6 and occasionally adenovirus, poxvirus, papillomavirus or polyomavirus, and may be used to treat these infections in immunocompromised hosts. Brincidofovir is an oral prodrug of cidofovir. Its side-effects include nausea, vomiting, diarrhoea and abdominal pain and it should not be used for prolonged treatment courses. It has been used in transplant infections caused by drug-resistant CMV, adenoviruses or JK virus. It has also been used to treat poxviruses including Mpox.

Foscarnet

This analogue of inorganic pyrophosphate acts as a non-competitive inhibitor of HSV, VZV, HHV-6/7 or CMV DNA polymerase. It does not require significant intracellular phosphorylation and so may be effective when HSV or CMV resistance is due to altered drug phosphorylation. It has variable CSF penetration.

Letermovir

Letermovir is a CMV DNA terminase inhibitor that plays a role in cleavage of viral DNA for packaging into mature virions. It is available in oral and intravenous formulations. It is well tolerated and is approved for prophylaxis of CMV in allogeneic haematopoietic stem cell transplant recipients. Gastrointestinal disturbance and drug–drug interactions occur and resistance may develop.

Anti-influenza agents

Zanamivir and oseltamivir

These agents inhibit influenza A and B neuraminidase, which is required for release of virus from infected cells (see Fig. 7.2). They are used in the treatment and prophylaxis of influenza. Administration within 48 hours of disease onset reduces the duration of symptoms by 1–1.5 days. In the UK, their use is limited mainly to adults with chronic respiratory or renal disease, significant cardiovascular disease, immunosuppression or diabetes, during known outbreaks. Peramivir has been developed as a distinct chemical structure, which means that it retains activity against some oseltamivir- and zanamivir-resistant strains. It has poor oral bioavailability and has been developed as an intravenous or intramuscular formulation for treatment of severe cases of influenza, e.g. in intensive care units. It is now approved for use in adults in a number of countries. An intravenous formulation of zanamivir is also in development for critically ill patients. Laninamivir is approved as an intranasal formulation in Japan.

Other anti-influenza agents

Amantadine and rimantadine inhibit viral M2 protein ion channel function, which is required for uncoating (see Fig. 7.2). Resistance is widespread, and these are only used to treat oseltamivir-resistant influenza A in patients unable to take zanamivir (e.g. ventilated patients) and when the strain is susceptible to these agents. Baloxavir marboxil inhibits a component of viral RNA synthesis. It is licensed for uncomplicated influenza but is likely to be reserved for neuraminidase-resistant strains. Favipiravir is an oral or intravenous RNA-dependent RNA polymerase that may also play a role against resistant strains of influenza but also other RNA viruses and has been studied against SARS-CoV-2.

Antiretroviral agents

These agents are used predominantly against HIV.

Nucleoside and nucleotide reverse transcriptase inhibitors (NRTIs)

The nucleoside reverse transcriptase inhibitors are nucleoside analogues which, once phosphorylated, are incorporated into the DNA strand and act as chain terminators during reverse transcription of HIV RNA to DNA. NRTIs are used in combination with other antiretrovirals as combination therapy.

Currently recommended NRTIs are, most often, tenofovir, which is a nucleotide analogue of adenosine monophosphate, combined with either lamivudine or emtricitabine, which are cytosine analogues. These NRTIs are also active against hepatitis B virus.

Lamivudine or emtricitabine are very well tolerated. A single resistance mutation in reverse transcriptase confers high-level resistance, which is referred to as a low genetic barrier to resistance. By contrast, high-level resistance to other NRTIs only occurs after a series of resistance mutations have been selected for, which is referred to as a high genetic barrier to resistance.

Tenofovir is available as two prodrugs – tenofovir disoproxil fumarate (TDF) and tenofovir alafenamide (TAF). Tenofovir is generally well tolerated but can cause nephrotoxicity, presenting as either a decline in estimated glomerular filtration rate or as a proximal renal tubulopathy resembling Fanconi syndrome. Tenofovir can also reduce bone mineral density due to increased urine phosphate excretion from proximal renal tubulopathy. TAF is less toxic to kidney and bones than TDF as it is a prodrug of TDF that is selectively concentrated in lymphoid tissues, but is more likely to be the victim of drug–drug interactions when co-administered with drugs that are strong inducers or inhibitors of its metabolism. TDF and TAF are used in pre-exposure prophylaxis (PrEP) in people at high risk of acquiring HIV (p. 335). TDF and TAF are also active against HBV.

Abacavir is a guanosine analogue, which is generally used to replace tenofovir in people who develop or who are at high risk of tenofovir-induced nephrotoxicity. Abacavir can cause a severe systemic hypersensitivity reaction typically presenting with rash, fever and gastrointestinal or respiratory symptoms. This hypersensitivity reaction is strongly associated with HLA-B*57:01, which should be tested for before using abacavir if resources permit to prevent the hypersensitivity reaction. If a hypersensitivity reaction occurs abacavir must be stopped and must not be used again.

Non-nucleoside reverse transcriptase inhibitors (NNRTIs)

NNRTIs bind non-competitively to the reverse transcriptase, but not at the active site of the enzyme. First generation NNRTIs are no longer recommended because they are poorly tolerated and have a low genetic barrier to resistance. They were widely used previously but are less often used now. The second generation NNRTIs doravirine and rilpivirine are currently recommended as they are well tolerated and have a higher genetic barrier to resistance. Doravirine and rilpivirine can cause rashes or abnormal liver function tests, and can be the victims of drug–drug interactions when co-administered with strong inducers (e.g. rifampicin) or inhibitors of the cytochrome P450 enzyme CYP3A4, which metabolises both drugs. Rilpivirine needs gastric acidity for absorption and cannot be used with proton pump inhibitors. Rilpivirine can be co-administered with dolutegravir as a two-drug oral combination or with cabotegravir as a long-acting injectable combination.

Protease inhibitors

These agents inhibit viral protease. The first generation protease inhibitors had poor gastrointestinal tolerability and frequently caused metabolic complications, notably dyslipidaemia. Protease inhibitors are substrates of CYP3A4 – they are always administered with a CYP3A4 inhibitor, either ritonavir or cobicistat, to boost protease inhibitor drug concentrations and reduce dosing frequency. Protease inhibitors are involved in extensive drug–drug interactions – they cannot be co-administered with strong inducers of CYP3A4 (e.g. rifampicin) and can cause marked increases in the concentrations of drugs that are also CYP3A4 substrates (e.g. statins).

Atazanavir and darunavir are generally well tolerated and are the currently preferred agents in this class. Darunavir is generally well tolerated. Atazanavir commonly causes unconjugated hyperbilirubinaemia, which is benign but cosmetically unacceptable to many people. Atazanavir needs gastric acidity to aid absorption. Protease inhibitors, especially darunavir, have a high genetic barrier to resistance. These agents are now mainly reserved for individuals with resistance to NNRTIs or INSTIs.

Integrase strand transfer inhibitors (INSTIs)

These agents act by blocking viral DNA incorporation into the host genome through integrase strand transfer inhibition. INSTIs are the most commonly prescribed antiretroviral agents world-wide. INSTIs are generally well tolerated. The second generation INSTIs dolutegravir, bictegravir and cabotegravir are recommended because they have a higher genetic barrier to resistance than the first generation agents, e.g. raltegravir. INSTIs should not be co-administered with strong inducers (e.g. rifampicin), but dolutegravir can be used with an increased dose. INSTIs are usually co-administered with two NRTIs but dolutegravir can be administered in two drug combinations with lamivudine or rilpivirine. Cabotegravir can be combined with rilpivirine as part of long-acting injectable therapy.

Anti-SARS-CoV-2 agents

Remdesivir

Remdesivir is an intravenous RNA-dependent RNA polymerase inhibitor that has a broad antiviral spectrum in vitro and has decreased the time to recovery following SARS-CoV-2 infection. It is a prodrug of a nucleotide and requires intracellular phosphorylation to act as a ribonucleotide analogue and to inhibit the RNA polymerase. It is indicated both for hospitalised patients with pneumonia requiring supplemental oxygen and for patients with mild to moderate infection (including those in the community) at high risk of progression to severe disease. The main side-effects include abnormal liver function tests and infusion reactions. It is metabolised by several cytochrome P450 enzymes but no clinically significant drug–drug interactions are usually encountered with CYP3A4 inducers. It is not recommended for people with alanine aminotransferase (ALT) > 5 times normal in people without a history of chronic liver disease or pregnant women. It is administered as a 200 mg loading dose and 100 mg daily infused over 30 minutes, usually for a five-day course in hospitalised patients.

Nirmatrelvir/ritonavir (Paxlovid)

Nirmatrelvir is a SARS-CoV-2 protease inhibitor boosted by the CYP3A4 inhibitor ritonavir. It is an oral drug. It is used in people with SARS-CoV-2 who have mild to moderate COVID-19 and do not require supplemental oxygen and who are at high risk of progression to severe disease. It is licensed on the basis of high efficacy in preventing severe disease when administered within five days of symptom onset in unvaccinated individuals but is now used on vaccinated individuals who are at high risk of progression to severe disease, although the degree of efficacy is less certain. Due to the presence of ritonavir, it is subject to many drug–drug interactions, which limits its use in many patients. Side-effects include altered sense of taste (dysgeusia), diarrhoea, myalgia, skin rash, elevated liver function tests and elevation of blood pressure. It is taken as 300 mg nirmatrelvir and 100 mg ritonavir twice daily for five days. As with other agents, there may be a rebound in symptoms and in positive tests for SARS-CoV-2 after completing the course.

Molnupiravir

Molnupiravir is a prodrug for a synthetic nucleoside and during viral replication it is incorporated into the viral RNA by the RNA-dependent RNA polymerase introducing multiple mutations that compromise viral survival. It is used in patients with mild to moderate COVID-19 who are at risk of progression to severe disease. To date there are limited data on efficacy in vaccinated patients and it is usually reserved for those who are unable to take Paxlovid due to drug–drug interactions and who need to take an oral drug. Side-effects include nausea, diarrhoea and dizziness.

Other agents used to treat viruses

Antiviral agents used to treat hepatitis B and C virus are discussed on pages 904 and 908.

Ribavirin

Ribavirin is a guanosine analogue that inhibits nucleic acid synthesis in a variety of viruses. It is used in particular in the treatment of hepatitis C virus but also against certain viral haemorrhagic fevers, e.g. Lassa fever, although it has not been useful against Ebola virus.

Antiparasitic agents

Antimalarial agents

Artemisinin (qinghaosu) derivatives

Artemisinin originates from a herb (sweet wormwood, *Artemisia annua*), which was used in Chinese medicine to treat fever. Its derivatives, artemether and artesunate, were developed for use in malaria in the 1970s. Their mechanism of action is unknown. They are used in the treatment, but not prophylaxis, of malaria, usually in combination with other antimalarials, and are effective against strains of *Plasmodium* spp. that are resistant to other antimalarials. Artemether is lipid-soluble and may be administered via the intramuscular and oral routes. Artesunate is water-soluble and is administered intravenously or orally. Serious adverse effects are uncommon. Current advice for malaria in pregnancy is that the artemisinin derivatives should be used to treat uncomplicated *falciparum* malaria in the second and third trimesters, but should not be prescribed in the first trimester until more information becomes available.

Atovaquone

Atovaquone inhibits mitochondrial function. It is an oral agent, used for treatment and prophylaxis of malaria, in combination with proguanil (see below), without which it is ineffective. It is also employed in the treatment of mild cases of *Pneumocystis jirovecii* pneumonia, or as prophylaxis, where there is intolerance to co-trimoxazole. Significant adverse effects are uncommon.

Folate synthesis inhibitors (proguanil, pyrimethamine–sulfadoxine)

Proguanil inhibits dihydrofolate reductase and is used for malaria prophylaxis. Pyrimethamine–sulfadoxine may be used in the treatment of malaria.

Quinoline-containing compounds

Chloroquine and quinine are believed to act by intraparasitic inhibition of haem polymerisation, resulting in toxic build-up of intracellular haem. The mechanisms of action of other agents in this group (quinidine, amodiaquine, mefloquine, primaquine, etc.) may differ. They are employed in the treatment and prophylaxis of malaria. Primaquine is used for radical cure of malaria due to *Plasmodium vivax* and *P. ovale* (destruction of liver hypnozoites). Chloroquine may also be given for extraintestinal amoebiasis.

Chloroquine can cause significant pruritus. If used in long-term, high-dose regimens, it causes an irreversible retinopathy. Overdosage leads to life-threatening cardiotoxicity. The side-effect profile of mefloquine includes neuropsychiatric effects ranging from mood change, nightmares and agitation to hallucinations and psychosis. Quinine may cause hypoglycaemia and cardiotoxicity, especially when administered parenterally. Primaquine causes haemolysis in people with glucose-6-phosphate dehydrogenase deficiency, which should be excluded before therapy. Chloroquine is considered safe in pregnancy but mefloquine should be avoided in the first trimester.

Chloroquine (and its metabolite hydroxychloroquine) exhibits in vitro activity against the virus SARS-CoV-2 but has not demonstrated clinical efficacy.

Lumefantrine

Lumefantrine is used in combination with artemether to treat uncomplicated *falciparum* malaria, including chloroquine-resistant strains. Its mechanism of action is unknown. Significant adverse effects are uncommon.

Drugs used in trypanosomiasis

The antiparasitic agents used to treat human African trypanosomiasis (HAT) and American trypanosomiasis (Chagas disease) (benznidazole, eflornithine, fexinidazole, melarsoprol, nifurtimox, pentamidine and suramin) are discussed in detail on pages 378 and 379.

In addition to its use in HAT, pentamidine is used in leishmaniasis (p. 381) and in severe *Pneumocystis jirovecii* pneumonia, if co-trimoxazole cannot be tolerated or is ineffective. It is administered via intravenous or intramuscular routes. It is a relatively toxic drug, commonly causing rash, renal impairment, profound hypotension (especially on rapid infusion), electrolyte disturbances, blood dyscrasias and hypoglycaemia.

Other antiprotozoal agents

Pentavalent antimonials

Sodium stibogluconate and meglumine antimoniate inhibit protozoal glycolysis by phosphofructokinase inhibition. They are used parenterally (intravenous or intramuscular) to treat leishmaniasis. Adverse effects include arthralgia, myalgias, raised hepatic transaminases, pancreatitis and electrocardiogram changes. Severe cardiotoxicity leading to death is not uncommon.

Diloxanide furoate

This oral agent is used to eliminate luminal cysts following treatment of intestinal amoebiasis, or in asymptomatic cyst excreters. The drug is absorbed slowly (enabling luminal persistence) and has no effect in hepatic amoebiasis. It is a relatively non-toxic drug, the most significant adverse effect being flatulence.

Iodoquinol (di-iodohydroxyquinoline)

Iodoquinol is a quinoline derivative with activity against *Entamoeba histolytica* cysts and trophozoites. It is used orally to treat asymptomatic cyst excreters or, in association with another amoebicide (e.g. metronidazole), to treat extraintestinal amoebiasis. Long-term use of this drug is not recommended, as neurological adverse effects include optic neuritis and peripheral neuropathy.

Nitazoxanide

Nitazoxanide is an inhibitor of pyruvate–ferredoxin oxidoreductase-dependent anaerobic energy metabolism in protozoa. It is a broad-spectrum agent, active against various nematodes, tapeworms, flukes and intestinal protozoa. Nitazoxanide also has activity against some anaerobic bacteria and viruses. It is administered orally in giardiasis and cryptosporidiosis. Adverse effects are usually mild and involve the gastrointestinal tract (e.g. nausea, diarrhoea and abdominal pain).

Paromomycin

Paromomycin is an aminoglycoside that is used to treat visceral leishmaniasis and intestinal amoebiasis. It is not significantly absorbed when administered orally, and is therefore given orally for intestinal amoebiasis and by intramuscular injection for leishmaniasis. It showed early promise in the treatment of HIV-associated cryptosporidiosis but subsequent trials have demonstrated that this effect is marginal at best.

Drugs used against helminths

Benzimidazoles (albendazole, mebendazole)

These agents act by inhibiting both helminth glucose uptake, causing depletion of glycogen stores, and fumarate reductase. Albendazole is used for hookworm, ascariasis, threadworm, *Strongyloides* infection, trichinellosis, *Taenia solium* (cysticercosis) and hydatid disease. Mebendazole is used for hookworm, ascariasis, threadworm and whipworm. The drugs are administered orally. Absorption is relatively poor but is increased by a fatty meal. Significant adverse effects are uncommon.

Bithionol

Bithionol is used to treat fluke infections with *Fasciola hepatica*. It is well absorbed orally. Adverse effects are mild (e.g. nausea, vomiting, diarrhoea, rashes) but relatively common (approximately 30%).

Diethylcarbamazine

Diethylcarbamazine (DEC) is an oral agent used to treat filariasis and loiasis. Treatment of filariasis is often followed by fever, headache, nausea, vomiting, arthralgia and prostration. This is caused by the host response to dying microfilariae, rather than the drug, and may be reduced by pre-treatment with glucocorticoids.

Ivermectin

Ivermectin binds to helminth nerve and muscle cell ion channels, causing increased membrane permeability. It is an oral agent, used in *Strongyloides* infection, filariasis and onchocerciasis. Significant side-effects are uncommon.

Niclosamide

Niclosamide inhibits oxidative phosphorylation, causing paralysis of helminths. It is an oral agent, used in *Taenia saginata* and intestinal *T. solium* infection. Systemic absorption is minimal and it has few significant side-effects.

Piperazine

Piperazine inhibits neurotransmitter function, causing helminth muscle paralysis. It is an oral agent, used in ascariasis and threadworm *(Enterobius vermicularis)* infection. Significant adverse effects are uncommon but include neuropsychological reactions such as vertigo, delirium and convulsions.

Praziquantel

Praziquantel increases membrane permeability to Ca^{2+}, causing violent contraction of worm muscle. It is the drug of choice for schistosomiasis and is also used in *T. saginata*, *T. solium* (cysticercosis) and fluke infections *(Clonorchis*, *Paragonimus)* and in echinococcosis. It is administered orally and is well absorbed. Adverse effects are usually mild and transient, and include nausea and abdominal pain.

Pyrantel pamoate

This agent causes spastic paralysis of helminth muscle through a suxamethonium-like action. It is used orally in ascariasis and threadworm infection. Systemic absorption is poor and adverse effects are uncommon.

Thiabendazole

Thiabendazole inhibits fumarate reductase, which is required for energy production in helminths. It is used orally in *Strongyloides* infection and topically to treat cutaneous larva migrans. Significant adverse effects are uncommon.

Multiple Choice Questions

7.1. A 19-year-old student who had not received any childhood vaccines through parental choice attends a music festival. Nine days later she develops an illness consisting of conjunctivitis and malaise with some intraoral lesions, followed by a generalised maculopapular rash. With respect to the most likely causative organism, which of the following statements is false?

A. The basic reproduction number (R_0) for this pathogen is one of the highest encountered for an infectious disease
B. R_0 gives an estimate of how many infections are likely to arise from an infected individual and is dependent on vaccine uptake and previous infections
C. R_0 for this infection is higher than that for SARS-CoV-2 and Ebola
D. Since R_0 for this infection is high the proportion of the population who need to be immunised to prevent spread of infection is high
E. R_e gives an estimate of how many infections are likely to arise from an infected individual taking into account vaccine uptake in the population

Answer: B.

The case describes a measles infection. R_0 is an estimate of the number of cases that can be expected to be acquired from a single primary case when all individuals in the population are susceptible to infection, and is high for measles (usually cited as 12–18). R_0 is dependent on the inherent transmissibility of the organism and assumes susceptibility of the population. R_0 is affected by the social habits and interactions of a population at the time it is calculated, and therefore the R_0 for a disease transmitted by close contact will be higher if calculated in a densely populated area than a sparsely populated area. Because measles has a high R_0, the number of people in the population who need to be vaccinated to control measles is high. R_e gives a more accurate assessment of the number of infections that can be expected to arise within a population than R_0 because it takes into account the number of susceptible individuals within the population (i.e. considers the impacts of vaccination programmes and those who have acquired immunity through natural infection) as well as *changes* in behaviour (e.g. the introduction of social distancing, use of personal protective equipment etc.). R_e therefore varies with time and population behaviour.

7.2. A 23-year-old woman with cystic fibrosis and a history of multiple infectious exacerbations is admitted to hospital with increasing breathlessness. A chest X-ray reveals patchy infiltrates throughout the right lower lung on a background of bronchial dilatation in both lungs. Sputum culture yields profuse growth of an oxidase-positive gram-negative bacillus. The patient has a history of rash with piperacillin–tazobactam but has tolerated cephalosporins without previous problems. Which of the following would be a suitable agent to treat the most likely causative organism?

A. Cefaclor
B. Cefazolin
C. Ceftriaxone
D. Ceftazidime
E. Cephalexin

Answer: D.

The patient has a history of cystic fibrosis with multiple infectious exacerbations. Although an oxidase-positive gram-negative bacillus could describe several organisms, the most likely one in a setting of cystic fibrosis with multiple infective exacerbations is *P. aeruginosa*. As the patient has tolerated cephalosporins previously with no problems, it is reasonable to treat her with an anti-pseudomonal cephalosporin despite her history of rash with another β-lactam antibiotic (piperacillin–tazobactam). Ceftazidime is the only anti-pseudomonal cephalosporin on this list. The only other third-generation cephalosporin that has good gram-negative coverage on the list is ceftriaxone, but it lacks activity against *P. aeruginosa*.

7.3. A 58-year-old man with diabetes mellitus is hospitalised with an acute myocardial infarction. He develops cardiac failure and acute kidney injury (AKI) and spends a period of time in the cardiac intensive care unit. He subsequently develops a fever and his blood cultures are positive for a yeast, which is identified as *Candida krusei*. An antifungal agent is selected on the basis of likely susceptibility and patient comorbidities. The mechanism of action of this antifungal is:

A. Accumulation of toxic 14α-methylated sterols
B. DNA topoisomerase inhibition
C. Ergosterol synthesis inhibition in the cell membrane
D. Impairment of DNA synthesis due to inhibition of thymidylate synthase
E. Inhibition of β-1,3-glucan synthesis in the cell wall

Answer: E.

The candidaemia is likely to be related to a central venous catheter infection and *Candida krusei* is resistant to antifungal azoles. The best initial therapy is therefore an echinocandin such as caspofungin, which acts by inhibiting fungal β-1,3-glucan synthase. It would not be appropriate to treat this patient with an amphotericin B preparation because of his AKI and the potential for nephrotoxicity. Antifungal azoles act by inhibiting ergosterol synthesis resulting in toxic accumulation of 14αmethylated sterols. Flucytosine (5-fluorocytosine) inhibits DNA synthesis by its actions on thymidylate synthase. Inhibition of bacterial DNA topoisomerases is the mechanism of action of fluoroquinolones, but not of any antifungals.

7.4. A 26-year-old man who grew up on a farm in rural Argentina is investigated for chronic abdominal pain and weight loss. He is found on investigation to have infection with *Taenia saginata* and treatment is recommended. Guidelines suggest you should prescribe praziquantel but your pharmacy is not able to obtain any supplies of this drug. What would be a suitable alternative agent to use to treat this infection?

A. Bithionol
B. Diethylcarbamazine
C. Niclosamide
D. Piperazine
E. Thiabendazole

Answer: C.

Infections with intestinal tapeworms such as *T. saginata* are often asymptomatic but can occasionally give rise to symptoms, as in this case. The preferred treatment for *Taenia* infections is praziquantel but niclosamide or nitazoxanide are alternatives. The other agents listed are used for other helminth infections.

7.5. A 37-year-old from Vietnam is diagnosed with HIV infection and a low CD4 T-cell count. He starts antiretroviral therapy to treat his HIV infection and co-trimoxazole to prevent *Pneumocystis* pneumonia. After two months his HIV viral load has become undetectable with a significant increase in his CD4 T-cell count, which is now over 200 cells/mm^3. Pneumococcal vaccination has not yet been performed, but he admits to stopping his co-trimoxazole. He is now experiencing fevers, weight loss and increasing shortness of breath. His chest X-ray reveals mediastinal and hilar lymph nodes, bilateral pulmonary infiltrates and a left-sided pleural effusion. What are his symptoms most likely due to?

A. HIV-related lymphoma
B. *Pneumocystis* pneumonia
C. Immune response inflammatory syndrome
D. Pneumococcal pneumonia
E. Drug-related side effects due to antiretroviral therapy

Answer: C.

The symptoms in this case have come on after therapy was commenced, which raises suspicion of a drug-related side-effect, but the nature of the lesions on chest X-ray are not consistent. They have occurred at a time when the immunodeficiency associated with HIV has been reversed, which raises suspicion of an immune response inflammatory syndrome, in this case due to tuberculosis, which he is likely to have been previously exposed to growing up. Although lymphoma could explain lymphadenopathy and fevers, the pulmonary infiltrates would be less likely. Although he has stopped his prophylaxis, his rise in CD4 counts makes *Pneumocystis* pneumonia less likely. People with HIV remain at risk of pneumococcal disease, but although he remains at risk and has not been vaccinated, the clinical presentation with lymphadenopathy and the radiological appearances make this less likely.

7.6. Your hospital has had four cases of blood-stream infection in the last 5 weeks due to *Serratia marcescens*. The cases commenced approximately 4 weeks after a major change in the hospital's antimicrobial stewardship policy and the recommendations on antimicrobials to use in patients with post-surgical infections. You typically have 1–2 cases of blood-stream infection due to this microorganism per year. The cases were cared for in different units and there was no direct contact between the cases while hospitalised. All cases had surgery performed but in three different units. The hospital infection control team start to investigate the cases. How would you best describe the relationship between these cases?

A. Hospital outbreak
B. Epidemic
C. Increased incidence due to changes in antimicrobial stewardship policy
D. Pandemic
E. Common source outbreak

Answer: E.

The cases are most consistent with a common source outbreak that is linked to some common environmental factor. As the cases are geographically dispersed, the team will consider other shared factors such as shared infusions or injected agents that could be contaminated. Since the patients were cared for in different units, there is no evidence of a hospital outbreak. The numbers are not consistent with a pandemic or epidemic. While changes in antimicrobial prescribing might impact incidence, it would be unlikely to explain the incidence of this infection, which is resistant to many commonly used antimicrobials.

Cancer represents a significant global health, social and economic burden. In 2022 there were 20 million new cases of cancer worldwide and 9.7 million cancer deaths, making it the second leading cause of death. By 2050, it is projected that there will be over 35 million new cancer cases, which represents a 77% increase compared to 2022. This significant increase in global cancer burden is due to population growth and ageing, and to exposure to risk factors including tobacco, obesity, alcohol and air pollution. The proportional increase in cancer incidence is most marked in low (142%) and medium (99%) human development index (HDI) countries, where cancer mortality is projected to double by 2050. Inequity in cancer outcomes according to human deprivation is clearly demonstrated by breast cancer figures. In the highest HDI countries, 1 in 12 women will develop breast cancer in their lifetime and 1 in 71 will die from it, whereas in the lowest HDI countries, 1 in 27 will develop breast cancer, but 1 in 48 will die from it. This disproportionately high cancer mortality happens in countries with limited or no access to investigations, leading to late diagnosis, and with low per capita expenditure on health care, resulting in insufficient access to appropriate treatments.

The most common solid organ malignancies arise in the lung, breast, colon/rectum, prostate and stomach (Fig. 8.1), and the leading cause of cancer death is lung (19%) then colorectal cancer (9%). Cigarette smoking accounts for more than 20% of all global cancer deaths, 80% of lung cancer cases in men and 50% of lung cancer cases in women worldwide, which could be prevented by smoking cessation. Diet and alcohol contribute to a further 30% of cancers, including those of the stomach, colon, oesophagus, breast and liver. Lifestyle modification could reduce these if steps were taken to avoid animal fat and red meat, reduce alcohol, increase fibre, fresh fruit and vegetable intake, avoid obesity and increase physical activity. Infections account for a further 15% of cancers (25% of cancers in low and medium HDI countries), including those of the cervix, stomach, liver, nasopharynx, anus and bladder, some of which could be prevented by infection control and vaccination.

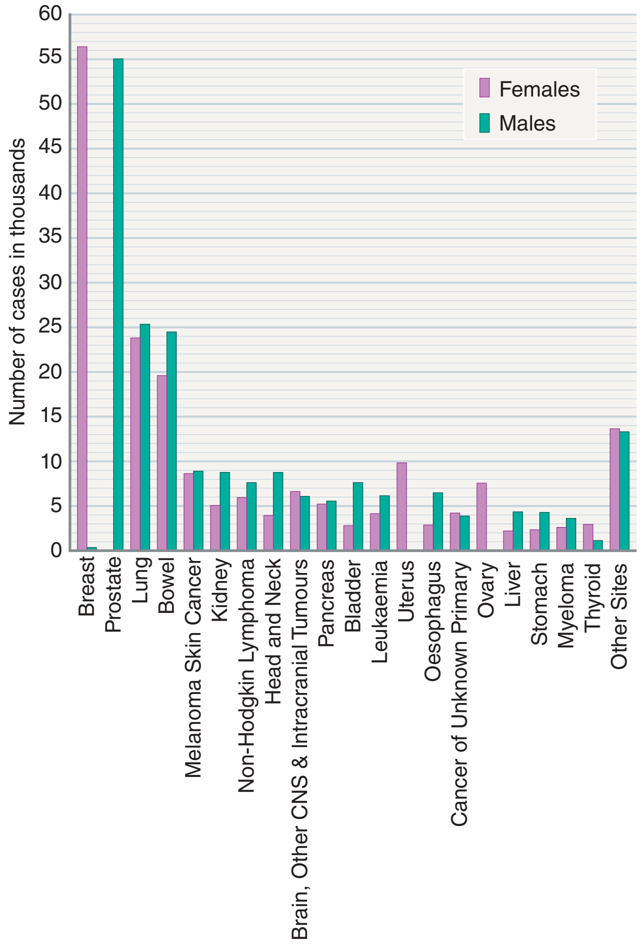

Fig. 8.1 The 20 most common cancers in the UK. (CNS = central nervous system) *Statistics from Cancer Research UK website (cancerresearchuk.org), accessed Feb 2025.*

The 10 hallmarks of cancer

The formation and growth of cancer is a multistep process, during which normal cells are transformed into malignant cells. Ten key characteristics that underlie these steps, collectively referred to as the 'hallmarks of cancer', have been described.

1. Genome instability and mutation

Random genomic aberrations occur continuously throughout all cells of the body. This may include somatic point mutations, insertions, deletions and chromosome structural changes (i.e. copy number changes, chromosomal translocations). Epigenomic aberrations, such as DNA methylation and histone modification, may also occur. Rarely, aberrations will confer a selective survival advantage on single cells, 'driving' overgrowth and dominance in local tissue environments. Multistep carcinogenesis results from successive clonal expansions of pre-malignant cells, each expansion being triggered by acquisition of a random driver aberration.

Under normal circumstances, genome maintenance systems and DNA repair mechanisms are so effective that almost all spontaneous genomic aberrations are repaired, or damaged cells are forced into senescence or apoptosis. In cancer cells, though, the accumulation of mutations can be accelerated by compromising these maintenance mechanisms. In turn, this leads to the accumulation of driver genomic aberrations, which lead to cancer growth and progression. Genomic sequencing technology demonstrates that the pattern of aberrations varies dramatically between cancer types. However, defects in genome maintenance mechanisms leading to genome instability are common findings across all cancers. This enabling characteristic may lead to the acquisition of other hallmarks.

2. Resisting cell death

There are three principal mechanisms through which cell death occurs in healthy tissues: apoptosis, autophagy and necrosis.

Apoptosis

This is programmed cell death. It is frequently found at markedly reduced rates in cancers, particularly those of high grade or those resistant to treatment. The cellular apoptotic system has regulatory elements that sense intrinsic and extrinsic pro-apoptotic signals. This initiates a cascade of proteolysis and cell disassembly with nuclear fragmentation, chromosomal condensation and shrinking of the cell with loss of intercellular contact, followed by cellular fragmentation and the formation of apoptotic bodies that are phagocytosed by neighbouring cells. The most important regulator of apoptosis is the *TP53* tumour suppressor gene, often described as the 'guardian of the genome' as it is able to induce apoptosis in response to sufficient levels of genomic damage. The largest initiator of apoptosis via *TP53* is cellular injury, particularly that due to DNA damage from cytotoxic chemotherapy, oxidative damage and ultraviolet (UV) radiation. Disruption of p53 protein function as a result of mutations in the *TP53* gene are found in over half of cancers.

Autophagy

This is a catabolic process during which cellular constituents are degraded by lysosomal machinery within the cell. It is an important physiological mechanism; it usually occurs at low levels in cells but can be induced in response to environmental stresses, particularly radiotherapy and cytotoxic chemotherapy, which induce elevated levels of autophagy that are cytoprotective for malignant cells, thus impeding rather than perpetuating the killing actions of these stress situations. Severely stressed cancer cells have been shown to shrink via autophagy to a state of reversible dormancy.

Necrosis

This is the premature death of cells and is characterised by the release of cellular contents into the local tissue microenvironment, in marked contrast to apoptosis, where cells are disassembled in a step-by-step fashion and the resulting cellular fragments are phagocytosed. Necrotic cell death results in the recruitment of inflammatory immune cells, promotion of angiogenesis and release of stimulatory factors that increase cellular proliferation and tissue invasion, thereby enhancing rather than inhibiting carcinogenesis.

3. Sustaining proliferative signalling

The 'cell cycle' is tightly controlled at different stages. Normal cells grow and divide in response to external signals, typically growth factors. These are able to bind to cell surface–bound receptors that activate an intracellular tyrosine kinase–mediated signalling cascade, ultimately leading to changes in gene expression that promote cellular proliferation and growth.

The cell cycle

The cell cycle is composed of four ordered, strictly regulated phases referred to as G_1 (gap 1), S (DNA synthesis), G_2 (gap 2) and M (mitosis) (Fig. 8.2). Normal cells grown in culture will stop proliferating and enter a quiescent state called G_0 once they become confluent or are deprived of serum or growth factors. The first gap phase (G_1) prior to the initiation of DNA synthesis represents the period of commitment that separates M and S phases as cells prepare for DNA duplication. Cells in G_0 and G_1 are receptive to growth signals, but once they have passed a restriction point, they are committed to enter DNA synthesis (S phase). Cells demonstrate arrest at different points in G_1 in response to different inhibitory growth signals. Mitogenic signals promote progression through G_1 to S phase, utilising phosphorylation of the retinoblastoma gene product (pRB; p. 38). Following DNA synthesis, there is a second gap phase (G_2) prior to mitosis (M), allowing cells to repair errors that have occurred during DNA replication and thus preventing propagation of these errors to daughter cells. Although the duration of individual phases may vary, depending on cell and tissue type, most adult cells are in a G_0 state at any one time.

Stimulation of the cell cycle

Many cancer cells produce growth factors, which drive their own proliferation by a positive feedback mechanism known as autocrine stimulation. Examples include transforming growth factor-alpha (TGF-α) and platelet-derived growth factor (PDGF). Other cancer cells express growth factor receptors at increased levels due to gene amplification or express abnormal receptors that are permanently activated. This results in abnormal cell growth in response to physiological growth factor stimulation or even in the absence of growth factor stimulation (ligand-independent signalling). The epidermal growth factor receptor (EGFR) is often over-expressed in lung and gastrointestinal tumours and the human epidermal growth factor receptor 2 (HER2)/neu receptor is frequently over-expressed in breast cancer. Both receptors activate the Ras–Raf–mitogen activated protein (MAP) kinase pathway, causing cell proliferation.

4. Evading growth suppressors

The cell cycle is orchestrated by a number of molecular mechanisms, most importantly by cyclins and cyclin-dependent kinases (CDKs). Cyclins bind to CDKs and are regulated by both activating and inactivating phosphorylation, with two main checkpoints at G_1/S and G_2/M transition. The genes that inhibit progression play an important part in tumour prevention and are referred to as tumour suppressor genes (e.g. *TP53*, *TP21*, *TP16* genes). The products of these genes deactivate the cyclin–CDK complexes and are thus able to halt the cell cycle. The complexity of cell cycle control is susceptible to dysregulation, and mutations within inhibitory proteins are common in cancer.

Fig. 8.3 **Oncogenesis**. The multistep origin of cancer, showing events implicated in cancer initiation, progression, invasion and metastasis.

5. Enabling replicative immortality

Normal cells have a limited number of divisions before they are unable to divide further (senescence) or before they die (crisis). These limits are controlled by telomeric DNA sequences, which protect and stabilise chromosomal ends. During replication, telomeres shorten progressively as small fragments of telomeric DNA are lost with successive cycles of replication. This shortening process represents a mitotic clock and eventually prevents the cell from dividing further. Telomerase, a specialised polymerase enzyme, adds nucleotides to telomeres, allowing continued cell division and thus preventing premature arrest of cellular replication. The telomerase enzyme is almost absent in normal cells, but is expressed at significant levels in the majority of human cancers.

6. Inducing angiogenesis

All cells and body tissues require sustenance in the form of nutrients and oxygen, as well as an ability to evacuate metabolic waste products and carbon dioxide. Tumours require a functional vascular network to ensure continued growth and are unable to grow beyond 1 mm^3 without stimulating the development of a vascular supply through angiogenesis (Figs. 8.3 and 8.4).

Angiogenesis is dependent on the production of angiogenic growth factors, of which vascular endothelial growth factor (VEGF) and platelet-derived growth factor (PDGF) are the best characterised. During tumour progression, an angiogenic switch is activated and remains on, causing normally quiescent vasculature to develop new vessels continually to help sustain expanding tumour growth. Angiogenesis is governed by a balance of pro-angiogenic stimuli and angiogenesis inhibitors, such as thrombospondin (TSP)-1, which binds to transmembrane receptors on endothelial cells and evokes suppressive signals. A number of cells can contribute to the maintenance of a functional tumour vasculature and therefore sustain angiogenesis. These include pericytes and a variety of bone marrow–derived cells such as macrophages, neutrophils, mast cells and myeloid progenitors.

(VEGF = vascular endothelial growth factor)

7. Activating invasion and metastasis

The ability to invade neighbouring tissue determines whether a tumour is benign or malignant. Clinically, the presence of metastases often determines whether a cancer can be cured. The invasion-metastatic cascade is a complex multistep process. The initiation of this process is enabled by epithelial–mesenchymal transition (EMT). Cancer cells in a tumour lose normal cell–cell adhesion through the down-regulation or, occasionally, mutational inactivation of E-cadherin, a calcium-dependent cell–cell adhesion glycoprotein. After breaking through the basement membrane, cancer cells enter the blood stream (intravasation). These circulating tumour cells (CTCs) then exit the blood stream into distant tissues (extravasation) to form small nodules of cancer cells (micrometastases). Following mesenchymal–epithelial transition these micrometastatic lesions develop into macroscopic tumours (colonisation) (see Fig. 8.3).

Cross-talk between cancer cells and cells of the surrounding stromal tissue is involved in the acquired capability for invasive growth and metastasis. Mesenchymal stem cells in tumour stroma have been found to secrete CCL5, a protein chemokine that helps recruit leucocytes into inflammatory sites. With the help of particular T cell–derived cytokines (interleukin (IL)-2 and interferon-gamma (IFN-γ)), CCL5 induces proliferation and activation of natural killer cells and then acts reciprocally on cancer cells to stimulate invasive behaviour. Macrophages at the tumour periphery can foster local invasion by supplying matrix-degrading enzymes such as metalloproteinases and cysteine cathepsin proteases.

8. Deregulating cellular energetics

Under aerobic conditions, oxidative phosphorylation functions as the main metabolic pathway for energy production; cells process glucose, first to pyruvate via glycolysis and thereafter to carbon dioxide in the mitochondria. While under anaerobic conditions, glycolysis is favoured to produce adenosine triphosphate (ATP). Cancer cells can reprogram their glucose metabolism to limit energy production to glycolysis, even in the presence of oxygen. This has been termed 'aerobic glycolysis'. Up-regulation of glucose transporters, such as GLUT1, is the main mechanism through which aerobic glycolysis is achieved.

This reprogramming of energy metabolism appears paradoxical, as overall energy production from glycolysis is significantly lower (18-fold) than that from oxidative phosphorylation. One explanation may be that the increased production of glycolytic intermediates can be fed into various biosynthetic pathways, including those that generate the nucleosides and amino acids, necessary for the production of new cells.

9. Tumour-promoting inflammation

Almost all tumours show infiltration with immune cells on pathological investigation and historically this finding was thought to represent an attempt by the immune system to eradicate the cancer. It is now clear that tumour-associated inflammatory responses contribute to several hallmark capabilities and promote tumour formation and cancer progression. Immune cells may promote invasive behaviour, and bioactive molecules such as cytokines, growth factors and pro-angiogenic factors may be released into the tumour microenvironment. In particular, the release of reactive oxygen species, which are actively mutagenic, will accelerate the genetic evolution of surrounding cancer cells, enhancing growth and contributing to cancer progression.

10. Evading immune destruction

Cancer cells continuously shed antigens into the circulatory system, prompting an immune response that includes cytotoxic T-cell, natural killer cell and macrophage production. The immune system is thought to provide continuous surveillance, with resultant elimination of cells that undergo malignant transformation. However, if not all cancer cells are eliminated there may be a period of equilibrium where tumour growth is controlled by the immune system and cancer cells may enter a dormant state, sometimes for many years. Alternatively, cancer cells may escape immune control and grow into clinically apparent tumours. Several factors may contribute to immune escape, including reduced immune recognition, increased resistance or survival and the development of an immunosuppressive tumour microenvironment.

Immune checkpoints are increasingly recognised as key factors in the immune escape of tumours. These pathways are crucial for regulating the immune response to normal cells by down-regulating the immune system and promoting self-tolerance by suppressing T-cell immune activity. However, some cancers co-opt these protective mechanisms by stimulating immune checkpoint molecular targets such as the programmed cell death ligand (PD-L1), a protein that helps stop immune cells from attacking other cells in the body (see Fig. 4.14).

Environmental and genetic determinants of cancer

The majority of cancers do not have a single cause, but rather are the result of a complex interaction between genetic factors and exposure to environmental carcinogens. These are often tumour type-specific, but some general principles do apply.

Environmental factors

Environmental triggers for cancer have mainly been identified through epidemiological studies that examine patterns of distribution of cancers in patients in whom parameters such as age, sex, presence of other illnesses, social class, geography and diet differ. Sometimes these give strong pointers to the molecular or cellular causes of the disease, such as the association between aflatoxin production within contaminated food supplies and hepatocellular carcinomas. For most solid cancers, however, there is evidence of a multifactorial pathogenesis, even when there is a principal environmental cause (Box 8.1).

Smoking is now established beyond all doubt as a major cause of lung cancer, but there are additional predisposing factors since not all smokers develop cancer. Similarly, most carcinomas of the cervix are related to infection with human papillomavirus (HPV subtypes 16 and 18). For carcinomas of the bowel and breast, there is strong evidence of an environmental component. For example, the risk of breast cancer in women of Far Eastern heritage remains relatively low when they first migrate to a country with a Western lifestyle, but rises in subsequent generations to approach that of the resident population of the host country. The precise environmental factors that cause this change are unclear but may include diet (higher intake of saturated fat and/or dairy products), reproductive patterns (later onset of first pregnancy) and lifestyle (increased use of artificial light and shift in diurnal rhythm).

Genetic factors

A number of inherited cancer syndromes are recognised and account for 5%–10% of all cancers (Box 8.2). Their molecular basis is discussed in Chapter 3, but in general they result from inherited mutations in driver genes that regulate cell growth, cell death and apoptosis. Although carriers of these pathogenic variants have a greatly elevated risk of cancer, none has 100% penetrance, and additional modulating factors, both genetic and environmental, are likely to be operative. Exploration of a possible genetic contribution is a key part of cancer management. It may inform anti-cancer therapy decisions in people with cancer. Patients and their family members may also benefit from screening investigations to detect cancer early and/or to enable preventative treatments, such as prophylactic mastectomy in women with a pathogenic variant in *BRCA1* or *BRCA2* or chemoprevention with aspirin in Lynch syndrome (p. 848 and Box 3.11).

Investigations

When a patient is suspected of having cancer, a full history should be taken. Attention should be paid to potential risk factors such as smoking and occupational exposures, any family history of cancer and elucidating potential complications of the disease. A thorough clinical examination

8.1 Environmental factors that predispose to cancer

Environmental aetiology	Processes	Diseases
Occupational exposure (see 'Radiation' below)	Dye and rubber manufacturing (aromatic amines)	Bladder cancer
	Asbestos mining, construction work, shipbuilding (asbestos)	Lung cancer and mesothelioma
	Vinyl chloride (PVC) manufacturing	Liver angiosarcoma
	Petroleum industry (benzene)	Acute leukaemia
Chemicals	Cytotoxic chemotherapy (e.g. melphalan, cyclophosphamide)	Acute myeloid leukaemia
Cigarette smoking	Exposure to carcinogens from inhaled smoke	Lung, throat, oesophagus and bladder cancer
Viral infection	Epstein–Barr virus	Burkitt lymphoma and nasopharyngeal cancer
	Human papillomavirus	Cervical cancer, anal cancer, oropharyngeal cancer
	Hepatitis B and C viruses	Hepatocellular carcinoma
Bacterial infection	*Helicobacter pylori*	Gastric MALT lymphomas, gastric cancer
Parasitic infection	Liver fluke *(Opisthorchis sinensis)*	Cholangiocarcinoma
	Schistosoma haematobium	Squamous cell bladder cancer
Dietary factors	Low roughage/high fat content diet	Colonic cancer
	High nitrosamine intake	Gastric cancer
	Aflatoxin from contamination of *Aspergillus flavus*	Hepatocellular cancer
Obesity	Reduced physical activity, increased insulin	Colon cancer
	Increased oestrogen	Breast and endometrial cancer
Radiation	UV exposure	Basal cell carcinoma Melanoma Non-melanocytic skin cancer
	Nuclear fallout following explosion (e.g. Hiroshima, Chernobyl)	Leukaemia Solid tumours, e.g. thyroid
	Diagnostic exposure (e.g. CT)	Cholangiocarcinoma following Thorotrast usage
	Occupational exposure (e.g. beryllium and strontium mining)	Lung cancer
	Therapeutic radiotherapy	Papillary thyroid cancer Sarcoma
Inflammatory diseases	Ulcerative colitis	Colon cancer
Hormonal	Use of diethylstilbestrol	Vaginal cancer
	Oestrogens	Endometrial cancer Breast cancer

(CT = computed tomography; MALT = mucosa-associated lymphoid tissue; UV = ultraviolet)

is essential to identify both the primary cancer site and possible sites of metastases, and to discover any other conditions that may have a bearing on the management plan. The earlier a cancer is detected, the better the outcome.

In order to plan the most appropriate investigations and management, information is needed on:

- the extent of disease
- the type of cancer
- the patient's fitness.

Determining the extent of disease (staging)

The extent of disease, such as how large a tumour is and if it has spread, is determined by the process of staging. It entails clinical examination, imaging (e.g. CT, MRI, PET), specialised investigations (e.g. mammography, colonoscopy, endoscopy, laparoscopy, mediastinoscopy) and, in some cases, surgery. The outcome is recorded using a standard staging classification that allows comparisons to be made between different groups of patients. One of the most commonly used systems is the T (tumour), N (regional lymph nodes), M (metastatic sites) approach of the International Union against Cancer (UICC; Box 8.3). For most cancers, staging will define patients into having:

- *early, localised disease*, which can be cured with surgery or other localised therapy (e.g. radiotherapy or ablative therapies)
- *locally advanced disease*, which can often be cured with a combination of surgery and/or systemic anti-cancer therapy and/or radiotherapy
- *metastatic disease*, where the cancer has spread to distant sites, which can only rarely be cured with systemic anti-cancer therapy, radiotherapy and/or surgery.

Imaging plays a critical role in the diagnosis and staging of cancer. It is also used to determine the response to treatment. The imaging modality employed depends primarily on the site of the disease and likely patterns of spread.

Computed tomography

Computed tomography (CT) is a key investigation in cancer patients and is particularly useful in imaging the thorax and abdomen (Fig. 8.5). With modern scanners it is possible to visualise the large bowel if it is prepared (CT colonography), allowing accurate detection of colorectal cancers and adenomas ≥ 10 mm.

Ultrasound

Ultrasound is useful in characterising lesions within the liver, kidney, pancreas and reproductive organs. It may be used for guiding biopsies of tumours in the breast and liver. Endoscopic ultrasound is helpful in staging lung, upper gastrointestinal and pancreatic cancers, involving a special endoscope/bronchoscope with an ultrasound and biopsy probe attached.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) has a high resolution and is the preferred technique for brain, bone and pelvic imaging. It is widely employed for the staging of rectal, cervical and prostate cancers.

i 8.2 Inherited cancer predisposition syndromes

Syndrome	Malignancies	Inheritance	Gene
Ataxia telangiectasia	Leukaemia, lymphoma, ovarian, gastric, brain, colon	AR	*AT*
Bloom syndrome	Leukaemia, tongue, oesophageal, colonic, Wilms tumour	AR	*BLM*
Breast/ovarian	Breast, ovarian, colonic, prostatic, pancreatic	AD	*BRCA1*, *BRCA2*
Cowden syndrome	Breast, thyroid, gastrointestinal tract, pancreatic	AD	*PTEN*
Familial adenomatous polyposis	Colonic, upper gastrointestinal tract	AD	*APC*, *MUTYH*
Familial atypical multiple mole melanoma (FAMMM)	Melanoma, pancreas	AD	*CDKN2A (TP16)*
Fanconi anaemia	Leukaemia, oesophageal, skin, hepatoma	AR	*FACA*, *FACC*, *FACD*
Gorlin syndrome	Basal cell skin, brain	AD	*PTCH1*
Hereditary diffuse gastric cancer	Diffuse gastric cancer	AD	*E-cadherin*
Hereditary non-polyposis colon cancer (HNPCC)	Colonic, endometrial, ovarian, pancreatic, gastric	AD	*MSH2*, *MLH1*, *MSH6*, *PMS1*, *PMS2*
Li–Fraumeni syndrome	Sarcoma, breast, osteosarcoma, leukaemia, glioma, adrenocortical	AD	*TP53*
Multiple endocrine neoplasia (MEN) 1	Pancreatic islet cell, pituitary adenoma, parathyroid adenoma and hyperplasia	AD	*MEN1*
MEN 2	Medullary thyroid, phaeochromocytoma, parathyroid hyperplasia	AD	*RET*
Neurofibromatosis 1	Neurofibrosarcoma, phaeochromocytoma, optic glioma	AD	*NF1*
Neurofibromatosis 2	Vestibular schwannoma	AD	*NF2*
Papillary renal cell cancer syndrome	Renal cell cancer	AD	*MET*
Peutz–Jegher syndrome	Colonic, ileal, breast, ovarian	AD	*STK11*
Prostate cancer	Prostate	AD	*HPC1*
Retinoblastoma	Retinoblastoma, osteosarcoma	AD	*RB1*
von Hippel–Lindau syndrome	Haemangioblastoma of retina and CNS, renal cell, phaeochromocytoma	AD	*VHL*
Wilms tumour	Nephroblastoma, neuroblastoma, hepatoblastoma, rhabdomyosarcoma	AD	*WT1*
Xeroderma pigmentosum	Skin, leukaemia, melanoma	AR	*XPA*, *XPC*, *XPD (ERCC2)*, *XPF*

(AD = autosomal dominant; AR = autosomal recessive; CNS = central nervous system)

Positron emission tomography

Positron emission tomography (PET) uses a radioactive tracer (often ^{18}F-fluorodeoxyglucose, or FDG) to visualise metabolic activity of tumour cells and is often used in combination with CT (PET-CT) to evaluate the extent or spread of the disease, particularly when a radical treatment approach is being considered. Not all tumour types are 'FDG PET-avid' and the metabolic activity of small but malignant cancer deposits or lymph nodes may not be detected, limiting the sensitivity of FDG PET-CT. Other radiopharmaceuticals can be used with PET in specific tumours; for example, the gallium-68 prostate-specific membrane antigen (^{68}Ga-PSMA) is highly sensitive in the detection of prostate cancer that has returned or spread to other parts of the body.

Biochemical markers

Many cancers produce substances called tumour markers, some of which may assist in diagnosis, response evaluation and detection of relapse. Unfortunately, most tumour markers are neither sufficiently sensitive nor sufficiently specific to be used in isolation for diagnosis and need to be interpreted in the context of other clinical features. Some can be used for antibody-directed therapy or imaging, where they have a greater role in diagnosis. Tumour markers in routine use are outlined in Box 8.4.

i 8.3 TNM classification

Extent of primary tumour*	
TX	Not assessed
T0	No tumour
T1	Increase in primary tumour size or depth of invasion
T2	
T3	
T4	
Increased involvement of nodes*	
NX	Not assessed
N0	No nodal involvement
N1	Increases in involvement
N2/3	
Presence of metastases	
MX	Not assessed
M0	Not present
M1	Present

*Exact criteria for size and region of nodal involvement have been defined for each anatomical site.

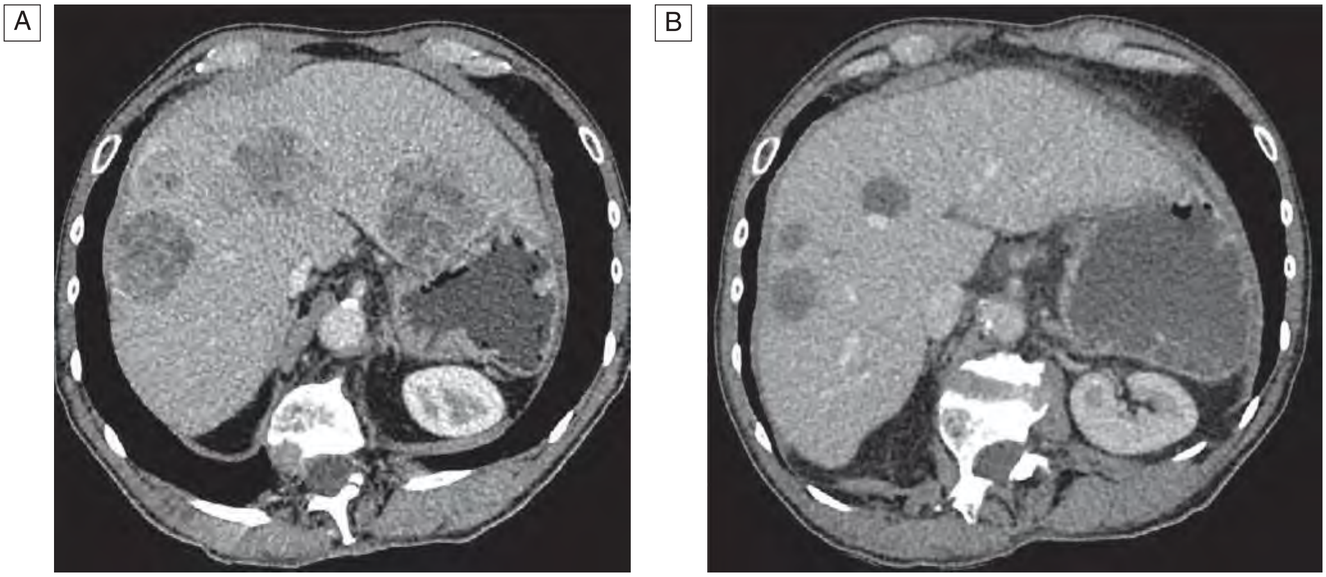

Fig. 8.5 **Computed tomography (CT) images.** A Extensive liver metastases in a patient with a neuroendocrine cancer of unknown primary. B Repeat imaging after cytotoxic chemotherapy showing a partial radiological response following systemic treatment.

8.4 Commonly used serum tumour markers

Name	Natural occurrence	Tumours
Alpha-fetoprotein (AFP)	Glycoprotein found in yolk sac and fetal liver tissue. Transient elevation in liver diseases. Has a role in screening during pregnancy for the detection of neural tube defects and Down syndrome	Ovarian non-seminomatous germ cell tumours (80%), testicular teratoma (80%), hepatocellular cancer (50%)
Beta-2-microglobulin	A human leucocyte antigen (HLA) common fragment present on surface of lymphocytes, macrophages and some epithelial cells. Can be elevated in autoimmune disease and renal glomerular disease	Non-Hodgkin lymphoma, myeloma
Calcitonin	32-amino-acid peptide from C cells of thyroid.	Medullary cell carcinoma of thyroid
Cancer antigen 125 (CA 125)	Differentiation antigen of coelomic epithelium (Müller duct). Raised in any cause of ascites, pleural effusion or heart failure. Can be raised in inflammatory conditions	Ovarian epithelial cancer (75%), gastrointestinal cancer (10%), lung cancer (5%) and breast cancer (5%)
Cancer antigen 19-9 (CA 19-9)	A mucin found in epithelium of fetal stomach, intestine and pancreas. It is eliminated exclusively via bile and so any degree of cholestasis can cause levels to rise	Pancreatic cancer (80%), mucinous tumour of the ovary (65%), gastric cancer (30%), colon cancer (30%)
Carcinoembryonic antigen (CEA)	Glycoprotein found in intestinal mucosa during embryonic and fetal life. Elevated in smokers, cirrhosis, chronic hepatitis, ulcerative colitis, pneumonia	Colorectal cancer, particularly with liver metastasis, gastric cancer, breast cancer, lung cancer, mucinous cancer of the ovary
Cancer antigen 15-3 (CA 15-3)	Part of the MUC1 protein family, which plays a role in cell signalling and forming protective barriers on epithelial surfaces. Naturally produced by cells in the breast. Elevated in liver disease, benign breast disease, pelvic inflammatory disease	Breast cancer (especially advanced stage). Can be seen at lower levels in lung cancer, ovarian cancer, pancreatic cancer, prostate cancer
Human chorionic gonadotrophin (hCG)	Glycoprotein hormone, 14 kD α subunit and 24 kD β subunit from placental syncytiotrophoblasts. Used for disease monitoring in hydatidiform mole and as the basis of a pregnancy test	Choriocarcinoma (100%), hydatidiform moles (97%), ovarian non-seminomatous germ cell tumours (50%–80%), seminoma (15%)
Placental alkaline phosphatase (PLAP)	Isoenzyme of alkaline phosphatase	Seminoma (40%), ovarian dysgerminoma (50%)
Prostate-specific antigen (PSA)	Glycoprotein member of human kallikrein gene family. PSA is a serine protease that liquefies semen in excretory ducts of prostate. Can be elevated in benign prostatic hypertrophy and prostatitis	Prostate cancer (95%)
Thyroglobulin	Matrix protein for thyroid hormone synthesis in normal thyroid follicles	Papillary and follicular thyroid cancer

(MEN = multiple endocrine neoplasia)

Establishing the type of cancer

In most cases assessment of tumour tissue is required to establish the tumour type. Tumour samples may be obtained in a variety of ways. Where surgical resection is planned the entire tumour, or parts of the tumour, may be available for examination. Tumour biopsies may be taken at endoscopy, surgery or by ultrasound- or CT-guided biopsy with the help of interventional radiology. At times examination of cells (cytology) from fluid (e.g. pleural or peritoneal), from a smear (e.g. cervical) or by doing fine needle aspiration of a palpable or visible lump (Box 8.5) may be acceptable.

Histopathology

Histopathology is the study of the microscopic appearance of tissue and cells (i.e. morphology). Examination of tumour samples by light microscopy, typically with histological staining to help identify important features and differentiate structural elements, remains pivotal in identifying the type of cancer. The majority (80%–90%) of cancers are carcinomas; malignant neoplasms of epithelial origin. Carcinoma comprises two major subtypes: adenocarcinomas, which develop in an organ or gland, and squamous cell carcinomas, which originate in squamous epithelium. Specific morphological appearances may give clues to the origin of a tumour. For example, signet cells favour a gastric primary and clear cells those of renal or ovarian cancers. However, the results of histopathological analysis are most informative when combined with knowledge of the clinical picture; results should therefore be reviewed and discussed within the context of a multidisciplinary team meeting.

Histopathological examination also provides details of a cancer's biological behaviour. The most commonly reported feature is the tumour grade, a prognostic marker describing how abnormal the cancer cells appear. Low grade, or well-differentiated, tumour cells look most like normal cells and are often slow growing. High-grade, or poorly/undifferentiated, tumour cells look most abnormal and typically grow and spread more rapidly. Other prognostic features such as the presence of lymphovascular invasion and the mitotic rate may also be reported.

Molecular pathology

Historically, all cancers with the same morphology were treated in similar ways. Molecular testing, including analyses of proteins, DNA or RNA, is increasingly used in the pathological assessment of cancer. Specific molecular tests, considered alongside histopathological findings and clinical information, may provide additional diagnostic, prognostic or predictive information to better inform a patient's management. This is often referred to as precision, or personalised oncology, the aim of which is to identify the optimal therapy for a patient that will maximise their quality of life and survival. Molecular pathology is a term that encompasses many different laboratory techniques.

8.5 How to perform a fine needle aspiration (FNA) of a tumour/lesion

- Ensure the patient is in a comfortable position with the lesion accessible to the operator.
- Identify the tumour, confirm that it is easily palpable and make sure there are no nearby critical structures.
- If tumour is not palpable or there is concern about nearby critical structures, perform FNA under ultrasound guidance.
- Clean the skin over the lesion.
- Inject local anaesthetic (if required) into the skin over the lesion.
- Label glass slide(s) and have ready near to the patient.
- Immobilise the lesion between thumb and forefinger of one hand.
- Introduce needle (usually with syringe attached) into lesion with the other hand.
- When the needle tip is at the edge of the lesion, apply negative pressure by pulling on the syringe and continue to enter the lesion.
- Make multiple rapid passes through the lesion, varying the angles if necessary.
- Stop sampling if blood is seen in the syringe hub as blood reduces the quality of the sample.
- Release the negative pressure while the needle is still in the lesion.
- Withdraw the needle and expel the cellular material from the needle onto the labelled glass slide(s) for pathological evaluation.

Immunohistochemistry

Immunohistochemistry (IHC) is a laboratory technique that uses antibodies to identify antigens in tumour tissue samples. Commonly used examples of IHC in clinical practice include:

- Oestrogen (ER) and progesterone (PR) receptor positivity indicate that the cancer may be sensitive to hormonal manipulation.
- Alpha-fetoprotein (AFP) and human chorionic gonadotrophin (hCG) favour germ cell tumours.
- Prostate-specific antigen (PSA) favours prostate cancer.
- Cytokeratins and epithelial membrane antigen (EMA) favour epithelial carcinomas.
- T-cell receptor and cluster designation (CD) antigen expression aid in the diagnosis and classification of lymphomas.
- PD-L1 expression levels may indicate that cancer is sensitive to anti-PD1 immune checkpoint inhibitor therapies.

In situ hybridisation

In situ hybridisation is a laboratory technique that is used to localise specific nucleic acid sequences on chromosomes or in tumour tissue. Fluorescence in situ hybridisation (FISH) utilises a fluorescent probe that may be visualised under a microscope. Commonly used examples of FISH in clinical practice include:

- HER2 receptor overexpression in breast or gastric cancers, which indicate that the tumour may respond to HER2 inhibitor targeted therapy.
- ALK or ROS1 rearrangements in non-small-cell lung cancer, which indicate that a tumour may respond to ALK inhibitor targeted therapy.
- The detection of translocations between chromosome 11 and 22: t(11;22)(q24;q12) and amplification of MDM2 can assist in the subtyping of sarcoma.

Genomic sequencing

In molecular pathology the primary genomic sequencing technique used is next generation sequencing (NGS). Whole genome sequencing (i.e. analysis of the entire genome) or whole exome sequencing (i.e. analysis of the protein-coding regions of the genome) provide extensive information, but are time consuming and costly. Targeted gene panel sequencing, which focuses on specific genes known to be involved in a particular cancer type, is most typically employed in clinical practice as it is quicker, less costly and provides clinically relevant selected information. Commonly used examples of targeted panel NGS in clinical practice include:

- *EGFR* mutations – predict response to EGFR inhibitor targeted therapy in lung cancer
- *RAS/BRAF* mutations – predict resistance to EGFR inhibitor targeted therapy in colon cancer
- *BRAF* mutations – predict response to BRAF/MEK inhibitor therapy in melanoma

Assessing fitness

When making decisions about investigations and management in patients with cancer it is important to consider an individual's general condition and comorbidities. The Eastern Cooperative Oncology Group (ECOG) performance status (PS) scale is used to formally assess a patient's fitness (Box 8.6). Outcomes for patients with PS 3–4 are worse in almost all malignancies than for those with PS 0–2, and this has a

8.6 Eastern Cooperative Oncology Group (ECOG) performance status scale

0	Fully active, able to carry on all usual activities without restriction and without the aid of analgesics
1	Restricted in strenuous activity but ambulatory and able to carry out light work or pursue a sedentary occupation. This group also contains patients who are fully active, as in grade 0, but only with the aid of analgesics
2	Ambulatory and capable of all self-care but unable to work. Up and about more than 50% of waking hours
3	Capable of only limited self-care, confined to bed or chair more than 50% of waking hours
4	Completely disabled, unable to carry out any self-care and confined totally to bed or chair

strong influence on the approach to treatment in the individual patient. Additionally, outcomes are typically worse for patients with a low albumin and raised inflammatory markers (i.e. white blood cell count, C-reactive protein). Comorbidities also frequently influence treatment options. For example, hepatic or renal dysfunction means some systemic therapies cannot be used or can only be given in lower doses. In some patients, poor fitness or comorbidities may preclude any anti-cancer therapy options, in which case comprehensive diagnostic and staging investigations add little clinical value and may not be in the best interests of the patient.

Although the incidence of cancer increases with patient age, the approach to investigation and management is similar at all ages (Box 8.7). However, assessing fitness in this group of patients can be difficult, with increasing comorbidity and declining physiological reserve in particular placing patients at increased risk of treatment toxicity. Geriatric assessment tools to assess patient fitness and toxicity risks have been developed.

Multidisciplinary teams

The multidisciplinary team (MDT) is well established in oncology and meets on a regular basis to provide a forum for patient-centred, interdisciplinary communication to coordinate care and decision-making. It is a platform on which individual clinicians can discuss complex cases or situations and draw on the collective experience of the team membership to decide on the best approach for an individual patient. This can be particularly important when discussing patients with a rare or complex condition or in an unusual situation. As a minimum, most MDTs include a radiologist, pathologist, specialist physician, specialist surgeon, radiation oncologist, medical oncologist, nurse specialist, auditor and scheduler. Additional staff may be relevant to different MDTs, e.g. dermatologists in skin cancer MDTs, dietitians in upper gastrointestinal cancer MDTs, stoma nurses in colorectal cancer MDTs, palliative care doctors in pancreatic cancer or cancer of unknown primary (CUP) MDTs. Specific roles of the MDT are outlined in Box 8.8.

Acute oncology

Cancer centres are usually based in cities and have busy radiotherapy and systemic anti-cancer therapy units containing specialist equipment and teams of highly trained physicians, surgeons, nurses, pharmacists, radiographers, physicists and support workers amongst others. Most patients with cancer undergo investigations, assessments and treatment as outpatients. However, patients may present acutely to any specialty in any hospital with a new cancer, cancer-related symptoms, emergency complications of cancer or with treatment-related toxicities.

8.7 Cancer in old age

- **Incidence**: around 50% of cancers occur in the 15% of the population aged over 65 years.
- **Screening**: women over 65 in the UK are not invited to breast cancer screening but can request it. Uptake is low despite increasing incidence with age.
- **Presentation**: may be later for some cancers. When symptoms are non-specific, patients (and their doctors) may initially attribute them to age alone.
- **Life expectancy**: an 80-year-old woman can expect to live 8 years, so cancer may still shorten life and an active approach remains appropriate.
- **Prognosis**: histology, stage at presentation and observation for a brief period are better guides to outcome than age.
- **Rate of progression**: malignancy may have a more indolent course. This is poorly understood but may be due to reduced effectiveness of angiogenesis with age, inhibiting the development of metastases.
- **Response to treatment**: equivalent to that in younger people – well documented for a range of cancers and for surgery, radiotherapy, cytotoxic chemotherapy and hormonal therapy.
- **Toxicity of treatment**: may be greater due to subclinically reduced baseline hepatic, renal and bone marrow function and reduced baseline energy.
- **Treatment selection**: chronological age is of minor importance compared to comorbid illness and patient choice. Although older patients can be treated effectively and safely, aggressive intervention is not appropriate for all. Symptom control may be all that is possible or desired by the patient.

8.8 Specific roles of the cancer multidisciplinary team (MDT)

- Agreeing on cancer type and final stage.
- Deciding on the appropriate primary treatment modality (most commonly surgery but the use of neoadjuvant systemic anti-cancer therapy and/or radiotherapy before surgery is increasing).
- Arranging review by the appropriate team to coordinate management.
- Planning surveillance strategies.
- Diagnosing cancer recurrence or metastases.
- Ensuring the appropriate transition from treatment with curative intent to that of palliation.
- Promoting recruitment into clinical trials.
- Agreeing on operational policies to deliver high-quality care to patients.
- Planning and reviewing audit data to ensure delivery of quality care to patients.
- Identifying late effects of cancer treatments.

Acute presentation of new cancer

Despite cancer screening initiatives, most patients still present with symptomatic disease. They may have symptoms related to the local effect of a primary tumour or metastatic deposit, such as finding a lump, dysphagia, bleeding or persistent pain. These are sometimes called 'red flag' symptoms of cancer (Box 8.9). Patients may present with constitutional symptoms such as unexplained weight loss, fatigue or fevers. Paraneoplastic syndromes due to the production of biologically active hormones by the tumour, or as the result of an immune response to the tumour, may also be the presenting symptom of new cancer (see p. 172; Box 8.10). The pattern of symptoms, detailed clinical history and examination will most often direct the initial investigations and early referral to the appropriate specialist multidisciplinary team.

Cancer of unknown primary (CUP)

When a patient is found to have advanced or metastatic cancer but history, examination and imaging are unable to define a primary cancer site, an assessment of patient fitness, disease extent, comorbidities and patient wishes should be made. Selected investigations should be carried out promptly, avoiding delays for investigations seeking to try to 'hunt down' the primary (Box 8.11). Investigations should be limited to

i 8.9 Red flag symptoms of malignancy

Symptom	Typical site or possible tumour
Lump	Breast, lymph node (any site), testicle
Skin abnormality	Melanoma, basal cell carcinoma
Bleeding	Stomach, colon, lung, endometrium, bladder, kidney
Dysphagia, odynophagia	Oesophagus, bronchus, gastric, head and neck
Change in bowel habit	Colon, rectum, ovary
Cough, hoarseness, stridor	Lung, head and neck, thyroid
Bone pain or fracture	Bone (primary sarcoma, secondary metastasis from breast, prostate, bronchus, thyroid, kidney)
Abdominal swelling (ascites)	Ovary, stomach, pancreas
Unexplained weight loss, anorexia	Lung, gastrointestinal tract, CUP
Unexplained fatigue	Any

(CUP = cancer of unknown primary)

i 8.10 Examples of common paraneoplastic syndromes

Clinical feature	Detectable auto-antibody or other factor	Common cancer type associated
Endocrine (see Box 8.17)		
SIADH, Cushing syndrome, hypercalcaemia, hypoglycaemia, carcinoid		
Neurological (see also Box 27.63)		
Lambert–Eaton myasthenic syndrome, cerebellar syndrome	AGNA/SOX1	Small-cell lung
Sensory or autonomic neuropathy, encephalomyelitis	Hu (ANNA-1)	Lung, neuroblastoma
Cerebellar/brainstem syndrome	Ri (ANNA-2)	Breast, lung
Limbic encephalitis	ANNA-3	Lung
Cerebellar syndrome	Yo (PCA-1) Tr (DNER)	Ovary, breast Hodgkin lymphoma
Musculocutaneous (see also Box 25.79)		
Hypertrophic osteoarthropathy		Lung adenocarcinoma
Acanthosis nigricans	Epidermal growth factor	Gastric or oesophageal adenocarcinoma
Pemphigus		B-cell lymphoproliferative disorders, Kaposi sarcoma, thymus
Sweet syndrome		MDS or AML
Dermatomyositis		Ovary, breast, gastric, lung
Migratory thrombophlebitis	Mucin activation of clotting actors	Pancreas, lung
Haematological		
Polycythaemia	Erythropoietin	Renal cell cancer, hepatocellular carcinoma
DIC	Tissue factor	PML, lung cancer, mucinous adenocarcinoma
Leukemoid reaction	Cytokines e.g. GCSF, TNF-α, ILs	Lung cancer, biliary tract cancers

(AML = acute myeloid leukaemia; ANNA = antineuronal nuclear antibody; DIC = disseminated intravascular coagulation; GCSF = granulocyte colony-stimulating factor; IL = interleukin; MDS = myelodysplasia; NHL = non-Hodgkin lymphoma; PML = promyelocytic leukaemia; TNF-α = tumour necrosis factor alpha)

those that will help management. Specialist investigations (e.g. endoscopies) are indicated when there is radiological suspicion or if there are localising symptoms.

In some cases, such as those with clinical suspicion of germ cell tumours, high-grade lymphoma or small-cell cancer, or those presenting with oncological emergencies, urgent referral directly to oncology or haematology is essential to allow rapid initiation of anti-cancer therapy, sometimes before investigations are completed (Fig. 8.6).

If patients are fit to undergo investigations and fit enough to be considered for treatment then a core biopsy of the most accessible metastatic lesion is usually the quickest way of obtaining tissue for pathological evaluation of cancer type. Review of tumour morphology, immunohistochemistry and molecular pathology will usually be sufficient to plan appropriate treatment. Patients with clinicopathological features suggestive of a particular cancer should be identified early and referred promptly to the appropriate multidisciplinary/oncology team for consideration of further investigations and treatment. Where the primary site remains unclear following comprehensive investigations, a patient is said to have a cancer of unknown primary (CUP).

Whilst it is crucial to identify patients with highly treatable CUPs (Box 8.12), some of whom can live for years (see Fig. 8.5), or even be cured by treatment, most CUPs are poorly differentiated cancers or adenocarcinomas with liver and/or multi-site metastases and poor prognosis. These cancers often present at an advanced stage and behave aggressively so early discussion with oncology, within the context of a specialist MDT, is essential to streamline investigations and assess fitness for anti-cancer treatment. Increasingly whole genome sequencing, or panel sequencing by next generation sequencing of either cancer biopsies or circulating tumour DNA (ctDNA), are providing greater information about likely tissue of origin or possible targetable genomic aberrations. Discussion of these results in multidisciplinary molecular tumour boards allows recognition of likely driver mutations, genomic/molecular patterns and druggable targets, which may ultimately lead to improved understanding of CUP and better outcomes.

Metastatic malignant disease of undefined primary origin (MUO)

Patients who present as emergencies to hospital with symptomatic new metastatic cancer often have a short prognosis. Features associated with poor prognosis, irrespective of subsequent diagnosis, include: poor performance status (PS 2–4), requirement for hospital admission, bulky or multi-organ metastatic disease, significant comorbidity, raised lactate dehydrogenase (LDH), raised inflammatory markers and low albumin. Further investigations, including biopsy, may not be warranted and honest conversations about palliative care and end-of-life planning are often preferable. Appropriate analgesia, palliative radiotherapy (for bleeding or pain) and interventional/surgical palliation can all help improve symptoms.

Oncological emergencies

Oncological emergencies are a group of potentially life-threatening conditions that occur as a direct result of cancer or its treatment. Positive outcomes depend upon prompt recognition and implementation of appropriate management.

Malignant spinal cord compression

Malignant spinal cord compression complicates 5% of cancers and is most common in myeloma, prostate, breast and lung cancers that most

8.11 Initial diagnostic tests in patients presenting with carcinoma of unknown primary

- Detailed medical history and examination, including breast, nodal areas, skin, genital, rectal and pelvic regions
- Full blood count, urea and electrolytes, renal function, liver function tests, albumin, calcium, urinalysis, lactate dehydrogenase, CRP
- Myeloma screen (if lytic bone lesions)
- CT scan of chest, abdomen and pelvis
- CT neck if thyroid lump or neck nodes
- Histological examination by biopsy, with immunohistochemistry and/or molecular pathology if required
- Upper or lower gastrointestinal endoscopy if gastrointestinal symptoms
- Mammography and/or breast MRI for women with axillary nodes or adenocarcinoma
- Breast MRI for women with adenocarcinoma limited to axillary nodes
- Testicular ultrasound (if midline disease in young man or clinical features suggest germ cell tumour)
- Naso-endoscopy for squamous neck nodes
- PET scan for single-site disease or squamous neck nodes with no primary on endoscopic evaluation
- Tumour markers: prostate-specific antigen (PSA) in men with bone lesions, CA 125 in women with peritoneal malignancy or ascites, α-fetoprotein (AFP) in liver-limited disease, α-fetoprotein (AFP) and human chorionic gonadotrophin (hCG) in midline disease in young men

(CA 125 = cancer antigen 125; CRP = C-reactive protein; CT = computed tomography; MRI = magnetic resonance imaging; PET = positron emission tomography)

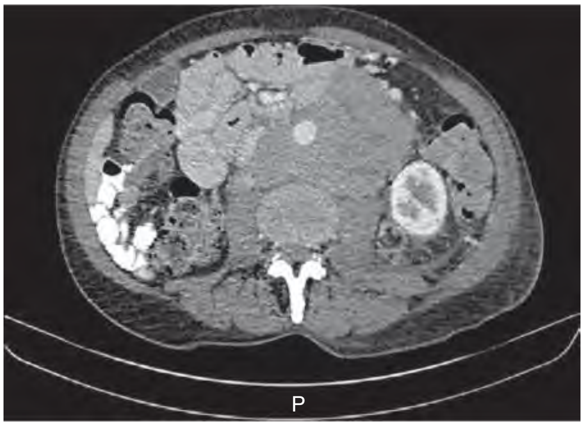

Fig. 8.6 **Young male patient presenting with a bulky midline tumour and elevated hCG and AFP suggestive of a non-seminomatous testicular cancer.**

frequently involve bone. Malignant spinal cord compression often results from posterior extension of a vertebral body mass, but intrathecal spinal cord metastases can cause similar signs and symptoms. The thoracic region is most commonly affected (Fig. 8.7).

Clinical features

The earliest sign is back pain, often rapidly worsening or in a ‘band’, most marked on coughing and lying flat. Subsequently, sensory changes develop in dermatomes below the level of compression, and motor weakness distal to the block occurs. Finally, sphincter disturbance, causing urinary retention and bowel incontinence, is observed. Involvement of the lumbar spine may cause conus medullaris or cauda equina compression (Box 8.13). Physical examination usually identifies signs consistent with an upper motor neuron lesion, but lower motor neuron findings may predominate early on or in cases of nerve root or cauda equina compression.

Management

Malignant spinal cord compression is a medical emergency and should be treated with analgesia and high-dose glucocorticoid therapy (Box 8.14). Neurosurgical intervention produces superior outcomes and survival compared to radiotherapy alone, and should be considered first for all patients. Neurosurgery is the preferred treatment if there is a single site of disease, low volume metastatic disease, if a biopsy is required to make a diagnosis or if it is a treatable cancer (e.g. lymphoma, breast cancer). Radiotherapy is used for the remaining patients and selected tumour types when the cancer is likely to be radiosensitive. The prognosis varies considerably, depending on tumour type, but the degree of neurological dysfunction at presentation is the strongest predictor of outcome, irrespective of the underlying diagnosis. Mobility can be preserved in more than 80% of patients who are ambulatory at presentation, but neurological function is seldom regained in patients with established deficits such as paraplegia.

8.12 Cancer of unknown primary – favourable clinicopathological features

Clinicopathological features	Management
Women with serous papillary adenocarcinoma of the peritoneal cavity	Treat like ovarian cancer
Women with isolated adenocarcinoma of axillary lymph nodes	Treat like breast cancer
Men with poorly differentiated carcinoma with midline distribution	Treat like germ cell cancer
Poorly differentiated neuroendocrine carcinoma of unknown origin	Treat like small-cell cancer
Well-differentiated neuroendocrine tumour (NET)	Treat with somatostatin analogues or as per NETs of known primary sites
Squamous cell carcinoma of non-supraclavicular cervical lymph nodes	Treat like head and neck squamous cell cancer
Adenocarcinoma with a colorectal-IHC profile ($CK20^{+}$, $CK7^{-}$, $CDX2^{+}$)	Treat like colon cancer
Men with blastic bone metastases or elevated prostate-specific antigen (adenocarcinoma)	Treat like prostate cancer
Isolated inguinal adenopathy squamous carcinoma	Treat like anogenital squamous cancer
Patients with one small, potentially resectable tumour	Assess for surgical resection

(CD = cluster of differentiation; CK = cytokeratin; IHC = immunohistochemistry)

Superior vena cava obstruction

Superior vena cava obstruction (SVCO) is a common complication of cancer that can occur through extrinsic compression or intravascular blockage. The most common causes of extrinsic compression are lung cancer, lymphoma and metastatic tumours (Fig. 8.8). Patients with cancer can also develop SVCO due to intravascular blockage associated with a central catheter or thromboembolism secondary to the tumour.

Clinical features

The classical presentation is with breathlessness, oedema of the arms and face, distended neck and arm veins and dusky skin coloration over the chest, arms and face. Collateral vessels may develop over a period of weeks and the flow of blood in the collaterals helps to confirm the diagnosis. Headache secondary to cerebral oedema arising from the back-flow pressure may also occur and tends to be aggravated by bending forwards, stooping or lying down. The severity of symptoms is related to the rate of obstruction and the development of a venous collateral circulation. Accordingly, symptoms may develop rapidly or gradually. Clinical features are summarised in Box 8.15.

Investigations and management

The investigation of choice is a CT scan of the thorax to confirm the diagnosis and distinguish between extra- and intravascular causes.

A biopsy should be obtained when the tumour type is unknown because tumour type has a major influence on treatment. CT of the

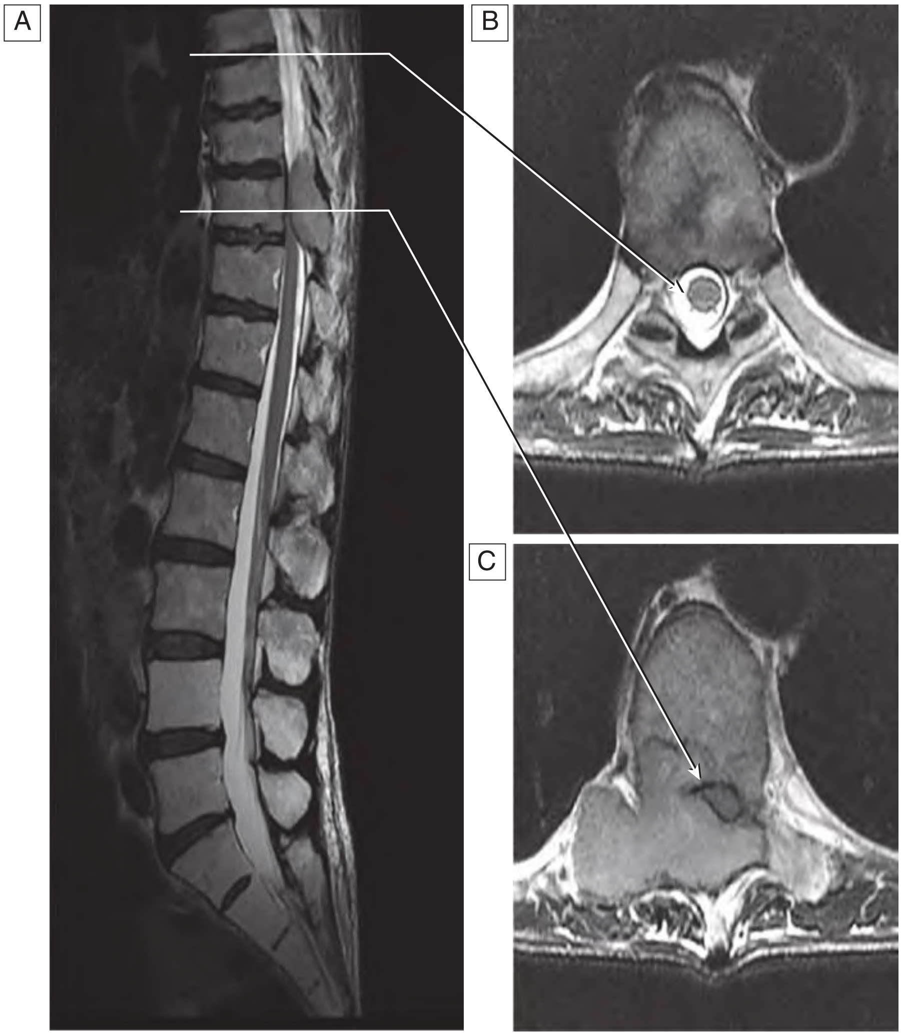

Fig. 8.7 **A** Sagittal T2 MRI thoracolumbar spine image in a patient presenting with back pain and lower limb neurological disturbance secondary to spinal cord compression by a metastasis in the T10 vertebra. **B** Axial section at T7/T8 demonstrating normal spinal cord. **C** Axial section at T10 demonstrating spinal cord compression by the metastasis involving the posterior vertebral body.

i 8.13 Comparison of features of neurological deficit

Clinical feature	Spinal cord	Conus medullaris	Cauda equina
Weakness	Symmetrical and profound	Symmetrical and variable	Asymmetrical, may be mild
Reflexes	Increased (or absent) knee and ankle reflexes with extensor plantar reflex	Increased knee reflex, decreased ankle reflex, extensor plantar reflex	Decreased knee and ankle reflexes with flexor plantar reflex
Sensory loss	Symmetrical, sensory level	Symmetrical, saddle distribution	Asymmetrical, radicular pattern
Sphincters	Late loss	Early loss	Often spared
Progression	Rapid	Variable	Variable

head may be indicated if cerebral oedema is suspected. Tumours that are exquisitely sensitive to cytotoxic chemotherapy, such as germ cell tumours and lymphoma, can be treated with cytotoxic chemotherapy alone. For most other patients with symptomatic SVCO, SVC stenting provides the best outcomes although mediastinal radiotherapy may also be considered. Where possible, these measures should be followed by treatment of the primary tumour, as long-term outcome is strongly dependent on the prognosis of the underlying cancer.

8.14 Management of suspected spinal cord compression

- Confirm diagnosis with urgent MRI scan of whole spine
- Administer high-dose glucocorticoids:
  - Dexamethasone 16 mg IV or oral stat
  - Dexamethasone 8 mg twice daily orally
- Ensure adequate analgesia
- Refer for surgical decompression or urgent radiotherapy

(IV = intravenous; MRI = magnetic resonance imaging)

Hypercalcaemia of malignancy

Hypercalcaemia is the most common metabolic disorder in patients with cancer and has a prevalence of up to 20% in cancer patients. The incidence is highest in myeloma and breast cancer (approximately 40%), intermediate in non-small-cell lung cancer, and uncommon in colon, prostate and small-cell lung carcinomas. It is most commonly due to production of parathyroid hormone-related peptide (PTHrP; 80% of cases), which binds to the parathyroid hormone (PTH) receptor and elevates serum calcium by stimulating osteoclastic bone resorption and increasing renal tubular reabsorption of calcium. Direct invasion of bone by metastases accounts for around 20% of cases, while other mechanisms are rare.

Clinical features

The symptoms of hypercalcaemia are often non-specific and may mimic those of the underlying malignancy. They include drowsiness, delirium, nausea and vomiting, constipation, polyuria, polydipsia and dehydration.

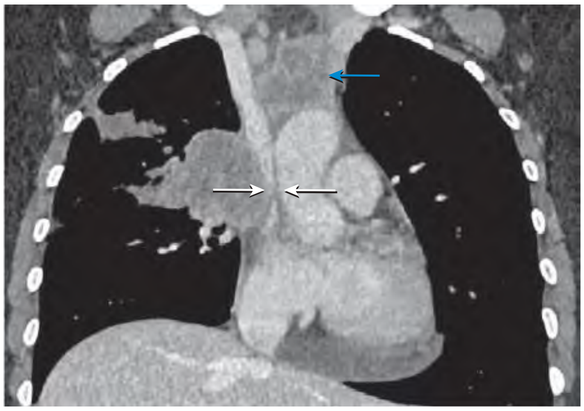

Fig. 8.8 **Coronal CT demonstrating extrinsic SVC compression (white arrows) by a right upper lobe lung tumour**. The patient also has nodal spread to the superior mediastinum (blue arrow).

i 8.15 Common symptoms and physical findings in superior vena cava obstruction*

Symptoms

- Dyspnoea (63%)
- Facial swelling and head fullness (50%)
- Cough (24%)
- Arm swelling (18%)
- Chest pain (15%)
- Dysphagia (9%)

Physical findings

- Venous distension of neck (66%)
- Venous distension of chest wall (54%)
- Elevated, non-pulsatile jugular venous pulse (66%)
- Facial oedema (46%)
- Cyanosis (20%)
- Plethora of face (19%)
- Oedema of arms (14%)

*Percentage of patients affected.

Investigations and management

The diagnosis is made by measuring serum total calcium and adjusting for albumin. It is especially important to correct for albumin in cancer because hypoalbuminaemia is common and total calcium values under-estimate the level of ionised calcium. The principles of management are outlined in Box 8.16.

Patients should initially be treated with intravenous 0.9% saline to improve renal function and increase urinary calcium excretion. This alone often results in clinical improvement. Concurrently, intravenous bisphosphonates should be given to inhibit bone resorption. Calcitonin acts rapidly to increase calcium excretion and to reduce bone resorption, and can be combined with fluid and bisphosphonate therapy for the first 24–48 hours in patients with life-threatening hypercalcaemia. Bisphosphonates will usually reduce the serum calcium levels to normal within 5 days, but, if not, treatment can be repeated. The duration of action is up to 4 weeks and repeated therapy can be given at 3- to 4-weekly intervals in the outpatient department. Hypercalcaemia is frequently a sign of tumour progression and the patient requires further investigation to establish disease status and review the anti-cancer treatment strategy.

Other acute presentations in oncology

Venous thromboembolism

Venous thromboembolism (VTE) is the second leading cause of death amongst patients with cancer. Malignancy is a strong risk factor for VTE and may be the first presenting feature of an underlying cancer. Several mechanisms lead to a prothrombotic state in cancer. This includes the ability of cancer cells to produce procoagulant/fibrinolytic substances and inflammatory cytokines and the physical interaction between tumour cells and blood (monocytes, neutrophils, platelets) or endothelial cells. Anti-cancer therapy (i.e. surgery, cytotoxic chemotherapy, hormone therapy and radiotherapy) and any in-dwelling access devices (i.e. central venous catheters) further increase the risk. As in patients without cancer, the management of cancer-associated VTE primarily involves anticoagulation therapy. However, the choice of therapy must take into account bleeding risk and possible interactions with anti-cancer therapies and their side-effects, such as thrombocytopenia. In patients with metastatic cancer, anticoagulation therapy will often be lifelong.

8.16 Medical management of severe hypercalcaemia

- IV 0.9% saline 2–4 L/day
- Zoledronic acid 4 mg IV *or* pamidronate 60–90 mg IV
- For patients with severe, symptomatic hypercalcaemia that is refractory to zoledronic acid, denosumab (initial dose 60 mg SC, with repeat dosing based on response) is an alternative option

(IV = intravenous; SC = subcutaneous)

Paraneoplastic syndromes

Paraneoplastic syndromes are a group of disorders resulting from cancer, but not directly caused by tumour compression, invasion or metastasis. They arise from the secretion by tumours of functional peptides or hormones, cytokines or autoreactive antibodies causing immune cross-reactivity between tumour and host tissue. These may affect diverse organ systems including endocrine, neurologic, musculocutaneous or haematologic systems. The most commonly associated malignancies include small-cell lung cancer, breast cancer, gynaecological or haematological malignancies (see Box 8.10). The symptoms arising from paraneoplastic syndromes can cause significant morbidity and their recognition can sometimes lead to the detection of an occult cancer at an early stage. Treatment of the underlying cancer often improves symptoms from the syndrome, but immunosuppression with glucocorticoids, immunoglobulins or plasmapheresis is sometimes indicated.

Ectopic hormone production/endocrine

Some cancers are associated with metabolic abnormalities due to ectopic production of hormones by tumour cells, including insulin, adrenocorticotrophic hormone (ACTH), vasopressin (antidiuretic hormone, ADH), fibroblast growth factor (FGF)-23, erythropoietin and parathyroid hormone-related peptide (PTHrP). This can result in a wide variety of presentations, as summarised in Box 8.17. These paraneoplastic conditions are often associated with lung cancers and usually occur after cancer diagnosis. Successful treatment of the underlying tumour often improves the associated metabolic derangement.

Neurological

These form a group of conditions resulting from immune-mediated neurological effects associated with tumours (benign or malignant). These tumours express specific autoantibodies, which can target the central or peripheral nervous system (see Box 27.63 and p. 1209). The most common conditions are Lambert–Eaton myasthenic syndrome, limbic encephalitis, paraneoplastic cerebellar degeneration and encephalomyelitis. The cancers most commonly implicated are lung, breast, or lymphoma. Paraneoplastic neural autoantibodies associated with carcinoma often bind intracellular antigens and the resulting nerve damage can be long-lasting and difficult to treat. Lymphoma-related autoantibodies often bind extracellular antigens and resulting paraneoplastic neurological conditions can improve with anti-cancer treatment and immune suppression or plasma exchange.

8.17 Ectopic hormone production by tumours

Clinical feature	Ectopic hormone	Common cancer type associated
SIADH	Vasopressin (ADH) and atrial natriuretic peptide	Small-cell lung cancer
Hypercalcaemia	PTHrP (or more rarely PTH)	Squamous cancers
Cushing syndrome	ACTH	Small-cell lung cancer or bronchial carcinoid tumour
Hypoglycaemia	IGF-2	HCC, sarcoma, adrenocortical tumours
	Insulin	Pancreatic neuro-endocrine tumours
Carcinoid	Serotonin or bradykinin	Bronchial carcinoid Gastrointestinal neuro-endocrine tumours
Hypophosphataemic osteomalacia	FGF23	Mesenchymal tumours
Polycythaemia	Erythropoetin	Renal cell carcinoma, HCC, cerebellar haemangioblastoma
Watery diarrhoea	Vasoactive intestinal polypeptide	Pancreatic neuro-endocrine tumours
Zollinger–Ellison syndrome	Gastrin	Duodenal/pancreatic neuroendocrine tumours

(ACTH = adrenocorticotrophic hormone; ADH = antidiuretic hormone; FGF23 = fibroblast growth factor; HCC = hepatocellular carcinoma; IGF = insulin-like growth factor; PTH = parathyroid hormone; PTHrP = parathyroid hormone related peptide; SIADH = syndrome of inappropriate antidiuretic hormone secretion)

Specific detectable immune biomarkers include antibodies to pre-synaptic calcium channels (Lambert–Eaton syndrome), anti-Hu antibodies (encephalomyelitis) and anti-Yo or anti-Tr antibodies (cerebellar degeneration). Detection of these paraneoplastic autoantibodies can predate cancer diagnosis by up to 5 years, but results are not always specific and negative results do not exclude the diagnosis. The management of these syndromes is multidisciplinary and includes treatment of the underlying cancer and treatment of the syndrome with immunosuppressive agents.

Haematological

Polycythaemia, thrombocytosis, granulocytosis, eosinophilia, red cell aplasia, leukemoid reactions and disseminated intravascular coagulation (DIC) can result from secretion of growth factor cytokines or tissue factor by cancers including renal cell cancer. Treatment of the underlying cancer can improve things but advanced DIC is associated with poor outcomes.

Musculocutaneous

Cancers can present with rheumatological or skin manifestations that are not due to metastases, including hypertrophic osteoarthropathy, acanthosis nigricans, dermatomyositis and migratory thrombophlebitis, but specific causative humoral factors for each condition have not been identified.

Symptoms from locally advanced cancer or metastatic sites

Metastatic disease is the major cause of death in cancer patients and the principal cause of morbidity. For the majority of patients with metastatic disease the goal of treatment is to control cancer, maintain quality of life, treat symptoms and prolong life (i.e. 'palliative treatment'). Patients of PS 3–4 (see Box 8.6) or with low albumin plus high inflammatory markers often have a limited prognosis irrespective of anti-cancer treatments. Systemic anti-cancer therapies have resulted in improved survival for many cancers so that some patients live a good quality life for many years with metastatic cancer. Treatment of a solitary metastasis or highly treatable cancers (e.g. germ cell) can be curative.

Brain metastases

Brain metastases occur in 10%–30% of adults and 6%–10% of children with cancer and are an increasingly important cause of morbidity. Cancers of lung, breast, melanoma and gastrointestinal tract most commonly metastasise to the brain. Most involve the brain parenchyma but can also affect the meninges, cranial nerves, the blood vessels and other intracranial structures. In cases of solitary metastasis to the brain, the use of surgery followed by adjuvant radiotherapy, or alternatively stereotactic radiotherapy, has been shown to increase survival in patients whose disease is otherwise controlled. Outcomes for patients with more advanced brain metastases depend on the primary cancer, extent of extracranial disease and what systemic treatment options are available. For patients with advanced untreatable cancer and multiple brain metastases, prognosis is often short. Glucocorticoids can improve symptoms, particularly where there is evidence of peri-lesional oedema. In treatable cancers, whole brain radiotherapy can allow the glucocorticoid dose to be reduced whilst systemic therapy is used to treat the remaining cancer. With improved systemic therapies, including targeted therapies and immunotherapy, some patients are now living for several years with brain metastases.

Clinical features

Presentation is with headaches and nausea (40%–50%), focal neurological dysfunction (20%–40%), cognitive dysfunction (35%), seizures (10%–20%) and papilloedema ($< 10\%$).

Investigations and management

The diagnosis can be confirmed by CT or contrast-enhanced MRI. Treatment options include high-dose glucocorticoids for tumour-associated oedema (dexamethasone 4–12 mg daily depending on amount of oedema), anticonvulsants for seizures, whole-brain radiotherapy and systemic anti-cancer therapy. Surgery may be considered for single sites of disease and can be curative; stereotactic radiotherapy may also be considered for solitary site involvement or where surgery is more difficult or not possible.

Lung metastases

Lung metastases are common in breast cancer, colon cancer, renal cancer, sarcoma and tumours of the head and neck. The presentation is usually with a lesion on chest X-ray or CT. Solitary lesions require investigation, as single metastases can be difficult to distinguish from a primary lung tumour. Patients with two or more pulmonary nodules can be assumed to have metastases, especially if these grow over time. The approach to treatment depends on the extent of disease in the lung and elsewhere. For solitary lesions, thoracoscopic surgery should be considered, with a generous wedge resection. Alternatively, if available, radiofrequency ablation or stereotactic ablative radiotherapy (SABR) can be used. External beam radiotherapy and systemic anti-cancer therapies can be used, dependent on the underlying primary cancer diagnosis (Fig. 8.9). Sometimes cancer infiltrates the lungs along lymphatic vessels, resulting in lymphangitis carcinomatosis, which causes progressive dyspnoea and hypoxia, and often carries a poor prognosis. Depending on the primary cancer, systemic anti-cancer therapies can be used to treat the cancer spread or glucocorticoids can be used to help symptoms.

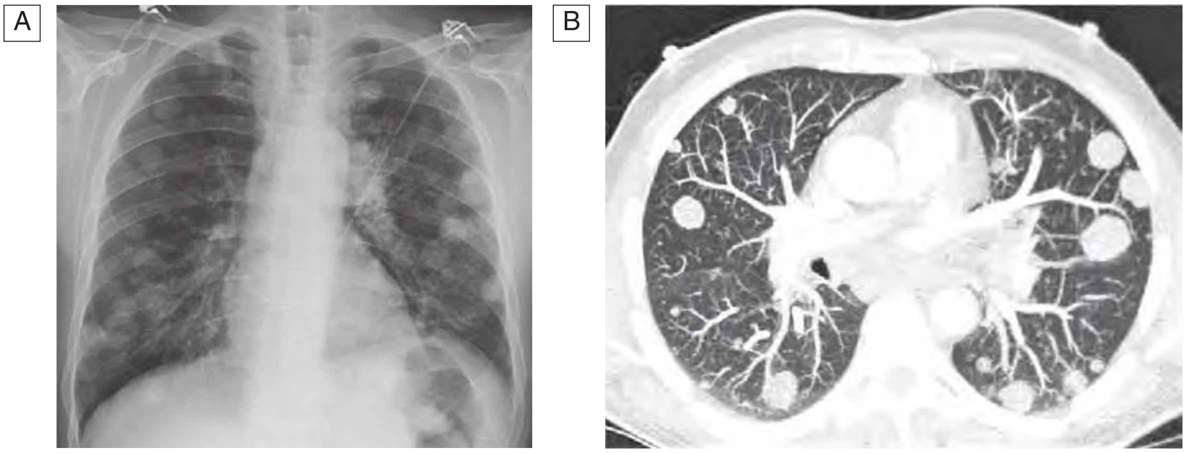

Fig. 8.9 A Chest X-ray and B CT images of diffuse metastatic lung lesions in a symptomatic patient.

Liver metastases

Metastatic cancer in the liver can represent the sole or life-limiting component of disease for many with colorectal cancer, ocular melanoma, neuroendocrine tumours (NETs) and, less commonly, other tumour types. The most common clinical presentations are with right upper quadrant pain due to stretching of the liver capsule, jaundice, deranged liver function tests or an abnormality detected on imaging. In selected cases, resection of the metastasis can be contemplated. In colorectal cancer, successful resection of metastases improves 5-year survival from 3% to 30%–40%. Other techniques, such as chemoembolisation, radiofrequency ablation or microwave ablation, can also be used, provided the number and size of metastases remain small. If these are not feasible, symptoms may respond to systemic anti-cancer therapy (see Fig. 8.5).

Bone metastases

Bone is the third most common organ involved by metastasis, after lung and liver. Bone metastases are a major clinical problem in patients with myeloma and breast or prostate cancers, but other tumours that commonly metastasise to bone include those of the kidney and thyroid. Bone metastases are increasingly seen in other tumour types that do not classically target bone, due to effective anti-cancer treatments prolonging survival of patients with many cancers. Accordingly, effective management of bony metastases has become a focus in the treatment of patients with many incurable cancers.

Clinical features

The main presentations are with pain, pathological fractures, spinal cord compression (see above) and hypercalcaemia. Cancer-induced bone pain (CIBP) tends to be progressive and worst at night, and may be partially relieved by activity, but subsequently becomes more constant in nature and is exacerbated by movement (see p. 201). Most pathological fractures occur in metastatic breast cancer (53%); other tumour types associated with fracture include the kidney (11%), lung (8%), thyroid (5%), lymphoma (5%) and prostate (3%).

Investigations and management

The most sensitive way of detecting bone metastases is by isotope bone scan. This can have false-positive results in healing bone, particularly as a flare response following treatment, and false-negative results occur in multiple myeloma due to suppression of osteoblast activity. Plain X-ray films or MRI scans are therefore preferred for any sites of bone pain, as lytic lesions may not be detected by a bone scan. In patients with a single lesion, it is especially important to perform a biopsy to obtain a tissue diagnosis, since primary bone tumours may look very similar to metastases on X-ray. The main goals of management are:

- pain relief
- preservation and restoration of function
- skeletal stabilisation
- local tumour control (e.g. relief of tumour impingement on normal structure).

Surgical intervention may be warranted where there is evidence of skeletal instability (e.g. anterior or posterior spinal column fracture) or an impending fracture (e.g. a large lytic lesion on a weight-bearing bone with more than 50% cortical involvement). Intravenous bisphosphonates are widely used for bone metastases and are effective at improving CIBP and in reducing further skeletal related events, such as fractures and hypercalcaemia. In certain types of cancer, such as breast and prostate, hormonal therapy may be effective. Radiotherapy, in the form of external beam therapy or systemic radionuclides (strontium treatment), can also help pain. In some settings (e.g. breast carcinoma or lymphoma), systemic anti-cancer therapy may be used in the management of bony metastases.

Malignant pleural effusion

This is a common complication of cancer and 40% of all pleural effusions are due to malignancy. The most common causes are lung and breast cancers, and the presence of an effusion indicates incurable disease. The presentation may be with dyspnoea, cough or chest discomfort, which can be dull or pleuritic in nature. Diagnosis and management of pleural effusion is discussed on page 531.

Investigations and management

Pleural aspirate is the key investigation and may show the presence of malignant cells. Malignant effusions are commonly blood-stained and are exudates with a raised fluid to serum LDH ratio (>0.6) and a raised fluid to serum protein ratio (>0.5). Treatment should focus on palliation of symptoms and be tailored to the patient's physical condition, treatment options and prognosis. Aspiration alone may be an appropriate treatment in frail patients with a limited life expectancy. Those who present with malignant pleural effusion as the initial manifestation of breast cancer, small-cell lung cancer, germ cell tumours or lymphoma should have the fluid aspirated and should be given systemic anti-cancer therapy to try to treat disease in the pleural space. Treatment options for patients with recurrent pleural effusions include pleurodesis, implanted drainage catheters, pleurectomy and pleuroperitoneal shunt.

Malignant abdominal ascites

Malignant ascites is commonly seen as a result of peritoneal metastases from ovarian, gastrointestinal or pancreatic cancers. It is usually caused by cancer-related lymphatic vessel obstruction, enhanced vascular permeability and inflammation. Biochemical evaluation of the ascitic fluid demonstrates an exudate and cytological examination detects cancer cells. Ascites can also result from cancer-induced portal vein obstruction, hepatic insufficiency and low albumin. In this situation, the ascitic fluid is a transudate and may not demonstrate cancer cells. Ascitic fluid accumulation can cause symptoms of gross abdominal swelling, early satiety, abdominal discomfort, breathlessness, leg swelling and fatigue.

Investigations and management

Treatment of malignant ascites includes treatment of the cause by way of systemic anti-cancer therapy, cytoreductive surgery and occasionally hyperthermic intraperitoneal therapy. Symptomatic management of ascites includes palliative aspiration/drainage (to reduce abdominal pressure and improve symptoms), paracentesis to drain ascites to dryness (usually prior to systemic anti-cancer therapy) and permanent drainage using an implanted catheter or a peritoneo-venous shunt (for patients with recurring symptomatic ascites and a reasonable prognosis). In gastrointestinal cancers, ascites and peritoneal metastases are associated with reduced survival and are often a late-stage event in metastatic pancreatic cancer. Drainage of ascites followed by systemic anti-cancer therapy can be helpful for gynaecological, colorectal and highly treatable cancers, but for pancreatic cancers, drainage of large volumes of ascites can increase symptoms and expedite decline.

Malignant hydronephrosis

Malignant ureteric obstruction is intrinsic or extrinsic obstruction of one or both ureters by malignancy resulting in swelling of ureter or kidney(s). It can be picked up as an incidental finding on radiology or by a step-increase in creatinine on routine blood testing in the context of cancer. It can also present symptomatically with urosepsis, metabolic derangement or intractable pain. It can be associated with poor prognosis in those for whom there are limited treatment options available. Interventions to decompress the kidney(s) include percutaneous nephrostomy or retrograde or anterograde ureteric stenting. These procedures can improve urosepsis, intractable pain or new obstructive renal impairment. However, they can result in considerable patient morbidity including pain, bleeding, infections and a need for regular stent replacements. Decompression is likely to be appropriate for life-threatening indications such as urosepsis and significant acute kidney injury and where impaired renal function compromises the ability to deliver effective anti-cancer therapy. It is often not indicated for unilateral hydronephrosis with normal renal function, or in the late stages of advanced cancers, where morbidity may outweigh the clinical benefit.

Other common symptoms

Other symptoms that commonly arise from metastatic cancer include gastrointestinal obstruction and cancer cachexia; these are discussed in Chapter 9.

Therapeutics in oncology

Anti-cancer therapy may be used with either curative or palliative intent, and this distinction influences the approach to management of individual patients. The goal of treatment should be recorded in the medical notes.

- *Curative therapy* is given with the aim of achieving complete remission. Surgery to remove all macroscopic disease is most frequently the primary curative intervention. However, in some circumstances radiotherapy, systemic anti-cancer therapy or a combination of these may be used with curative, or radical, intent.
- *Adjuvant therapy* is additional therapy given after the primary curative intervention to lower the risk of disease recurrence. Radiotherapy and/or systemic anti-cancer therapy may be given after surgery with the intention of eradicating any micrometastatic disease that remains.
- *Neoadjuvant therapy* is additional therapy given prior to the primary curative intervention. Systemic anti-cancer therapy may be administered prior to planned surgery. The principal aim is to lower the risk of disease recurrence. Any reduction in the volume of disease, or ‘downstaging’, may also allow less extensive surgery, increase the likelihood of successful debulking and improve subsequent surgical morbidity. Direct evaluation of the surgical specimen allows assessment of the effectiveness of neoadjuvant therapies, guiding subsequent management and lending this approach to translational research.
- *Palliative therapy* is primarily used to treat patients with metastatic disease, or where curative treatment is not possible. The goal is to control cancer, with the aim of improving or maintaining quality of life, treating and preventing symptoms and improving survival. The choice of therapy depends on the clinical situation and a careful evaluation of the risks and benefits of the intervention.

Surgical treatment

Surgery has a pivotal role in the management of cancer. It is the main curative management of most solid cancers. In early localised cases of colorectal, breast and lung cancer, cure rates are high with surgery. There is evidence that outcome is related to surgical expertise, and most multidisciplinary teams include surgeons experienced in the management of a particular cancer. There are some cancers for which surgery is one of two or more options for primary management, and the role of the MDT is to recommend appropriate treatment for an individual patient. Examples include prostate and transitional cell carcinoma of the bladder, in which radiotherapy and surgery may be equally effective. Specialised surgical or interventional radiology techniques may also be employed with curative intent. Radiofrequency ablation, microwave ablation or cryotherapy may be used to treat small renal cell carcinomas or hepatocellular carcinomas. Surgery has less of a role in lymphoma, high-grade neuroendocrine tumours or small-cell cancer, where systemic anti-cancer therapy is the main treatment used.

Surgical procedures are often the quickest and most effective way of palliating symptoms in patients with metastatic disease. Examples include the treatment of faecal incontinence with a defunctioning colostomy; fixation of pathological fractures; decompression of spinal cord compression; and the treatment of fungating skin lesions by ‘toilet’ surgery. Debulking cytoreductive surgery may improve survival in some cancers, including renal cell carcinoma and ovarian cancer. In very selected cases, such as patients with oligometastatic disease, resection of metastases may improve survival and reduce the need for other therapies.

Radiotherapy

Radiotherapy (radiation therapy) involves treating cancers with ionising radiation such as X-rays, gamma rays, electrons or charged atoms. Ionising radiation kills cancer cells by two mechanisms: directly damaging cancer DNA or indirectly by triggering the formation of very reactive molecules (free radicals) that also damage cancer DNA. Radiotherapy can be given alongside systemic therapy and some anti-cancer therapies act as radiosensitisers, which can make cancer cells more sensitive to radiation and allow reduced radiation doses.

There are several types of radiation therapy including external beam radiotherapy, stereotactic radiotherapy (a precisely targeted form of high-dose external beam radiotherapy), proton beam therapy, brachytherapy (internal or locally applied radiotherapy) and radioisotope therapy (systemically delivered radiotherapy).

External beam radiotherapy

External beam radiotherapy is most commonly delivered by a linear accelerator, which produces electron or photon beams. As normal tissues can also be damaged by radiotherapy, treatments are planned to

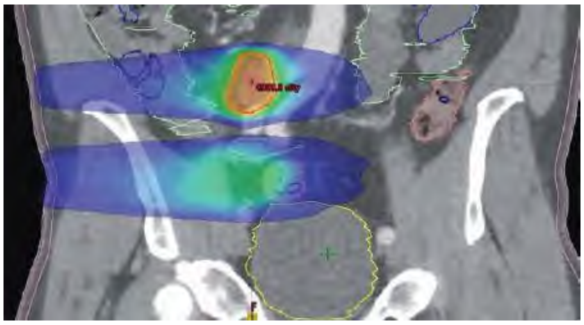

Fig. 8.10 Coronal planning CT from a patient with malignant abdominal lymph node metastasis (outlined in orange) undergoing stereotactic external beam radiotherapy. The shaded areas show the amount of ionising radiation (measured in centiGrays (cGy)) absorbed by tissues, with the lowest doses in blue, intermediate doses in green and the highest doses (which are centred on the tumour) in red. Important structures whose exposure to radiation must be minimised are outlined, to aid with the planning of the treatment (yellow = bladder; green = small bowel; red and blue = large bowel).

ensure maximum exposure of the tumour and minimal exposure of surrounding normal tissues (Fig. 8.10). Improved localisation of the target volume, or tumour, can be achieved by the use of surgical clips at the site of resection and fusion of radiotherapy planning CT scans with diagnostic MRI or PET-CT scans. Treatment-planning software controls the size and shape of the beam. *Intensity-modulated radiotherapy* (which allows for more homogeneous dose distribution) and *volumetric radiotherapy* (in which the shape of the radiation beam is designed to closely fit the tumour) have largely replaced conventional methods that use a limited number of square or rectangular beams. Biological differences between normal and tumour tissues are exploited to obtain therapeutic benefit. Fundamental to this is *fractionation*, which entails delivering the radiation as a number of small doses on a daily basis. This allows normal cells to recover from radiation damage, while recovery occurs to a lesser degree in malignant cells. Fractionation regimens vary depending on the tumour being treated, the total radiation dose to be delivered and the intent of treatment. Curative, or radical, treatments typically deliver a higher overall dose in 20–35 fractions over 4–7 weeks. For palliative treatments a smaller dose given over 1–10 fractions is usually adequate. Malignant tissues vary widely in their sensitivity to radiotherapy. Germ cell tumours and lymphomas are extremely radiosensitive, and relatively low doses are adequate for cure. However, most other cancers require higher doses. Normal tissue also varies in its radiosensitivity, with the central nervous system, small bowel and lung being among the most sensitive.

Stereotactic radiotherapy

Stereotactic radiotherapy is a highly targeted method of external beam radiotherapy, which delivers a high dose of radiation in a small number of treatments. It uses advanced imaging techniques to focus radiation beams from many different angles so that they converge precisely on the tumour with minimal damage to surrounding healthy tissues. This is commonly used to treat early-stage lung cancers or oligometastatic cancer sites.

Proton beam radiotherapy

Proton beam radiotherapy uses a cyclotron to produce beams of high-energy protons, which release their energy at a specific depth within the tumour, thereby delivering a high dose of radiation directly to cancer deposits while sparing surrounding healthy tissues. It can be used when treating sensitive areas like the brain or in treating cancers that are difficult to reach with other forms of radiotherapy.

Brachytherapy

Brachytherapy, or internal radiation therapy, involves the direct application of a radioactive source onto or into a tumour. This allows the delivery of a high, localised dose of radiation. Brachytherapy is a common treatment for cancers of the prostate, uterus and cervix. Most commonly, an applicator device is used to deliver a radioactive source directly to the tumour for a set time, typically 10–20 minutes. In other cases, such as in prostate cancer, small radioactive seeds may be permanently placed into the organ, releasing radiation slowly over several months.

Radioisotope therapy

Radioisotope therapy is a precise way to deliver systemic, targeted radiation therapy to certain cancers using radioactive substances, which are either ingested or injected into the bloodstream. Radioactive iodine (^{131}I) may be administered orally and is absorbed by thyroid cells (both normal and malignant). Radioactive iodine emits predominantly beta particles. It is used as an adjuvant therapy in differentiated thyroid cancer (following thyroidectomy), in the treatment of metastatic differentiated thyroid cancer (see p. 708) and to treat benign thyroid disease (such as Graves disease, see p. 704). Other therapeutic radiopharmaceuticals include radium-223 (^{223}Ra), strontium-89 (^{89}Sr) and samarium-153 (^{153}Sm), which are used to treat bone pain from prostate cancer metastases. These are administered by intravenous injection and are taken up by bony tissue due to their similarity to calcium or affinity to bone tissue with a high turnover. ^{223}Ra emits alpha particles, while ^{89}Sr and ^{153}Sm emit beta particles, to deliver high doses of radiation directly to cancer cells in the bone. Lutetium-177 (^{177}Lu)-DOTATATE and ^{131}I-MIBG are intravenous radiopharmaceuticals used to treat metastatic neuroendocrine tumours (p. 732) and advanced malignant phaeochromocytoma/paraganglioma (p. 730).

Side-effects of radiotherapy

The side-effects of radiotherapy depend on the site being treated, the tissue's radiosensitivity and the dose delivered. For example, skin reactions are common with high-dose radical head and neck cancer treatments, or proctitis and cystitis with treatment to the bladder or prostate. These acute reactions typically settle within a few weeks after treatment. Late effects of radiotherapy develop more than 6 weeks after treatment and occur in 5%–10% of patients. Examples include brachial nerve damage or lymphoedema after breast cancer treatment and fibrosis leading to bladder, bowel and sexual problems after pelvic radiotherapy. There is also a risk of inducing new cancers after radiotherapy, which varies depending on the site treated and on whether the patient has had other treatment such as cytotoxic chemotherapy. Systemic radioisotope therapies can cause bone marrow and renal toxicity.

Systemic anti-cancer therapy

Systemic anti-cancer therapy (SACT) is a collective term to describe the growing number of differing drug therapies used to treat cancer. These drugs reach throughout the body to treat cancer cells wherever they may be. Increasingly, treatment is tailored to a patient's particular cancer and its molecular profile, allowing more personalised therapy.

Whilst most anti-cancer therapies cause some side-effects, most of these can be managed with supportive medicines at home. Some patients will develop severe toxicities and an acute assessment will be needed. Examination of the patient on anti-cancer treatment should consider the type of anti-cancer treatment, duration since the last treatment and other concurrent toxicities. Patients on anti-cancer therapy can deteriorate quickly and prompt assessment and management is required. There may be specific management protocols to help manage treatment-related toxicities and advice should be sought from the patient's cancer centre or acute oncology team.

Cytotoxic chemotherapy

Cytotoxic chemotherapy drugs work by interfering with the processes involved in cell division. They are sub-classified by their mode of action (Fig. 8.11). Cytotoxic chemotherapies have their greatest activity in

	Antifolates	Fluoropyrimidines	Nucleoside analogues	Nitrogen mustards	Platinum agents	Topoisomerase I/II inhibitors	Mitotic inhibitors	Microtubule aggregators	Others – acting on DNA
Mechanism of action	Inhibit dihydrofolate reductase and so purine and pyrimidine synthesis	Inhibit thymidylate synthase and so pyrimidine synthesis	Incorporated into DNA during synthesis, leading to irreparable errors	Form covalent cross-links between DNA molecules by adding an alkyl group to DNA	Form inter-/intra-strand cross-links between DNA molecules, not by adding an alkyl group, so considered alkylating-like agents	Prevent re-ligation of DNA strands by topoisomerase I/II	Bind tubulin, blocking microtubule formation	Stabilise the microtubule polymer preventing its disassembly	1. Intercalate with DNA and inhibit the progression of topoisomerase I 2. Induce DNA strand breaks by oxidative damage 3. Bind to DNA to prevent transcription
Examples	Methotrexate	5-Fluorouracil, capecitabine	Gemcitabine, fludarabine	Cyclophosphamide, ifosfamide	Cisplatin, carboplatin, oxaliplatin	Etoposide (II); topotecan, irinotecan (I)	Vinca alkaloids: vincristine, vinblastine, vinorelbine	Taxanes: paclitaxel, docetaxel	1. Anthracyclines: epirubicin, doxorubicin 2. Bleomycin 3. Actinomycin D

Fig. 8.11 Commonly used cytotoxic chemotherapy agents and their mechanisms of action.

proliferating cells and this provides the rationale for their use in the treatment of cancer. However, they are not specific for cancer cells and the side-effects of treatment are largely a result of their antiproliferative actions in normal tissues such as the bone marrow, skin and gut (p. 159). Other organs, such as the heart, kidney and peripheral nervous system, may also be affected by some cytotoxic drugs.

The choice of cytotoxic chemotherapy agent, or combination of treatments, is determined by the cancer type. The dosing schedule is determined by the choice of treatments and recovery of normal tissues, usually the bone marrow. For most common cytotoxic chemotherapy regimens the treatment is administered in cycles. A course of treatment may constitute a pre-defined number of cycles, or may continue indefinitely until evidence of disease progression or until limiting side-effects.

Side-effects of cytotoxic chemotherapy

Supportive therapy is used to enable patients to tolerate therapy and achieve benefit. Nausea and vomiting are common, but with modern antiemetics, regimens such as the combination of dexamethasone and highly selective 5-hydroxytryptamine (5-HT_3, serotonin) receptor antagonists such as ondansetron, most patients now receive cytotoxic chemotherapy without any significant problems. Myelosuppression is common to almost all cytotoxics and this not only limits the dose of drug but also can cause life-threatening complications. The risk of neutropenia can be reduced with the use of specific growth factors that accelerate the repopulation of myeloid precursor cells. The most commonly employed is granulocyte colony-stimulating factor (G–CSF; see p. 944), which is widely used with prophylactic intent with cytotoxic chemotherapy regimens that induce a high rate of neutropenia.

Neutropenic fever

Neutropenia is a common complication of malignancy. It is usually secondary to cytotoxic chemotherapy but may occur with radiotherapy, if large amounts of bone marrow are irradiated, and some targeted therapy agents. It may also be a component of pancytopenia due to malignant infiltration of the bone marrow. After cytotoxic chemotherapy neutropenic fever is most commonly defined as a single oral temperature of ≥38.3°C or a temperature of ≥38°C sustained for over 1 hour in a patient with a neutrophil count of $<0.5 \times 10^9$/L (or $<1.0 \times 10^9$/L if the nadir is anticipated to drop to $<0.5 \times 10^9$/L in the next 48 hours). The risk of sepsis is greater with profound neutropenia (neutrophil count $<0.1 \times 10^9$/L), prolonged neutropenia (<0.5 neutrophils for ≥7 days) or a rapid rate of decline in neutrophils as well as the presence of other risk factors, such as intravenous cannulae or urinary catheters. Neutropenic fever is an emergency in cancer patients as, if left untreated, it can result in sepsis with a high mortality rate.

Clinical features

The typical presentation is with high fever, and affected patients may feel non-specifically unwell. If patients have been taking paracetamol or glucocorticoids then fever or symptoms may be masked. Examination is usually unhelpful in defining a primary source of the infection. Hypotension is an adverse prognostic feature and may progress to systemic circulatory shutdown and organ failure.

Investigations and management

An infection screen should be performed, including blood cultures (both peripheral and from central lines), urine culture, chest X-ray and swabs for culture (throat, central line, wound). High-dose intravenous antibiotics should be commenced (ideally within 1 hour of admission) for all febrile patients on systemic anti-cancer therapy, without awaiting test results. The standard approach is to commence empirical broad-spectrum antibiotics according to local hospital policies agreed with microbiologists and based on local antibiotic resistance patterns. Depending on the patient's MASCC risk index score (Box 8.18) and likely organisms, this may be either monotherapy (e.g. piperacillin–tazobactam or meropenem) or combination therapy (e.g. with the addition of gentamicin if high risk on MASCC score, metronidazole if anaerobic infection is suspected, or vancomycin/teicoplanin where gram-positive infection is suspected). Antibiotics should be adjusted according to culture results, although these are often negative. If there is no clinical improvement after 36–48 hours, antibiotics should be reviewed with microbiological advice, and antifungal cover should be considered (e.g. fluconazole or liposomal amphotericin B). G–CSF (granulocyte colony-stimulating factor) can be used to hasten neutrophil recovery in some patients with febrile neutropenia, in line with local guidelines. Other supportive therapy, including intravenous fluids, oxygen, inotrope therapy, ventilation or haemofiltration, may be required (see p. 235).

i 8.18 MASCC* risk index score for neutropenic fever

Characteristic	Score
Burden of current illness	
No or mild symptoms (normal function)	5
Moderate symptoms (uncomfortable or influences daily activities)	3
Severe symptoms (significant discomfort or limits daily activities)	0
No hypotension (systolic BP > 90 mmHg)	5
No chronic obstructive pulmonary disease	4
Solid tumour or lymphoma with no previous fungal infection	4
No dehydration requiring parenteral fluids	3
Outpatient at onset of fever	3
Age < 60 years	2
Score ≥ 21 = low risk febrile neutropenia Score < 21 = high risk febrile neutropenia	

*Multinational Association of Supportive Care in Cancer.

Tumour lysis syndrome

The acute destruction of a large number of cells can be associated with metabolic sequelae and is called tumour lysis syndrome. It is usually related to bulky, cytotoxic chemosensitive disease, including lymphoma, leukaemia and germ cell tumours. More rarely, it can occur spontaneously. Pre-treatment serum lactate dehydrogenase (LDH) correlates with tumour bulk and may indicate increased risk.

Clinical features

Cellular destruction results in the release of potassium, phosphate, nucleic acids and purines that can cause transient hypocalcaemia, hyperphosphataemia, hyperuricaemia and hyperkalaemia. This can lead to acute impairment of renal function and the precipitation of uric acid crystals in the renal tubular system. These can manifest with symptoms associated with multiple underlying electrolyte abnormalities, including fatigue, nausea, vomiting, cardiac arrhythmia, heart failure, syncope, tetany, seizures and sudden death.

Investigations and management

Prophylaxis with allopurinol and hydration for 24 hours should be considered for high-risk patients. In patients with bulky disease, when rapid tumour shrinkage is anticipated, recombinant urate oxidase (rasburicase) should also be given before the start of treatment. Serum biochemistry should be monitored regularly for 48–72 hours after treatment in patients at risk. Elevated serum potassium may be the earliest biochemical marker. In the treatment of tumour lysis syndrome, adequate hydration is vital, as it has a dilution effect on the extracellular fluid, improving electrolyte imbalance, and increases circulating volume, improving filtration in the kidneys. Rasburicase can be used to reduce uric acid levels when other treatments fail, and if these are not effective at correcting the problems, haemodialysis should be considered at an early stage to prevent progression to irreversibility.

Hormone therapy

Hormones are important cell-signalling molecules and, in some cancers, may be key drivers of tumour growth. Blocking hormonal signalling pathways in these cancers may be a very effective treatment strategy.

Approximately 80% of breast tumours are positive for expression of the oestrogen receptor (ER). Assessment of ER status is now standard in the diagnostic workup of breast cancer. Drugs that reduce oestrogen levels or block the effects of oestrogen on the receptor are widely used in the management of ER-positive breast cancer. Adjuvant hormone therapy may reduce the risk of relapse and death at least as much as cytotoxic chemotherapy and in advanced cases can induce stable disease and remissions that may last months to years, with acceptable toxicity.

Hormonal manipulation may be effective in other cancers. In prostate cancer, hormonal therapy (e.g. luteinising hormone releasing hormone

(LHRH) analogues such as goserelin and/or anti-androgens such as bicalutamide) aimed at reducing androgen levels can provide good long-term control of advanced disease. The side-effects of hormone therapies are linked to their hormonal targets.

Targeted therapies

Advances in knowledge about the molecular basis of cancer have resulted in the development of treatments to target specific genes and proteins that are involved in the growth and survival of cancer cells (Box 8.19). These signalling pathways may have broad importance to a range of cancer types or be specific to certain cancers. They may not be important in all tumours of the same cancer type, requiring specific molecular testing to predict whether the patient may benefit.

Targeted therapies are broadly divided into two groups: monoclonal antibodies (-mab) and small molecule inhibitors (-ib). The -mab family are typically utilised for targets that are overexpressed on the outside of the cancer cell. The -ib family typically target processes within the cell, such as the cytoplasmic tyrosine kinase, and are designed to be small enough to enter the cell.

A wide range of targeted therapies are now used routinely in oncological practice. Some of these are described below, linked to the hallmark of cancer growth being targeted (see Box 8.19 and p. 160). The side-effects of targeted therapies are determined by the molecular pathway being targeted (p. 159).

EGFR, BRAF and HER2 inhibitors to target sustained proliferative signalling

Epidermal growth factor receptor (EGFR) is an important transmembrane signalling protein. Mutations in the *EGFR* gene lead to overexpression of the EGFR protein or constitutive activation of the cell-signalling pathway, leading to uncontrolled cell division, in several cancer types. Approximately 15% of lung adenocarcinomas have activating mutations of *EGFR*, which may be targeted with drugs such as gefitinib, erlotinib or osimertinib. The latter of these agents has been designed to overcome a particular mutation (i.e. T790M) responsible for 50% of resistance to older EGFR inhibitors. In colorectal cancer, drugs such as cetuximab and panitumumab are only active against those cancers that do not have mutations in the *RAS/BRAF* family of genes (as these infer drug resistance).

Colon cancers harbouring a BRAF V600E mutation do not respond to BRAF inhibitors alone due to EGFR reactivation of the BRAF signalling pathway. This reactivation can be overcome by using BRAF inhibitors such as encorafenib at the same time as EGFR inhibitors, such as cetuximab, to inhibit the EGFR pathways.

HER2 is a member of the epidermal growth factor receptor family. Amplification or over-expression of HER2 is found in breast, gastric, pancreatic, lung and some uterine cancers. Approximately 20% of breast cancers are HER2-positive, where it is associated with increased risk of recurrence and poor prognosis. Several agents have been developed to target HER2, including trastuzumab and pertuzumab.

Antibody–drug conjugates are targeted therapies that deliver cytotoxic chemotherapy directly to cancer cells via a linker attached to a monoclonal antibody (see also Box 24.21). An advantage of this approach is the more precise delivery of cytotoxic chemotherapy to a cancer cell, potentially increasing its efficacy and reducing damage to other cells. The agent trastuzumab emtansine is an antibody–drug conjugate consisting of trastuzumab covalently linked to the cytotoxic chemotherapy agent emtansine, which is delivered specifically to HER2-positive breast cancer cells.

8.19 Examples of targeted anti-cancer therapies and their actions in relation to the 10 hallmarks of cancer

Hallmark of cancer	Examples of targeted treatment
Genome instability and mutation	PARP inhibitors
Resisting cell death	BCL-2 inhibitors
Sustaining proliferative signalling	EGFR, HER2 and BRAF inhibitors
Evading growth suppressors	Cyclin-dependent kinase 4/6 inhibitors
Enabling replicative immortality	Telomerase inhibitors
Inducing angiogenesis	VEGF inhibitors
Activating invasion and metastasis	HGF/c-MET inhibitors
Deregulating cellular energetics	IDH1 and IDH2 inhibitors
Tumour-promoting inflammation	Selective anti-inflammatory agents
Evading immune destruction	Checkpoint inhibitors or anti-CTLA4 immunotherapy

(BCL-2 = B cell lymphoma-2; BRAF = serine/threonine-protein kinase B-raf; CTLA = cytotoxic T-lymphocyte associated protein; EGFR = epidermal growth factor receptor; HER2 = human epidermal growth factor receptor 2; HGF = hepatocyte growth factor; IDH = isocitrate dehydrogenase; MET = mesenchymal-epithelial transition factor; PARP = poly (ADP-ribose) polymerase; VEGF = vascular endothelial growth factor)

CDK4/6 inhibitors to target evasion of growth suppressors

Cyclin-dependent kinases 4 and 6 (CDK4/6) inhibitors prevent the phosphorylation of the tumour suppressor retinoblastoma protein, thereby reducing DNA synthesis, cell cycle progression and reducing breast cancer cell proliferation. CDK4/6 inhibitors such as palbociclib, ribociclib and abemaciclib are commonly used in combination with hormone therapies to treat breast cancer.

Telomerase inhibitors to target replicative immortality

The enzyme telomerase helps cancer cells to divide indefinitely and is often overactive in cancer cells. Telomerase inhibitors cause progressive shortening of telomeres, which cause cancer cells to lose their ability to divide so that they eventually undergo apoptosis. The telomerase inhibitor imetelstat has been used in myelodysplastic syndromes to treat refractory anaemia (p. 993).

c-MET/HGF inhibitors to target activation of invasion and metastases

The c-MET receptor is a tyrosine kinase that is activated by its ligand, hepatocyte growth factor (HGF), to trigger downstream signalling pathways, like PI3K/AKT, to promote cell proliferation, invasion and metastases. The small molecule c-MET inhibitor crizotinib is used to treat non-small-cell lung cancers that harbour mutations of the *ALK* or *ROS1* genes.

Anti-inflammatory agents to target tumour promoting inflammation

Inflammatory cells release cytokines and growth factors that help promote cancer growth and create an environment enabling tumour progression. The COX-2 enzyme is often overexpressed in cancers and helps them proliferate and evade the immune system. Selective non-steroidal anti-inflammatory agents like the COX-2 inhibitor celecoxib may help the cancer immune response and is being investigated alongside immunotherapy. Glucocorticoids, like dexamethasone or prednisolone, are often used in combination with other anti-cancer therapies, for example as part of lymphoma and myeloma regimens, to improve responses (Ch. 24).

VEGF inhibitors to target the induction of angiogenesis

Activation of members of the vascular endothelial growth factor receptor (VEGFR) family play an important role in tumour angiogenesis and continued cancer growth. VEGFR small molecule inhibitors such as sunitinib, pazopanib and cabozantinib are pillars of renal cell carcinoma treatment and are used in the management of hepatocellular carcinoma and thyroid cancer. Bevacizumab, a monoclonal antibody therapy targeted at VEGF-A, is active in a number of cancers, including ovarian, colorectal and breast, when used alongside chemotherapy.

PARP inhibitors to target genome instability

Poly (ADP-ribose) polymerase (PARP) is involved in repairing DNA damage in cells. Some cancer cells, especially those with mutations of the *BRCA1* or *BRCA2* genes, have a faulty DNA repair system. PARP inhibitors specifically target these compromised cancer cells so that they are not able to repair DNA damage to effectively proliferate. PARP inhibitors including olaparib are used to treat ovarian and breast cancers. Some cancers have deficiency in mismatch repair genes, which are responsible for correcting mistakes during DNA replication. This deficiency results in microsatellite instability (MSI) and this can be a target for immunotherapy treatments such as checkpoint inhibitor therapy.

BCL-2 inhibitors as a target to resist cell death

The BCL-2 protein helps cancer cells avoid apoptosis and thereby allows ongoing proliferation of cancer growth. Venetoclax is a BCL-2 inhibitor that triggers apoptosis and is used to treat some patients with chronic lymphocytic leukaemia and acute myeloid leukaemia (Ch. 24).

IDH1 and IDH2 inhibitors to target the deregulation of cellular energetics and metabolism

Isocitrate dehydrogenases 1 and 2 (*IDH1* and *IDH2*) are some of the most frequently mutated metabolic genes in human cancers. Mutations in *IDH1* and *IDH2* lead to the production of an oncometabolite, which disrupts normal cellular metabolism and contributes to cancer development and growth. IDH inhibitors, such as vorasidenib for glioma harbouring *IDH1* or *IDH2* mutations, help to restore normal cellular metabolism and help slow tumour progression.

Side-effects of targeted therapies

Fatigue, nausea/vomiting, diarrhoea, rash and hepatic dysfunction are frequent side-effects of targeted therapies. However, the side-effect profiles of targeted therapy vary dependent on the class of targeted therapy used (p. 159). For example, EGFR inhibitors are commonly associated with adverse dermatological reactions, most frequently consisting of an acneiform rash, but also xerosis, pruritus, palmar plantar erythema, fissures or hair changes. Hypertension, proteinuria and bleeding are important side-effects to monitor for in patients treated with VEGFR inhibitors. The increased risk of significant cardiotoxicity warrants on-treatment monitoring of left ventricular ejection fraction for patients being treated with HER2 targeted therapies. The management of targeted therapy toxicity usually involves the use of supportive medications to help patients tolerate treatment. More severe toxicity may necessitate targeted therapy treatment breaks and/or dose reductions to enable treatment to continue safely.

Immunotherapy

The term immunotherapy encompasses a range of anti-cancer therapies that work by harnessing the immune system to attack cancer cells. Cytokines, such as interferon-alfa and interleukin-2, have been used with some success in melanoma and renal cell carcinoma. However, in recent years the development of other immunotherapy treatments has revolutionised the management of several cancer types.

Immune checkpoints are key regulators of the immune system which work to prevent the immune response from attacking normal healthy cells. Cancers may co-opt this mechanism to evade immune destruction. Immune checkpoint inhibitors (ICIs) are targeted therapies that inhibit these checkpoint molecules (CTLA4, PD-1) or their ligands (PD-L1) (see p. 84; Fig. 4.14). Their use has rapidly expanded and they are now licensed in the management of many cancers, including melanoma, renal cell carcinoma, lung, bladder, head and neck, and, more broadly, any cancers demonstrating microsatellite instability. ICIs may be used alone, or in combination with other ICIs, targeted therapies or cytotoxic chemotherapy.

Adoptive cell therapy, also known as cellular immunotherapy, is increasingly being used, particularly in haematological malignancies. Immune cells isolated from either the patient's tumour or bloodstream may be activated and expanded, before being infused back into the patient to attack cancer cells (i.e. tumour infiltrating lymphocyte (TIL) therapy). The immune cells may also be genetically modified to improve the likelihood that they identify the cancer cells (i.e. engineered T-cell (TCR) therapy, chimeric antigen receptor T-cell (CAR-T) therapy; see pp. 85 and 967).

Immunotherapy treatment is likely to become more prevalent in the future for many types of cancers and indications. In patients with advanced or metastatic disease, a key observation has been the potential for durable treatment responses. For example, average survival for patients with metastatic melanoma has improved from 6–8 months in the pre-immunotherapy era to over 5 years with the use of combination anti-CTLA4 and anti-PD-1 ICIs in clinical trials. However, many patients do not respond and others are affected by potentially life-threatening immune-related adverse events.

Side-effects of immunotherapy

Side-effects of ICIs occur when the immune system is stimulated to attack healthy cells and tissues in the body. These immune-related adverse events (irAEs) are increasingly being recognised as oncological emergencies as they have the potential to result in severe, life-threatening or life-long complications. They require prompt recognition, management and monitoring.

Clinical features

Almost any organ system may be affected, but inflammation of the colon, endocrine organs (thyroid, adrenal and pituitary glands), lungs, liver, kidney, skin and nervous system are more frequently seen (see p. 159). irAEs may occur at any point in a patient's treatment, or even after they have stopped receiving the checkpoint inhibitor immunotherapy agent. Multiple irAEs may occur in the same patient.

Investigations and management

Investigation and management of irAEs requires a multidisciplinary approach including oncologists and relevant system specialists. Specialist investigations may be required depending on the body system affected. The focus of treatment is on dampening the over-active immune response, often using high-dose glucocorticoids. Additional immunosuppressant therapies are sometimes required in steroid refractory or persistent cases. In patients who experience severe irAEs, ICI treatment will usually be permanently discontinued. In other cases it may be possible to reintroduce ICI treatment once glucocorticoids are weaned down.

The investigation and management of several irAEs are summarised below.

Colitis

Immune-related colitis is the most common gastrointestinal irAE, affecting up to 15% of those treated with anti-CTL4 therapy. The hallmark symptoms of immune-related colitis (ir-colitis) are diarrhoea and abdominal pain. Severe colitis can lead to dehydration, toxic megacolon, colonic perforation or death, especially in cases of diagnostic delay. Persistent diarrhoea or an increase ≥4 stools/day over baseline should prompt further investigations and management while immunotherapy is withheld. Specialist gastroenterology review should be considered. An infective screen and review of renal function and electrolytes should be conducted. Faecal calprotectin is a sensitive and specific non-invasive biomarker of gastrointestinal inflammation. Early endoscopic evaluation with biopsy is recommended. The mainstay of ir-colitis treatment is glucocorticoid therapy, given either orally or intravenously dependent on the severity, once bowel perforation has been excluded. A proportion of patients will experience glucocorticoid-refractory ir-colitis, in whom second-line immunosuppressants such as infliximab or vedolizumab should be considered.

Hepatitis

Hepatitis occurs in 5%–10% of patients treated with monotherapy and 25%–30% treated with immune checkpoint inhibitor combination therapy. Serum transaminases, alkaline phosphatase and bilirubin should be monitored during treatment. Many patients will be asymptomatic, but fever, malaise, abdominal discomfort, jaundice or anorexia may be present. An increase of liver transaminases ≥3 times above the upper limit of the normal range (ULN) should prompt further investigations and management whilst immunotherapy is withheld. Specialist hepatology review should be considered. Liver function tests, a coagulation screen and albumin should be measured regularly. A hepatitis screen including infective and autoimmune markers should be performed. Radiological imaging of the liver should be performed to evaluate the liver parenchyma and rule out metastases or thromboembolic events. In severe cases a liver biopsy should be considered. The mainstay of ir-hepatitis treatment is glucocorticoid treatment given either orally or intravenously dependent on the severity. Potentially hepatotoxic drugs should be withheld. Additional immunosuppressive agents such as mycophenolate mofetil should be considered in patients with no response to glucocorticoids within 2–3 days. In patients with poor response to initial glucocorticoids or liver transaminases ≥5× ULN, further ICI therapy will usually be discontinued.

Endocrinopathies

Immune-related endocrinopathies are relatively frequent. Any of the endocrine organs may be affected. Symptoms may be non-specific and hormone testing, particularly cortisol, should always be considered at an early stage. Ir-primary hypothyroidism is the most common ir-endocrinopathy, affecting approximately 10% of patients treated with ICI. Hypophysitis, primary adrenal insufficiency and type 1 diabetes mellitus are also common. The management of ir-endocrinopathies differs from other irAEs in several ways. ICI-therapy may continue, high-dose glucocorticoids are rarely required and endocrine deficiency usually persists, necessitating life-long hormone replacement. Specialist endocrinology review should be considered. Investigations and treatment depend on the endocrine organ involved. In cases of ir-hypophysitis, a full pituitary axis screen should be performed, with initiation of appropriate hormone replacement therapy and consideration of glucocorticoid therapy following consultation with a specialist endocrinologist. Visual field assessment and MRI pituitary should be performed to identify any inflammatory mass in the pituitary (and associated impingement on the optic nerves/chiasm) and to exclude metastatic disease as a cause of hypopituitarism.

Neurological

Neurological irAEs are relatively rare, affecting only 1%–5% of patients, but some are associated with a significant risk of mortality. Central nervous system irAEs may include encephalitis or aseptic meningitis. Approximately two-thirds affect the peripheral nervous system, most commonly presenting as polyradiculoneuropathy or cranial neuropathies. A common presentation is of a myopathy, which can be associated with neuromuscular junction involvement. A particularly concerning ICI-related complication is a myasthenia gravis–like syndrome (irMG). Typical symptoms include exercise-dependent fluctuating weakness of the proximal extremities or bulbar muscle groups, and ocular symptoms such as ptosis and diplopia. Early recognition and involvement of neurological specialists is necessary, along with consideration of early referral to intensive care specialists. Urgent assessment of respiratory function should be undertaken. It is also vital to assess for myocardial involvement, as ir-myopathies are frequently associated with myocarditis and the combination of respiratory and cardiac failure is life-threatening. Discontinuation of ICIs, glucocorticoids and pyridostigmine constitute first-line management of irMG-like syndrome, with consideration of intravenous immunoglobulins or plasmapheresis for severe cases. Other immunomodulatory or immunosuppressive drugs may also be required.

Evolving cancer therapies

Oncology is an ever-changing clinical specialty, driven by ongoing advances in our understanding of cancer. Every year, research leads to new treatments and tools being developed that improve patient outcomes. At the forefront of development is the expanding use of immunotherapy treatments, both in combination with other systemic therapies and also now as individualised mRNA cancer vaccines. These vaccines are synthesised following an analysis of an individual's tumour, to identify the most immunogenic tumour-associated antigens or neoantigens. mRNA sequences that encode these antigens are designed and encapsulated (e.g. into lipid nanoparticles) and injected into the individual to stimulate an immune response against the cancer cells.

Precision-oncology is also rapidly developing. Detailed profiling of tumour DNA by next-generation sequencing (NGS) is increasingly directing targeted treatments in both routine clinical practice and in clinical trials. Analyses of circulating tumour DNA (ctDNA) and/or circulating tumour cells (CTC) may be helpful for detecting cancer earlier, deciding who needs post-operative treatment, or for tracking the evolution of resistance pathways in an individual's cancer over time. This may allow treatments to be tailored to retain treatment-sensitive cells and inhibit the growth of drug-resistant cells. These adaptive therapy strategies are currently being explored in clinical trials.

Evaluation of treatment

In advanced or metastatic cancer, the evaluation of treatment is an ongoing process and includes assessments of treatment response, toxicity and quality of life. Clinical evaluation, patient-reported outcome measures, biochemical monitoring (including sequential tumour marker analysis), and radiological evaluation are commonly used to determine whether a treatment is being effective. Uniform criteria have been established to measure these, primarily measuring morphologic criteria using the response evaluation criteria in solid tumours (RECIST; Box 8.20), or iRECIST for immunotherapy treatments. Measurement of metabolic criteria using positron emission tomography (PET) response criteria in solid tumours (PERCIST) can be used to assess metabolic response depending on sequential ^{18}F-fluorodeoxyglucose (FDG) PET activity in tumours on treatment. It can be useful to detect metabolic changes in cancers, even if their size remains unchanged, or if there is residual tumour after treatment; however, consistent imaging protocols must be used. Side-effects of treatment are recorded using common toxicity criteria (e.g. common terminology criteria for adverse events (CTCAE)). This allows clinicians to inform patients accurately about the prognosis, effectiveness and toxicity of systemic anti-cancer therapy and empowers patients to take an active role in treatment decisions.

Late toxicity of therapy

The late toxicities of treatment for cancer are particularly important for patients where multimodality therapy is given with curative intent, where the patient is young and as more patients are living longer. This can cause considerable morbidity: for example, radiotherapy can retard bone

8.20 Response evaluation criteria in solid tumours (RECIST)

Response	Criteria
Complete response (CR)	Disappearance of all target lesions
Partial response (PR)	At least a 30% decrease in the sum of the longest diameter (LD) of target lesions, taking as reference the baseline sum LD
Progressive disease (PD)	At least a 20% increase in the sum of the LD of target lesions, taking as reference the smallest sum LD recorded since the treatment started and at least 5 mm increase or the appearance of one or more new lesions
Stable disease (SD)	Neither sufficient shrinkage to qualify for PR nor sufficient increase to qualify for PD, taking as reference the smallest sum LD since the treatment started

and cartilage growth, impair intellect and cognitive function, and cause dysfunction of the hypothalamus, pituitary and thyroid glands. Late consequences of cytotoxic chemotherapy include heart failure due to cardiotoxicity, pulmonary fibrosis, nephrotoxicity and neurotoxicity.

Premature gonadal failure can result from cytotoxic chemotherapy or radiotherapy and leave a patient subfertile. Patients should be made aware of this before treatment is initiated, as it may be possible to store sperm for male patients before treatment starts; this should always be offered, if practical. Egg storage or embryo banking after in vitro fertilisation may be an option for young women. Sterility develops at higher radiotherapy doses, but erectile dysfunction is seen in patients receiving high radiotherapy doses to the pelvis, as in prostate cancer. Additional social or psychological support may be required to address these issues. Infertility and pubertal delay are potential late effects of therapy in children, especially boys.

Second malignancies may be induced by cancer treatment and occur at greatest frequency following chemoradiation. Secondary acute leukaemia (mostly AML) can occur 1–2 years after treatment with topoisomerase II inhibitors, or 2–5 years after treatment with alkylating agents. The most common second malignancy within a radiation field is osteosarcoma, but others include soft tissue sarcoma and leukaemia.

Cancer clinical trials

Cancer clinical trials are embedded within routine practice in oncology. Close collaboration with laboratory scientists, active recruitment of cancer patients into clinical trials and robust translational research have led to many new cancer treatments, personalised therapies and a transformation of cancer management over the last 20 years. As many anti-cancer drugs are expected to have toxicities, which may ultimately limit the deliverable dose, clinical trials in cancer differ from trials of other medicines.

- Phase I cancer clinical trials take treatments of interest from laboratory studies and test them in patients with advanced cancer for whom no other standard anti-cancer treatment exists. Phase I trials assess the safety of a treatment and identify an optimal dose and dosing schedule. Initial doses are very low and each sequential cohort of patients receives a higher dose. Doses are escalated in controlled cohorts of 1–6 patients, according to toxicities, pharmacokinetics and pharmacodynamics, until the maximum tolerated dose, or optimum biological dose, is reached.
- Phase II cancer clinical trials treat patients with specific cancers of interest with the trial drug, using the dose established in phase I trials. Phase II trials may be randomised or non-randomised but will recruit enough patients to further assess the safety of the treatment and whether it results in enough anti-cancer activity in a specific cancer to develop the drug further by way of phase III trials.
- Phase III cancer trials are large, multi-centre randomised controlled trials to compare the new treatment of interest with the current established therapy for this indication. Cancer response, toxicity, quality of life and survival data will usually be assessed. Phase III trials may also compare current standard treatment with a different treatment, either looking for improved outcome or improved quality of life with non-inferior outcome. If a treatment is deemed to be safe and effective it will be licensed for clinical use.
- Phase IV trials involve the continuing safety surveillance of a treatment after it receives a licence for clinical use. This can be particularly useful to detect any rare or long-term adverse effects in a much larger population and longer time period than was possible during phase I–III trials.

Specific cancers

As cancer management becomes more complex and personalised, and incorporates multi-modality treatment approaches, oncology teams are increasingly subspecialised and work as part of tumour-specific multidisciplinary teams. The diagnosis and management of specific cancers are discussed in more detail elsewhere in the book (Box 8.21). Here we discuss the pathogenesis, clinical features, investigation and management of some common tumours that are not covered elsewhere.

Breast cancer

Globally, the incidence of breast cancer is second only to that of lung cancer, and the disease represents the leading cause of cancer-related deaths among women. Invasive ductal carcinoma with or without ductal carcinoma in situ (DCIS) is the most common histology, accounting for 70%, whilst invasive lobular carcinoma accounts for most of the remaining cases. DCIS constitutes 20% of breast cancers detected by mammography screening. It is multifocal in one-third of women and has a high risk of becoming invasive (10% at 5 years following excision only). Pure DCIS does not cause lymph node metastases, although these are found in 2% of cases where nodes are examined, owing to undetected invasive cancer. Lobular carcinoma in situ (LCIS) is a predisposing risk factor for developing cancer in either breast (7% at 10 years). The survival for breast cancer by stage is outlined in Box 8.22.

Pathogenesis

Both genetic and hormonal factors play a role: about 5%–10% of breast cancers are hereditary and occur in patients with pathogenic variants in *BRCA1*, *BRCA2*, *AT* or *TP53* genes. Prolonged oestrogen exposure associated with early menarche, late menopause and use of hormone

8.22 Five-year survival rates for breast cancer by stage

Tumour stage	Stage definition	5-year survival (%)
I	Tumour < 2 cm, no lymph nodes	98
II	Tumour 2–5 cm and/or mobile axillary lymph nodes	90
III	Chest wall or skin fixation and/or fixed axillary lymph nodes	72
IV	Metastasis	29

replacement therapy (HRT) has been associated with an increased risk. Other risk factors include obesity, alcohol intake, nulliparity and late first pregnancy. There is no definite evidence linking use of the contraceptive pill to breast cancer.

Clinical features

Breast cancer usually presents as a result of mammographic screening or as a palpable mass, with nipple discharge in 10% and pain in 7% of patients. Less common presentations include inflammatory carcinoma with diffuse induration of the skin of the breast, and this confers an adverse prognosis. Around 40% of patients will have axillary nodal disease, with likelihood correlating with increasing size of the primary tumour. Distant metastases are infrequently present at diagnosis and the most common sites of spread are bone (70%), lung (60%), liver (55%), pleura (40%), adrenals (35%), skin (30%) and brain (10%–20%).

Investigations

Following clinical examination, patients should undergo imaging with mammography or ultrasound evaluation, and a biopsy using fine needle aspiration for cytology or core biopsy for histology. Histological assessment should be carried out to assess tumour type and to determine oestrogen and progesterone receptor (ER/PR) status and HER2 status. If distant spread is suspected, CT of the thorax and abdomen and an isotope bone scan are required. Molecular subtyping is being used to classify tumours into four major subtypes: luminal A (ER+ and/or PR+, HER2−), luminal B (ER+ and/or PR+, HER2+), HER2 type (ER− and PR−, HER2+) and basal-like (often called 'triple negative', i.e. ER−, PR− and HER2−). Germline *BRCA* mutation is performed in high-risk patients, such as those with a family history. This information may allow more targeted selection of therapies.

Management

Surgery is the mainstay of curative treatment. This can range from a lumpectomy, where only the tumour is removed, to mastectomy, where the whole breast is removed. Breast-conserving surgery is as effective as mastectomy if complete excision with negative margins can be achieved. Lymph node sampling is performed at the time of surgery.

There is significant evidence to support the use of additional therapies to reduce the risk of breast cancer recurrence. Adjuvant radiotherapy is given to reduce the risk of local recurrence. In those patients considered at high risk of recurrence (i.e. tumour of > 1 cm, ER-negative disease or the presence of involved axillary lymph nodes), cytotoxic chemotherapy may be offered. In patients with HER2-positive breast cancer, adjuvant trastuzumab, a humanised monoclonal antibody to HER2, may be used alongside standard cytotoxic chemotherapy. ICI therapy may also be used in patients with triple-negative breast cancer or those with *BRCA* pathogenic variants. These treatments are increasingly being used in the neoadjuvant setting, with the aim of achieving a complete pathological response when the cancer is resected, often with a more organ-preserving surgical procedure. In patients with ER-positive tumours, adjuvant hormonal therapy may gain additional disease-free and overall survival benefits. Patients at low risk of recurrence (i.e. small, ER-positive disease) may require only adjuvant hormonal therapy. In post-menopausal women, adjuvant bisphosphonate therapy may also be used.

The treatment of metastatic breast cancer is complex. Radiotherapy may be used to palliate painful bone metastases. Systemic anti-cancer therapy decisions are made with consideration of ER status, HER2 status, PD-L1 status, the distribution of metastatic disease and previous neoadjuvant treatment, alongside assessments of performance status (PS) and comorbidities. For example, in a post-menopausal patient with ER-positive, HER2-negative bone-only metastatic disease who is PS 0, hormonal therapy (i.e. an aromatase inhibitor) in combination with a CDK4/6 targeted therapy (i.e. palbociclib, abemaciclib or ribociclib) may be used as first-line treatment. In a similar patient with additional symptomatic liver metastases, cytotoxic chemotherapy may be more appropriate. The addition of HER2 targeted therapy for HER2-positive breast cancer or ICI therapy for triple-negative breast cancer provides additional benefit.

Ovarian cancer

Most ovarian cancers are epithelial in origin (90%), and up to 7% of women with ovarian cancer have a positive family history. Patients often present late in ovarian cancer with vague abdominal discomfort, low back pain, bloating, altered bowel habit and weight loss. Occasionally, peritoneal deposits are palpable as an omental 'cake' and nodules in the umbilicus (Sister Mary Joseph nodules).

Pathogenesis

Genetic and environmental factors play a role. The risk of ovarian cancer is increased in patients with pathogenic variants in *BRCA1* or *BRCA2*, and Lynch type II families (a subtype of hereditary non-polyposis colon cancer, HNPCC) can have ovarian, endometrial, colorectal and gastric tumours due to mutations of mismatch repair enzymes (p. 848 and Box 3.11). Advanced age, nulliparity, ovarian stimulation and European descent all increase the risk of ovarian cancer, while suppressed ovulation appears to protect, so pregnancy, prolonged breastfeeding and the contraceptive pill have all been shown to reduce the risk of ovarian cancer.

Investigations

Initial workup for patients with suspected ovarian cancer includes imaging in the form of ultrasound and CT. Serum levels of the tumour marker CA-125 are often measured. Surgery plays a key role in the diagnosis, staging and treatment of ovarian cancer, and in early cases, palpation of viscera, peritoneal washings and biopsies are generally performed to define disease extent.

Management

In early disease, surgery followed by adjuvant cytotoxic chemotherapy with carboplatin, or carboplatin plus paclitaxel, is the treatment of choice. Surgery should include removal of the tumour along with total abdominal hysterectomy, bilateral salpingo-oophorectomy and omentectomy. Even in advanced disease, surgery is undertaken to maximally debulk the tumour and is followed by cytotoxic chemotherapy, typically using carboplatin and paclitaxel. Bevacizumab, a targeted therapy against VEGFR, is indicated for patients with high-grade tumours that are suboptimally debulked or those with a more aggressive biological pattern. Subsequent treatment decisions are made with consideration of response to first-line cytotoxic chemotherapy and germline *BRCA* mutation status. Options include further platinum/paclitaxel combination, liposomal doxorubicin or targeted therapy against poly (ADP-ribose) polymerase (PARP, e.g. olaparib, niraparib or rucaparib).

The serum tumour marker CA 125 and clinical examination may be used to monitor treatment response in ovarian cancer, with CT imaging for those with suspected progressive disease.

Endometrial cancer

Endometrial cancer primarily affects post-menopausal women, with a peak incidence at 65–75 years of age. Mortality from endometrial cancer is currently falling; however, 25% of patients will not survive for 5 years or more. The most common presentation is with post-menopausal bleeding, which often results in early detection of the disease before distant spread has occurred.

Pathogenesis

Oestrogen plays an important role in the pathogenesis of endometrial cancer, and factors that increase the duration of oestrogen exposure, such as nulliparity, early menarche, late menopause and unopposed HRT, increase the risk. Endometrial cancer is 10 times more common in obese women and this is thought to be due to elevated levels of oestrogens.

Investigations

The diagnosis is confirmed by endometrial biopsy. MRI scans are used to assess the primary tumour and pelvic lymph nodes, and CT scans assess for metastatic spread.

Management

Surgery is the treatment of choice for early-stage endometrial cancer and is used for staging. A hysterectomy and bilateral salpingo-oophorectomy are performed with peritoneal cytology and, in selected cases, lymph node dissection.

Adjuvant therapy may be considered and is dependent on the extent of myometrial invasion, grade, presence of lymphovascular invasion and molecular subtypes as classified by the Cancer Genome Atlas. Treatment may include vaginal vault brachytherapy, external beam radiotherapy and systemic anti-cancer therapy, either alone or in combination, dependent on the risk of recurrence. Locally advanced, metastatic or recurrent disease may be treated palliatively with radiotherapy and/or systemic anti-cancer therapy. Immunotherapy alone, or in combination with chemotherapy or other targeted therapies, is used increasingly in this patient group.

Cervical cancer

Cervical cancer is the leading cause of death from gynaecological cancer worldwide. The incidence is decreasing in high-income countries as a result of HPV vaccination and screening programmes, but continues to rise in low- and middle-income nations. Early-stage cervical cancer may not cause symptoms. In the UK the most common presentation of these cancers is with an abnormal smear test through the cervical cancer screening programme. Patients may also present with abnormal uterine bleeding, heavy menstrual or unexpected bleeding, including post-menopausal bleeding. New vaginal discharge, pelvic discomfort or dyspareunia may also occur. Locally advanced cervical cancer may cause renal impairment, bladder or rectal symptoms due to involvement of adjacent structures. Occasionally, patients present with distant metastases to bone and lung.

Pathogenesis

Almost all cases of cervical cancer are linked to high-risk human papillomaviruses (HPV), transmitted through sexual contact. This has underpinned the introduction of programmes to immunise adolescents against HPV in an effort to prevent up to 90% of cervical cancer.

Investigations

If cervical cancer is suspected, patients will be referred for colposcopy to examine the cervix and perform a biopsy. Further examination may require cystoscopy and flexible sigmoidoscopy if there are symptoms referable to the bladder, colon or rectum. Radiological investigations, including CT of the chest and abdomen and MRI of the pelvis, are performed to stage cervical cancer. In some cases PET is also required.

Management

This depends on the stage of disease. For patients with very early cervical cancer, a large loop excision of the transformation zone (LLETZ) or a cone biopsy may be employed, which may be the only treatment required. These treatments are most frequently used in women with abnormal cells picked up through cervical screening. For small, localised disease, radical surgery is performed. For bulky or locally advanced disease that has spread to tissue around the cervix or regional lymph nodes, chemoradiotherapy is most frequently recommended. Some women may also receive neoadjuvant chemotherapy or a 'boost' of brachytherapy, dependent on the extent of their disease. In the metastatic setting, palliative platinum-based cytotoxic chemotherapy, with or without bevacizumab, may be offered. In patients with PD-L1 positive disease, concurrent pembrolizumab may also be used.

Head and neck tumours

Head and neck cancers are typically squamous tumours that arise in the nasopharynx, hypopharynx and larynx. They are most common in older adult males, but oropharyngeal cancers now occur with increasing frequency in a younger cohort of patients, including in women. The rising incidence of oropharyngeal cancers, especially in high-income countries, is thought to be secondary to HPV infection. Presentation depends on the location of the primary tumour and the extent of disease. For example, early laryngeal cancers may present with hoarseness, while more extensive local disease may present with pain due to invasion of local structures or with a lump in the neck. Patients who present late often have pulmonary symptoms, as this is the most common site of distant metastases (Box 8.23).

Pathogenesis

The tumours are strongly associated with a history of smoking and excess alcohol intake, but other recognised risk factors include Epstein–Barr virus for nasopharyngeal cancer and HPV infection for oropharyngeal tumours.

Investigations

Careful inspection of the primary site is required as part of the staging process, and most patients will require endoscopic evaluation and examination under anaesthesia. Tissue biopsies should be taken from the most accessible site. CT of the primary site and the thorax is the investigation of choice for visualising the tumour, while MRI may be useful in certain cases.

Management

In general, the majority of patients with early or locally advanced disease are treated with curative intent. In localised disease where there is no involvement of the lymph nodes, long-term remission can be achieved in up to 90% of patients with surgery or radiotherapy. The choice of surgery versus radiotherapy often depends on patient preference, as surgical treatment can be mutilating with an adverse cosmetic outcome. Patients

i 8.23 Common presenting features by location in head and neck cancer

Hypopharynx

- Dysphagia
- Odynophagia
- Referred otalgia
- Enlarged lymph nodes

Mouth and tongue

- Non-healing ulcers
- Ipsilateral otalgia

Nasal cavity and sinuses

- Discharge (bloody) or obstruction

Nasopharynx

- Nasal discharge or obstruction
- Conduction deafness
- Atypical facial pain
- Diplopia
- Hoarse voice
- Horner syndrome

Oropharynx

- Dysphagia
- Pain
- Otalgia

Salivary gland

- Painless swelling
- Facial nerve palsy

with lymph node involvement are treated with a combination of surgery and radiotherapy (often with a radiosensitising agent such as cisplatin or cetuximab), and this produces long-term remission in approximately 60%–70% of patients. Recurrent or metastatic tumours may be palliated with further surgery or radiotherapy to aid local control, or systemic cytotoxic chemotherapy or immunotherapy may be used. Second malignancies are common (3% per year) following successful treatment for primary disease, and all patients should be encouraged to give up smoking and drinking alcohol to lower their risk.

Survivorship

Advances in cancer prevention, diagnosis and treatment mean that more people are surviving cancer. Cancer survival has doubled in the last 40 years in the UK. There are an estimated 2 million people living with, or beyond, cancer in the UK today and 50% of those diagnosed with cancer will survive their disease for 10 years or more. Cancer survivorship has at least two common meanings:

- completing treatment for cancer and having no signs of cancer after finishing treatment
- living with, through and beyond cancer, thus including people who receive curative treatment and people who receive intermittent anti-cancer treatment to control their cancer over a longer time.

Many people feel that life is never the same after a cancer diagnosis. There are often long-lasting physical, social and emotional consequences of both cancer and its treatment. These start at diagnosis and last through first treatment (acute survivorship), continue through and beyond cancer treatments (extended survivorship) and can be long-lasting, even when risk of cancer recurrence is low (permanent survivorship). An increasing awareness of survivorship, the impact of a cancer diagnosis and its wide-ranging effects on patients has highlighted the need for holistic and patient-centred care, support and services throughout and after cancer treatment.

Multiple Choice Questions

8.1. A 54-year-old woman presents to the emergency department with a fever and a sore throat. She has recently been diagnosed with left-sided breast cancer and associated axillary lymph node disease. Twelve days ago she received her first cycle of neoadjuvant cytotoxic chemotherapy (5-fluorouracil, epirubicin and cyclophosphamide). On clinical examination her temperature is 38.3°C, she appears dehydrated and there is evidence of oral candidiasis. An intravenous catheter is placed and bloods, including blood cultures, taken. What is the most appropriate next step in this patient's care?

A. Start oral fluconazole
B. Await blood test results to inform further management
C. Start intravenous fluids
D. Perform a chest X-ray, collect a urine sample and throat swab to complete the infection screen
E. Start high-dose broad-spectrum intravenous antibiotic therapy immediately

Answer: E.

The clinical features here are of fever in a patient at high risk of neutropenia. This is an oncological emergency. Patients are at risk of neutropenia at any point during their systemic anti-cancer therapy treatment cycle, with the highest risk typically 10–14 days after a treatment. In patients with potential neutropenic sepsis, high-dose broad-spectrum intravenous antibiotics should be commenced, ideally within 1 hour of admission, without awaiting test results. In this patient fluconazole (A) for oral candidiasis, intravenous fluids (C) and further tests (D) are also appropriate, but should not delay the first dose of antibiotic therapy. Test results may later inform changes to antimicrobial therapy and its duration.

8.2. A 61-year-old man recently diagnosed with sigmoid colon cancer with peritoneal, liver and lung metastases is seen in the oncology clinic. He is keen to talk about treatment for his cancer. His ECOG performance status is 1 and he has no significant comorbidities. He has some mild abdominal discomfort and 5 kg weight loss. His routine bloods demonstrate anaemia (Hb 105 g/L) and mild elevations in his liver enzymes. A biopsy of his tumour has shown a moderately differentiated adenocarcinoma which is KRAS/NRAS/BRAF wild type and microsatellite stable. What is the most appropriate treatment option for this patient?

A. Cytotoxic chemotherapy (5-fluorouracil, folinic acid and oxaliplatin) alone
B. Surgery to all cancer sites
C. Cytotoxic chemotherapy (5-fluorouracil, folinic acid and oxaliplatin) with an EGFR inhibitor (cetuximab)
D. BRAF inhibitor (encorafenib) alone
E. Refer to palliative care

Answer: C.

This man wishes to pursue anti-cancer therapy and, from the information provided, appears fit to do so. In patients with metastatic disease affecting several organs, systemic anti-cancer therapies are most often used. As the tumour is KRAS, NRAS and BRAF wild type, cytotoxic chemotherapy combined with an EGFR inhibitor, such as cetuximab, would be an appropriate option here. BRAF inhibitors, such as encorafenib, are only used in combination with EGFR inhibitors in colon cancers with BRAF mutations.

8.3. A 59-year-old woman is seen in the emergency department with a 2-day history of severe diarrhoea. She has had 10 loose stools today, the most recent of which have been bloody and associated with crampy abdominal pain. Her past medical history includes metastatic melanoma and she had her fourth cycle of ipilimumab and nivolumab therapy 20 days ago. At the time of her treatment she was constipated and the outpatient systemic anti-cancer therapy unit doctor prescribed her a macrogol laxative. She notes that the evening prior to the diarrhoea starting she had reheated some leftover rice for her supper. What is the most important likely diagnosis?

A. *Bacillus cereus*-associated food poisoning
B. Overflow diarrhea
C. Laxative overuse
D. Immunotherapy-related colitis
E. *Clostridioides difficile* infection

Answer: D.

Immune-related adverse events should be considered in all patients who present acutely unwell following immunotherapy treatments for cancer. Although the other options are on the differential diagnosis list, severe irAEs are oncological emergencies and prompt recognition and management are vital. This is a grade 3 colitis and should be treated with IV methylprednisolone in the first instance. Investigations such as bloods, stool sample, radiological imaging and flexible sigmoidoscopy or colonoscopy are also appropriate.

8.4. A 58-year-old man is seen in clinic with a diagnosis of metastatic lung cancer. He is coping well at home, where he lives alone. However, he has taken early retirement as a brick-layer as he feels unable to work due to increasing fatigue. He awakes early each morning and goes to the shops to collect his newspaper, but has taken to napping for an hour in the afternoon. What is this man's ECOG performance status?

A. 0
B. 1
C. 2
D. 3
E. 4

Answer: B.

This man is ambulatory and capable of self-care, but unable to undertake strenuous activity. He is up for more than 50% of waking hours. Performance status is a key assessment tool in patients with cancer.

8.5. You have been asked to see a 70-year-old man on a medical ward. He was admitted 2 weeks ago following a fall. On admission he had abnormal liver function tests and an elevated CRP. He has been treated for a urinary tract infection. A CT scan has demonstrated multiple liver, lung and bone metastases, but no obvious primary cancer. The ward nurses tell you he remains mildly confused at times, sleeps for most of the day and does not wish to engage with physiotherapy. What is the most appropriate management for this man?

A. Refer to the hepatobiliary pancreatic cancer multidisciplinary team
B. Ultrasound-guided liver biopsy
C. Colonoscopy
D. Palliative care
E. Cytotoxic chemotherapy

Answer: D.

This man has a new diagnosis of metastatic cancer of undefined primary origin (MUO). His ECOG performance status (3), requirement for hospital admission, multi-organ metastatic disease, end-organ dysfunction and raised inflammatory markers are poor prognostic features. Further investigations may not be warranted and honest conversations about the likely diagnosis, palliative care and end-of-life care, taking into account the patient's wishes, are often preferable.

8.6. A 56-year-old woman is seen in oncology clinic following surgery to remove a localised clear cell renal cell carcinoma. She is eligible for a phase III clinical trial comparing adjuvant immunotherapy to the current clinical standard of observation. Patients will be randomised to receive either the immunotherapy treatment or a placebo every 4 weeks for 1 year. Neither the patient nor the investigator will know what treatment she is receiving. Which of the following statements regarding randomised controlled trials (RCTs) is true?

A. Patients may choose which treatment they receive
B. RCTs are always 'double-blinded'
C. RCTs are considered to be the 'gold standard' for determining efficacy and safety in clinical research
D. RCTs always have a control arm that uses placebo
E. RCTs always equally divide patients between each treatment

Answer: C.

Phase III RCTs are often used to determine whether a treatment should be licensed for clinical use. Patients are randomised to each arm, sometimes with stratification to ensure equal allocation of patient subgroups. RCTs may be double-blinded, as is the case here, single-blinded or 'open-label'. The control arm should be the current clinical standard treatment. In this example a placebo is used in the place of observation only to ensure blinding and avoid potential bias of results. Patients may be divided in alternative ratios. This is sometimes the case when earlier studies suggest large differences between the investigational and current treatment.

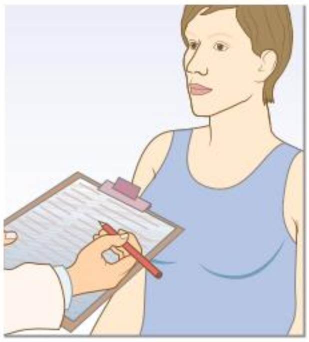
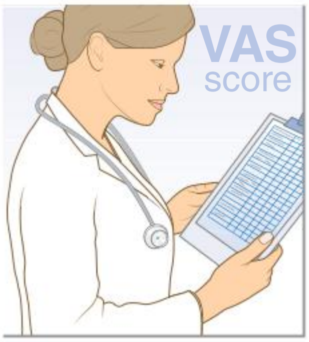
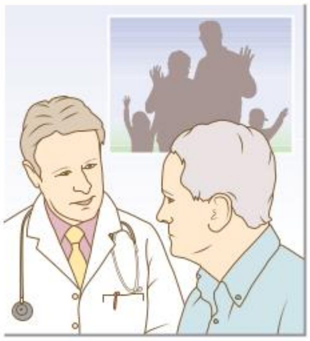
Clinical evaluation and management of a patient with pain in the palliative or supportive care setting



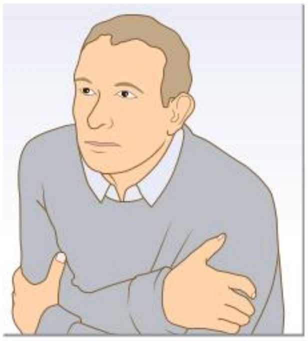
Take careful history, recording character and radiation of pain



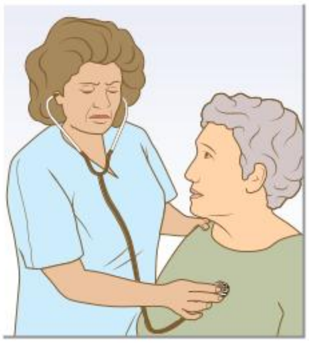
Record severity of pain



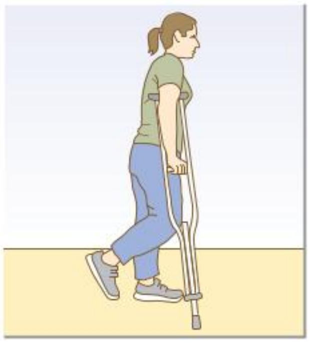
Conduct biopsychosocial assessment



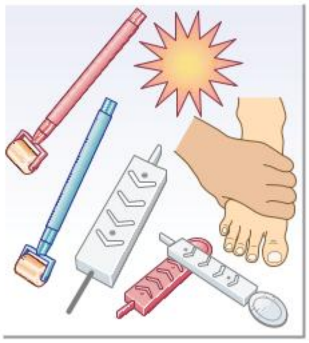
Assess mood and screen for depression



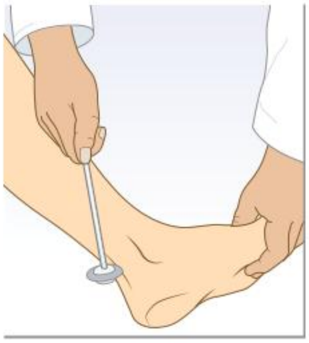
Conduct general examination



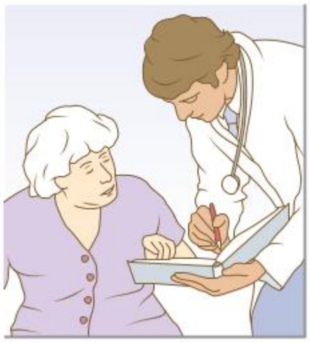
Check gait and whether using a walking aid



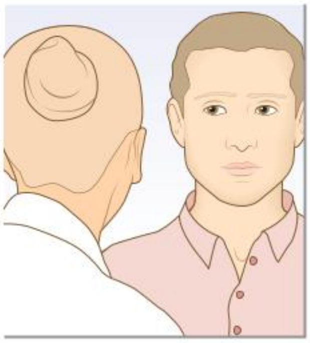
Assess pinprick, fine touch and heat/cold sensation



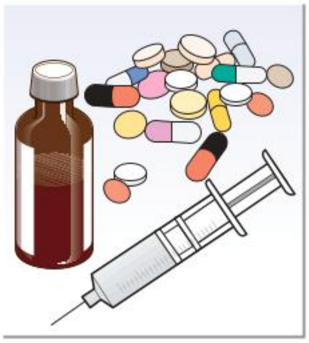
Conduct neurological examination



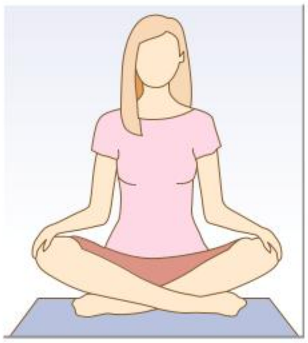
Educate patient on nature of pain and promote self-management



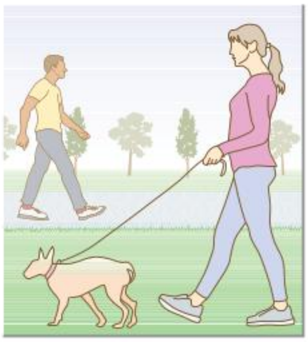
Formulate management plan with patient and set goals



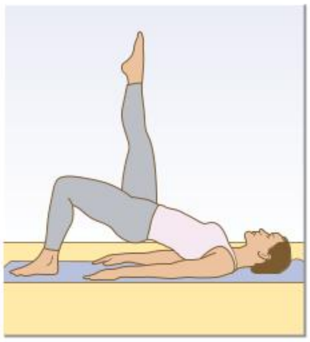
Optimise medication



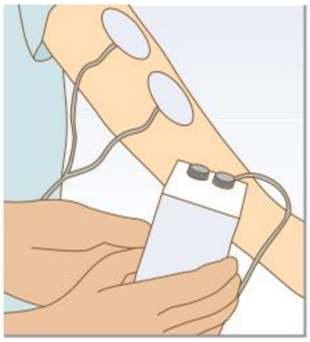
Consider psychological therapies and mindfulness



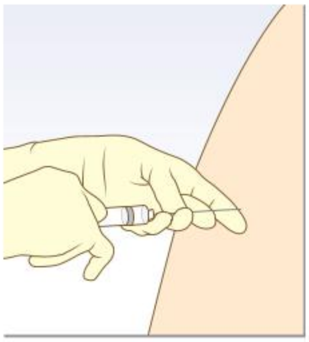
Increase physical activity



Consider yoga, pilates or tai chi



Consider TENS and acupuncture



Consider nerve block or ablation

(TENS = transcutaneous electrical nerve stimulation)

Definition of pain

Pain is an unpleasant sensory and emotional experience associated with, or resembling that associated with, actual or potential tissue damage (World Health Organization). The evolutionary purpose of pain is based on protection and healing, but the pain experience is one of the most common sources of distress in medicine. Pain was originally considered a purely physical experience ('specificity theory of pain'), whereby tissue damage triggered pain receptors to send one-way signals to the brain, where they were realised (Fig. 9.1). It is now understood that higher brain activity is involved in the modification of incoming pain signals, shaping the individual pain experience (the 'biopsychosocial model'). Factors that influence that pain experience include the individual's biology, physiology, life experiences and sociocultural landscape (Fig. 9.2).

Pain classification

There are several ways to classify pain, but two broad themes are duration (acute or chronic) and underlying mechanism (neuropathic or nociceptive).

Acute versus chronic pain

Pain can be broadly classified as acute or chronic. However, there are many subtypes of pain that fall under these headings (Fig. 9.3). Although the classification of pain is helpful to guide management, in practice patients often present with varying combinations of acute and chronic pain.

Acute pain occurs as a result of impending or actual tissue damage to skin, bone, muscle and visceral structures secondary to trauma, surgery, burns, infection or physiological states, such as labour pains. It protects against sustaining further damage at the time of injury and during healing. Pain improves as tissue damage recovers, and the expected outcome is that pain resolves within 3 months.

Chronic pain does not appear to serve any evolutionary purpose and persists beyond three months despite tissue healing. Chronic pain is broadly classified as primary or secondary, although patients often present with a combination of both in practice.

Primary chronic pain occurs in one or more anatomical regions associated with significant levels of emotional distress and produces varying

levels of functional disability. The pain cannot be better explained by another chronic condition, e.g. fibromyalgia.

Secondary chronic pain results from an injury or underlying disease process and is diagnosed when the pain lasts beyond three months and becomes a problem requiring management in its own right. Pain may be related to progressive tissue damage or may continue to evolve after the initial damage has resolved.

Neuropathic versus nociceptive pain

Neuropathic pain is caused by a lesion or disease of the somatosensory nervous system. Pain arises from damage to the peripheral nerves (see Box 27.96) or central nervous system (CNS), when it is termed central pain. Neuropathic pain may be acute, such as in sciatica, but is most debilitating when it becomes chronic, impacting on quality of life and function. The clinical features of neuropathic pain are detailed in Box 9.1.

Nociceptive pain is caused by noxious stimuli to body tissues, such as extreme temperatures, chemicals and mechanical force, causing activation of several receptors called nociceptors. This can be further classified as somatic (arising from the skin, bone etc.) or visceral (from organs, peritoneum etc.).

Functional anatomy and physiology

The functional anatomy of the somatosensory system is shown in Figures 27.3 and 27.11.

Nociceptors utilise specific ion channel transducers which trigger pain signal action potentials once stimuli exceed a given threshold (Fig. 9.4). The signals generated by nociceptors are relayed to the dorsal column of the spinal cord via sensory afferent neurons. Anatomical features of the afferent pain pathway are illustrated in Figure 9.5. Nociceptive signals from cutaneous and musculoskeletal tissues travel in myelinated $A\delta$ fibres (fast), producing somatic pain (sharp in nature and easily localised), while signals from internal organs and body structures travel in C fibres (slow) alongside autonomic nerves, producing visceral pain (diffuse and poorly localised).

Spinal cord

Sensory neurons terminate in the dorsal horn of the spinal cord, where they synapse with secondary order ascending neurons. Considerable modulation of pain messages occurs at this level by other incoming sensory fibres and descending neural pathways from the brain, as depicted in Figures 9.5 and 27.11. Several excitatory and inhibitory neurotransmitters are involved in pain processing at this level. Pharmacological modulation of these neurotransmitters and their target receptors underlie the mode of action of many analgesic medications.

i 9.1 Clinical features of neuropathic pain

Characteristic	Symptom or clinical feature*	Descriptive term
Spontaneous pain	No stimulus required to evoke pain	
Positive sensory disturbance	Light touch causes pain Pressure causes pain Cool and warm temperatures cause pain Increased pain on pin-prick Pain increases with subsequent pin-pricks	Dynamic allodynia Punctate allodynia Thermal allodynia Hyperalgesia Pain wind-up
Negative sensory disturbance	Numbness Tingling, 'pins and needles' Reduction of temperature/touch sensitivity	Loss of sensation Paraesthesia Hypoaesthesia
Other features	Feeling of insects crawling over skin Affected area feels abnormal Sweating/vasomotor skin changes Upper or lower motor neuron signs	Formication Dysaesthesia Autonomic dysfunction

*Symptoms may cluster, with a predominance of either positive or negative symptoms, or a mixture of both, reflecting differences in underlying mechanisms.

Referred pain may occur when incoming visceral pain fibres associate closely with somatic pain fibres in the same segment of the spinal cord.

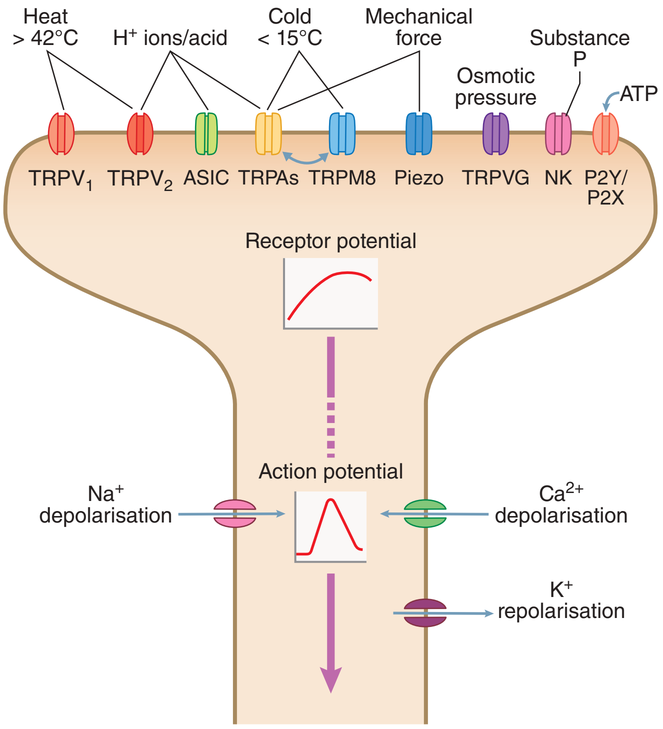

Fig. 9.4 **Nociceptor ion channel transducers**. Once a noxious stimulus reaches a certain threshold, the nociceptor ion channel opens, generating a receptor potential. Opening of sodium (Na$_v$) and calcium channels (Ca^{2+}) in response to this receptor potential leads to propagation of action potentials along the afferent nerve fibre. Potassium channel opening leads to repolarisation and cessation of action potentials under normal conditions. (ASIC = acid-sensing ion channel; NK = neurokinin; P2Y/P2X = purinergic receptors; TRP = transient receptor potential)

Pain is interpreted as arising from the superficial dermatome served by the somatic fibres rather than the original visceral source (Fig. 9.6; see Fig. 27.10).

Central processing of pain

Pain signals from the spinal cord travel to the sensory cortex via the thalamus. Individual experience of pain is then influenced by complex multidirectional interactions between a range of structures in the CNS, called the pain neuromatrix (see Fig. 9.5). It is here that sensory, cognitive, memory and emotional aspects of pain are integrated. Descending pain inhibition from the brainstem reduces input from peripheral stimuli via serotonergic and noradrenergic pathways.

Chronic and neuropathic pain mechanisms

The peripheral and central nervous systems adapt to the presence of pain, especially in response to sustained tissue damage, a process called neuronal plasticity. In chronic pain this produces prolonged changes in the pathways involved in detecting and processing nociceptive stimuli. Peripheral sensitisation occurs secondary to inflammation with the release of cytokines and mediators, including bradykinin, substance P and prostaglandins, which activate nociceptor to ion channel transducers (see Fig. 9.4). If these pain-provoking mediators persist, ion channel transducers are upregulated and their threshold for activation falls. In neuropathic pain this results in pain signalling in response to innocuous stimuli (allodynia) or spontaneous pain signalling.

Central sensitisation occurs at the level of the spinal cord. Activation of microglial cells in the region of nociceptive synapses triggers release of pro-inflammatory mediators and decreases re-uptake of excitatory neurotransmitters such as glutamate. Prolonged glutamate release causes prolonged activation of the *N*-methyl-D-aspartate (NMDA) receptor, causing over-amplification of afferent pain signals (hyperalgesia) and increasing amplitude of pain signals with repeated stimuli (pain wind-up) and continued neuronal firing after noxious stimuli have stopped.

Assessment of pain

Taking a pain history

Pain can be difficult for patients to describe. Acute pain can cause complete cognitive distraction, while chronic pain carries biopsychosocial elements that are hard to verbalise. Common medical descriptors (e.g. sharp, dull) or short phrases (e.g. radiating to the back) can oversimplify the person's pain experience. It is important to allow adequate time for patients to tell their pain story. Establishing a general rapport with the patient and taking a more general medical history before focusing on their pain can give valuable insight into the patient's understanding of their pain and treatments.

In general, the site, severity, nature, exacerbating/relieving factors and associated features should be documented for each individual pain the patient describes. These focused prompts are particularly useful for patients with acute pain, but they do not cover the emotional, psychological and functional impacts of pain. Aim to determine the extent to which pain is interfering with normal daily activities, such as work, leisure pursuits and sleep. Disruption of activities that give a person enjoyment and purpose in life can exacerbate an individual's perception of pain. All current and previously tried medications should be covered, whether these have been effective and any associated side-effects. Ask about over-the-counter medicines (including cannabinoid products), alternative medicines and previous or current substance misuse, all of which must be considered for safe and effective prescribing. Explore the patient's beliefs around what is causing their pain, as well as their expectations of treatment; unless these are addressed, management may be less effective. Social circumstances, support network and cultural background should be discussed, including employment status and their support network. If evidence of low mood is detected, a suicide risk assessment should be considered (see Fig. 29.1).

Pain scoring systems

A wide range of tools have been developed to assess pain (Box 9.2).

Unidimensional tools are used to grade the severity of pain and can be carried out verbally using the Numerical Rating Scale, which grades pain from 0 to 10, or by asking a patient to indicate their score on a Visual Analogue Scale from 0 to 10.

Multidimensional tools include the severity, distribution, character and psychological/functional impacts of pain. Verbal self-reporting of pain is seen as the gold standard, but not all patients will manage this. Assessing pain in some people with cognitive impairment or learning difficulties relies on using observational skills and working closely with their family or carers. Observational pain tools such as Doloplus-2 or the Abbey Pain Scale are used to assess pain in those with difficulties in communication. Documenting changes in pain scores over time helps assess treatment benefits, reducing the time taken to achieve acceptable level pain control.

Clinical examination

Patients experiencing pain may appear pale and develop sweating due to autonomic activity. This can also be reflected by tachycardia, tachypnoea and changes in blood pressure. Severe acute pain can produce vasovagal events and vomiting. Facial expressions such as grimacing, tightly closed eyes and lacrimation are common, as are vocalisations such as groaning. The patient's position and actions can give an indication of the severity, location and cause of pain. Patients may massage, hold or guard the painful area or indicate pain by rocking/inability to stay still. Shallow breathing or trying to remain still may indicate peritoneal or pleural pain. Fig. 9.5 **Ascending and descending pain pathways**. Ascending pathways are shown in blue and descending in red. Pain signals generated in the periphery are transmitted via the spinal cord to the thalamus before reaching the cerebral cortex. The intensity of pain signals is subject to extensive modulation at several levels within the central nervous system, which is collectively known as the neuromatrix. Cognitive influences derived from the frontal lobe, coupled with sensory influences from cortex and emotional influences from the amygdala, affect pain perception in the mid-brain around the periaqueductal grey matter (PAG) and the rostroventrolateral medulla (RVM). These structures form part of the descending modulatory systems, which, under normal circumstances, inhibit pain perception. In some chronic pain states, however, dysfunction of the descending pathways can occur, increasing pain.

9.2 Tools used in the assessment of pain and its impact

Instrument	Comments
Unidimensional tools – assess severity or location	
Visual Analogue Scale (VAS)	Patient marks pain intensity on a horizontal line that ranges from 'no pain' to 'worst possible pain' or 0–10
Verbal Pain Intensity Scale	Patient grades pain using descriptors: no pain, mild, moderate and severe
Numerical Rating Scale (NRS)	Patient allocates a score between 0 (no pain) up to 10 (worst possible pain)
Multidimensional tools – assess severity, pain type and impact on patient	
Brief Pain Inventory	Based on 0–10 ratings of pain intensity and impact on a range of domains, including sleep, work and enjoyment of life
McGill Pain Questionnaire	Assessment of sensory, affective and cognitive qualities of pain. Uses a body map and 78 pain descriptors
Edinburgh Pain Assessment and management Tool (EPAT)	Bedside tool developed for assessment of cancer pain linked to evidence-based algorithms for management
LANSS, DN-4	Screening questionnaires used to aid diagnosis of neuropathic pain
Observational tools	
Abbey Pain Scale **Doloplus-2, PACSLAC Scale**	Used to assess pain in people who have difficulty with communication

(DN-4 = Douleur Neuropathique questionnaire; LANSS = Leeds Assessment of Neuropathic Signs and Symptoms; PACSLAC = Pain Assessment Checklist for Seniors with Limited Ability to Communicate)

precipitate delirium or present as behavioural change in those with cognitive impairment, when it may present as emotional distress or aggression due to fear of pain during movement by carers or family.

Palpation may reveal superficial or deep tenderness. Deep inspiration or joint movement may elicit pain. A focused neurological examination using a simple set of tools helps identify neuropathic elements of pain. Lightly touching the skin with cotton-wool tests for reduced fine touch and allodynia. Response to pin-prick can identify mechanical hyperalgesia and central wind-up. Touching the patient's skin with warm and cool thermal rollers (or cool swab) tests for abnormalities of thermal sensation. An unaffected area of skin should be tested first, to establish normal sensation, before testing the affected area.

Investigations

Blood tests

Blood tests may help identify the underlying cause, e.g. in patients with peripheral neuropathy (see Box 27.98). Biochemical evidence of liver and/or renal failure can help guide prescribing of opioids and other analgesics.

Imaging

Plain X-ray or CT scanning can identify pathological fractures and bone metastases (Fig. 9.7). Magnetic resonance imaging (MRI) is used to assess patients with suspected malignant spinal cord compression, disc prolapses, or pain that follows a nerve root distribution.

Nerve conduction studies

Nerve conduction studies can be helpful in demonstrating and quantifying a definitive nerve lesion. They can be used to help differentiate between central and peripheral neuropathic pain, but do not effectively examine small nerve fibre function.

Diagnostic nerve blocks

Performing a nerve block with infiltration of a local anaesthetic, such as 1% lidocaine, can be useful in assessing whether pain is due to involvement of a specific nerve or nerve root. Nerve blockade can also be used to assess whether more definitive therapies, such as nerve ablation, might be helpful in controlling pain.

Acute pain management

The management of acute pain is broadly similar regardless of the underlying pathology and focuses on identifying and treating the primary cause, providing adequate analgesia to allow rehabilitation and gradual reduction in analgesia as pain resolves. Undertreatment of acute pain can lead to prolonged hospital admission, musculoskeletal deconditioning and is a risk factor for developing chronic pain.

Non-pharmacological management

The underlying condition causing the pain should be treated whenever possible. Pain relief can be provided through immobilisation of the painful area using slings, braces and splints or by positioning the patient appropriately. Painful wounds can be dressed and the application of heat or cold can provide relief. Early physiotherapy input can help maintain function and promote functional recovery.

Pharmacological management

The choice of initial medication is based on clinical assessment and the severity of the pain. A simple numerical rating scale can be used to assess severity, dividing pain into mild (score 1–3), moderate (score 4–6) and severe (score 7–10). Mild pain can usually be managed using non-opioids, while moderate and severe pain may require the short-term use of opioid medications. A multimodal approach is recommended for acute pain; combining paracetamol with a non-steroidal anti-inflammatory drug (NSAID) or opioid can produce increased benefit while reducing individual drug dosage requirement. Regular re-assessment of response to drug treatment is vital.

Simple analgesics

Paracetamol is recommended for the treatment of mild to moderate pain. Its mechanism of action is incompletely understood, but it is believed to inhibit cyclooxygenase enzyme activity, enhance the endocannabinoid system and promote spinal serotonergic inhibition of pain. It is generally well-tolerated with few side-effects, but the dose must be reduced in people with low body weight (< 50 kg). Acute liver failure is a well-recognised complication of paracetamol overdose.

Non-steroidal anti-inflammatory drugs (NSAIDs)

NSAIDs are widely used in the treatment of inflammatory pain, but can be used as a general analgesic for mild to moderate pain. These drugs can be given systemically or locally and are discussed in more detail in Chapter 25. They are also useful in the management of pain in cancer patients, as discussed later in this chapter.

Opioid analgesics

The term 'opioids' covers a group of drugs that act on opioid receptors to produce pain relief. Morphine was originally obtained from the resin of the opium poppy *(Papaver somniferum)* and remains the most commonly prescribed opioid. A number of semi-synthetic opioids derived from morphine and fully synthetic opioids are available. The characteristics of commonly prescribed opioids are shown in Box 9.3. Opioids are traditionally divided into subclasses of weak

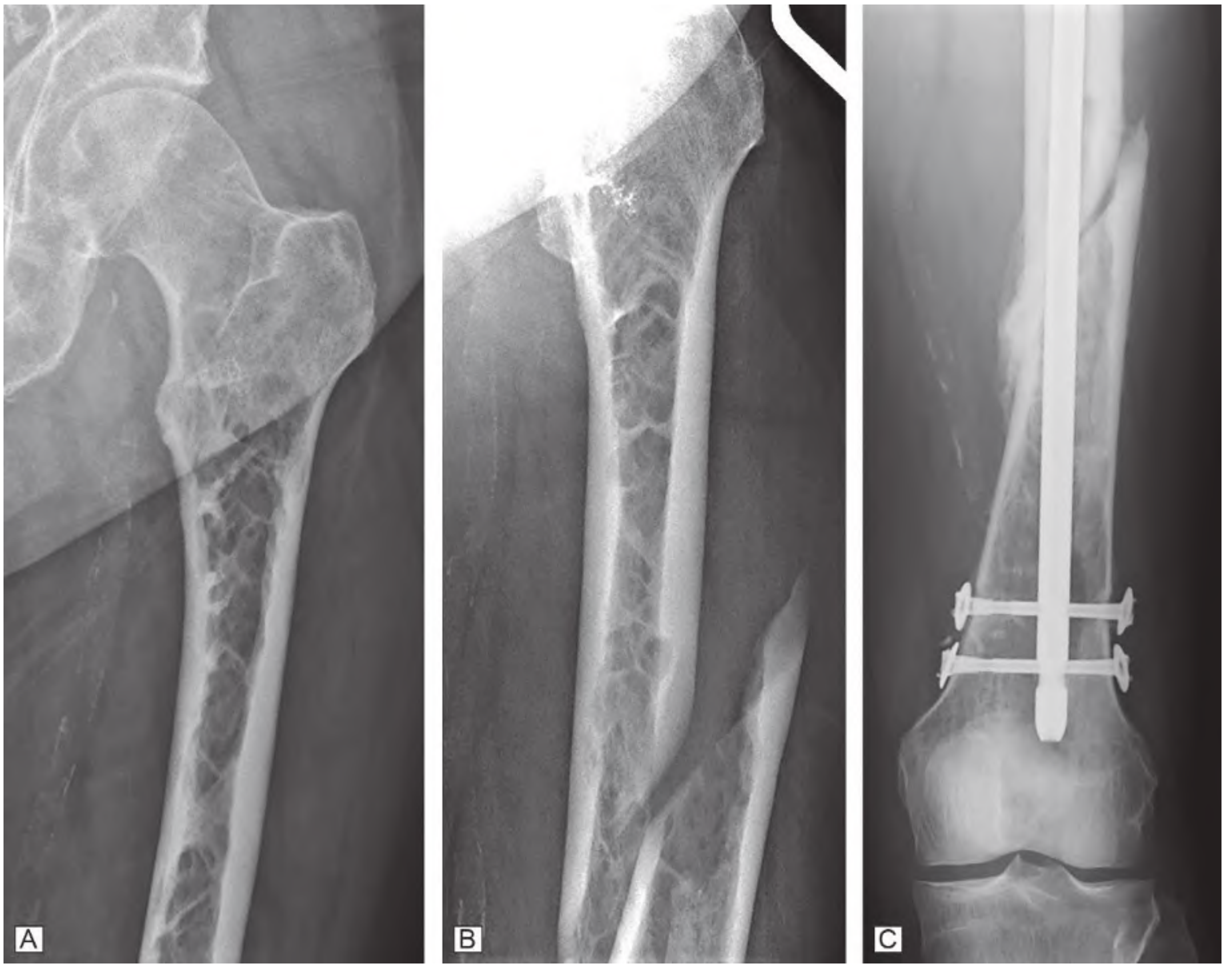

Fig. 9.7 A X-ray demonstrating multiple lytic metastases in the shaft of the femur. Later X-rays from same individual show B a pathological fracture through the bone metastases and C surgical pinning of the fracture.

opioids (e.g. codeine, dihydrocodeine and tramadol) and strong opioids (e.g. morphine). Weak opioids have a lower affinity for opioid receptors and have a 'ceiling dose' above which side-effects predominate over pain relief. Strong opioids bind more effectively to opioid receptors and are less limited by this ceiling of analgesia effect so they produce much more potent pain relief. All opioids carry the same inherent risks and side-effects.

Opioid effects are mediated through activation of a number of G-protein-coupled receptors. The most prevalent are μ, κ and δ receptors, with the μ receptor being the primary mediator of opioid-related analgesia. There is considerable inter-individual variability in response to opioids. There are many reasons for this, including genetic variations in the enzymes that metabolise drugs. For example, codeine is metabolised to morphine via the liver cytochrome P450 enzyme CYP2D6. Inherited differences in CYP2D6 expression results in varying morphine production when different individuals are given identical doses of codeine. While most people metabolise around 10% of a codeine dose to morphine, those who are rapid metabolisers (high CYP2D6 activity) produce more morphine and gain better pain relief, while poor metabolisers (low CYP2D6 activity) will experience minimal analgesia.

Opioid analgesic use for acute pain

Opioids are used to manage moderate to severe acute pain in combination with non-opioids. Weak opioids are used for moderate pain, with oral preparations combining paracetamol or an NSAID (with codeine commonly used). Strong opioids are reserved for severe pain or moderate pain that is refractory to a combination of weak opioid and non-opioid therapy. Opioids used for severe pain can be administered orally or via bolus injection using an intravenous, intramuscular or subcutaneous route. The onset of pain relief is faster when opioids are given via injection. Typical opioid doses used in acute pain are presented in Box 9.4. The lowest effective dose should be used for as short a time as possible. If opioid doses are not reduced in parallel with reducing pain severity, then patients can develop opioid toxicity or respiratory depression as their sympathetic arousal produced in response to pain reduces. A clear plan for discontinuing opioids should form part of the management plan for all patients with acute pain.

Patient-controlled analgesia (PCA)

Opioids such as morphine and oxycodone can be delivered intravenously using a computerised pump that is set up to deliver a bolus dose of the drug in response to the patient pressing a handheld button. When the patient develops worsening pain, they press the button. The bolus dose of drug, minimum interval between doses (lock out) and maximum number of doses in a fixed period, are all pre-set by a pain specialist. PCA is often used post-operatively and is usually delivered in a hospital setting to allow close monitoring and ongoing changes to the pump regimen.

Inhaled therapies

Entonox is a gaseous mixture of 50% oxygen and 50% nitrous oxide, which is used for the short-term relief of moderate to severe acute pain.

9.3 Commonly used opioids

Opioid	Routes of administration	Comments
Weak opioids (WHO step 2)		
Codeine	Oral IR	Metabolised to morphine by CYP2D6 enzyme Commonly prescribed in combined preparation with paracetamol or ibuprofen
Tramadol	Oral IR, oral MR, subcutaneous, intramuscular, intravenous	Metabolised to o-desmethyltramadol by CYP2D6 enzyme Serotonin–noradrenaline reuptake inhibitor Lower seizure threshold
Strong opioids (WHO step 3)		
Morphine	Oral IR, oral MR, subcutaneous, intramuscular, intravenous	Metabolised through glucuronidation to morphine-3-glucuronide and morphine-6-glucuronide Metabolites accumulate in renal failure Used in hepatic failure at low doses
Oxycodone	Oral IR, oral MR, subcutaneous, intramuscular, intravenous	More predictable bioavailability than morphine Metabolised to noroxycodone by CYP3A4 and oxymorphone by CYP2D6 Caution in hepatic failure and renal failure
Diamorphine	Subcutaneous, intravenous	Highly soluble, allowing larger doses to be administered via subcutaneous injection and infusion
Alfentanil	Sublingual, subcutaneous, intravenous	Selective μ-opioid receptor agonist Rapidly acting with short duration of action Mostly used as a continuous infusion Considered safer in renal failure
Hydromorphone	Oral IR, oral MR, subcutaneous, intramuscular, intravenous	Metabolised by glucuronidation to hydromorphone-3-glucuronide Caution in hepatic failure and renal failure
Buprenorphine	Transdermal patch, sublingual, intramuscular, intravenous	Partial opioid agonist Lower incidence of constipation and respiratory depression Considered safer in renal failure
Fentanyl	Transdermal patch, transmucosal (buccal, sublingual, transnasal), subcutaneous, intravenous	Acts mainly on μ-opioid receptor Transdermal patch only suitable if pain is stable Rapid onset analgesia when given transmucosally or as injection Opioid of choice in hepatic failure Considered safer in renal failure
Methadone	Oral, subcutaneous, intravenous	Opioid agonist, NMDA antagonist and serotonin–noradrenaline reuptake inhibitor Long duration of action and variable half-life Metabolites are inactive – safe in renal failure

(IR = immediate release; MR = modified release; NMDA = *N*-methyl-D-aspartate; WHO = World Health Organization)

9.4 Example analgesic starting doses in acute pain management (adults)

Medication	Typical starting dose and daily maximum dose	Route	Comments
Paracetamol	1000 mg up to 4 hourly; max 4000 mg in 24 hrs	Oral or intravenous	Reduce dose to 500 mg (max 2 g in 24 hrs) in those with body weight < 50 kg, renal failure, cachexia, malnutrition and decompensated liver disease
Ibuprofen	400–600 mg up to 3 times/day	Oral	Caution in the elderly and those with renal impairment
Codeine	30–60 mg; max 240 mg/24 hrs	Oral	Additional analgesic benefit at doses > 240 mg/24 hrs is minimal Caution with paracetamol doses in combined preparations
Tramadol	50–100 mg; max 400 mg/24 hrs	Oral	Avoid if history of seizures Risk of serotonin syndrome when used with drugs that enhance serotonin, e.g. SSRIs, TCAs
Morphine	5–10 mg	Oral	Use lower dose range in elderly Doses can be repeated up to 1 hourly with ongoing observation for response and adverse effects
	2.5–5 mg	Intravenous, intramuscular, or subcutaneous injection	

(SSRI = selective serotonin reuptake inhibitor; TCA = tricyclic antidepressant)

The patient activates the flow of the gas by inhaling through a mouthpiece; pain relief both occurs and wears off within minutes. Inhalation of methoxyflurane (Penthrox) via a handheld device is used for short-term relief of moderate to severe pain associated with traumatic injury. Inhaled therapies are used as bridging measures until more definitive management can be undertaken.

Peripheral nerve blocks

The targeted injection of local anaesthetic around a nerve sheath can produce temporary relief of pain while awaiting more definitive intervention, e.g. femoral nerve block in a patient awaiting surgery for a fractured neck of femur. Use of a peripheral nerve stimulator or ultrasound can help identify the target nerve. The duration of pain relief varies but can last up to 36 hours. The use of a peripheral nerve catheter attached to a pump, which infuses local anaesthetic into the tissues around a target nerve, can provide pain relief for up to 4 days.

Neuraxial blocks

Injection of a small volume of local anaesthetic +/– opioid into the subarachnoid space is known as spinal anaesthesia. This technique produces several hours of pain relief, absent sensation and loss of motor function. Spinal anaesthesia is used to manage pain associated with lower abdominal, pelvic and lower limb surgery (caesarean section, hip replacement). Spinal infusions called intrathecal infusions are used to manage chronic intractable cancer pain. The continuous infusion of local anaesthetic and/or opioids via a catheter into the epidural space is known as epidural anaesthesia, which can be used to manage pain associated with surgery, trauma, labour and some chronic conditions such as cancer. Epidurals can be used for pain in the thorax, and infusions can be adjusted allowing some sparing of motor function. Both techniques involve selecting a level of the spinal cord above that which innervates the painful area. Bladder function can be affected by both techniques, requiring urethral catheterisation, and close monitoring of the highest anatomical level of anaesthetic block is vital as extension into cervical spinal segments can lead to respiratory failure, hypotension and bradycardia.

Acute pain in specific conditions

It is important to recognise that the approaches above cover the general management of acute pain. Treating the underlying cause is important, and there are many conditions where pain can be relieved using specific approaches such as glyceryl trinitrate (GTN) spray to relieve angina or triptans to treat migraine.

Pain management – non-cancer-related chronic pain

Management of primary chronic pain

When a definitive underlying disease has not been identified, the management of chronic pain focuses on supporting the patient with the psychological, emotional and functional impacts to improve quality of life. In 2021 the UK National Institute for Health and Care Excellence (NICE) published guidance on managing primary chronic pain, which recommends multidisciplinary non-pharmacological interventions as the mainstay of treatment. The only pharmacological agents recommended are antidepressants (amitriptyline, duloxetine, citalopram, sertraline or paroxetine), which may improve pain and sleep. The guidelines advise against initiating any other drug therapy, including paracetamol, NSAIDs, opioids, gabapentin and pregabalin. For those already taking these medications, it is recommended that a review of benefit versus harms is carried out. For patients obtaining benefit from any of these medications and not experiencing harmful effects, a shared care plan for ongoing use and review should be agreed upon with the patient.

Management of secondary chronic pain

The principles of managing chronic primary pain largely apply to secondary chronic pain. Treatment of the underlying disease or injury, when possible, is recommended, and non-pharmacological approaches remain the foundations of management. NICE has also produced guidance specific to several chronic painful diseases, including rheumatoid arthritis, endometriosis and osteoarthritis.

Chronic neuropathic pain

NICE guidelines recommend that a trial of amitriptyline, duloxetine, pregabalin or gabapentin can be considered for the patient with neuropathic pain.

9.5 Pharmacological management of chronic neuropathic pain

Drug	Mode of action	Clinical use	Side-effects
Anti-convulsants[1]			
Gabapentin	Binds to $\alpha_2\delta$ subunit of calcium channels in spinal cord and brainstem	First-line option for neuropathic pain (NICE) Dose reduction needed in renal failure	Sedation, tremor, ataxia, delirium, peripheral oedema Exacerbation of opioid-related side-effects Dose reduction needed in renal failure
Pregabalin	See gabapentin, above	First-line option for neuropathic pain (NICE)	See gabapentin
Antidepressants[2]			
Amitriptyline	Tricyclic antidepressant Inhibits reuptake of serotonin and noradrenaline enhancing descending pain inhibition	First-line choice for neuropathic pain (NICE)	Sedation, postural hypotension, delirium, dry mouth, constipation, urinary retention
Duloxetine	Selective serotonin–noradrenaline reuptake inhibitor that enhances descending pain inhibition	First-line choice for neuropathic pain (NICE) First choice for diabetic peripheral neuropathy and chemotherapy-induced peripheral neuropathy	Sedation, nausea, dry mouth, headache, dizziness, agitation
Topical lidocaine 5% plasters	Local blockade of sodium channels in afferent sensory nerves	Post-herpetic neuralgia	Local skin irritation

[1] Caution is required in those who are elderly due to the risk of delirium and falls.
[2] Risk of serotonin syndrome when taken with other drugs that increase CNS serotonin levels.

Further information on these drugs is presented in Box 9.5. Combinations of these drugs may be required in some patients. Prescribing of opioids is not recommended for neuropathic pain. Duloxetine is licensed for the management of diabetic peripheral neuropathy, while the pain of trigeminal neuralgia may respond to the anti-convulsant carbamazepine. Outcomes are often disappointing for patients, so it is vital when trialling medications to set realistic expectations of reducing pain rather than eradicating pain completely. Nerve blocks and neuraxial techniques (see above) may be required in carefully selected patients.

Non-pharmacological management of chronic pain (all causes)

Physiotherapy

Physiotherapy has a key role in the multidisciplinary approach to chronic pain, especially in the prevention of muscle spasm, contractures, reduced mobility and lymphoedema. Rehabilitation based on patient-led goal setting and the use of focused exercise has been shown to improve outcomes and reduce medication use.

Psychological techniques

Individual and group-based approaches aim to train patients to use coping strategies and behavioural techniques to manage pain and its impacts. Cognitive behavioural therapy can help change behavioural responses that may be exacerbating the patient's pain experience. Support can also be provided to manage anxiety and depression as well as the impacts of underlying chronic diseases.

Stimulation therapies

Acupuncture and transcutaneous electrical nerve stimulation (TENS) are low-risk therapies that may be useful in some patients. Acupuncture has been used successfully in Eastern medicine for centuries. The mechanisms are incompletely understood, although endorphin release may play a role. Acupuncture is particularly effective in pain related to muscle spasm, with some evidence of short-term benefit for patients with low back pain. Similar mechanisms probably apply to TENS, which is worth considering in many types of chronic pain.

Complementary and alternative therapies

Complementary techniques, such as herbal medicines, vitamins, homeopathy and reflexology, have been used for the treatment of chronic pain but lack robust evidence of efficacy. It is important that patients are encouraged to discuss any alternative medicines they are considering, given the potential interactions with prescribed therapies.

Pain management – cancer-related pain

Pain can be the initial presenting symptom or can occur at any time throughout a wide spectrum of cancer disease (Box 9.6). Cancer is universally feared by patients and the term cancer is commonly associated with pain, suffering and shortening of life expectancy, which can add an additional existential component to pain. Worsening pain is often interpreted by patients as the cancer returning or progressing, while dying in pain is the most common fear of people with advanced cancer.

Acute pain in cancer

Acute cancer pain is generally somatic or visceral nociceptive pain and occurs in the context of investigations or surgical intervention. The assessment and management is broadly similar to acute pain arising from other causes. Concern over impending diagnostic biopsy and scan results can increase the distress related to acute pain.

Cancer-related chronic pain

It is estimated that about two-thirds of patients with cancer experience moderate or severe chronic pain, and a quarter have three or more different sites of pain. Chronic cancer pain is most commonly of mixed aetiology with a combination of nociceptive and neuropathic elements. Pain may be persistent and unremitting as the result of advancing malignant tissue destruction; minimal healing occurs, and the patient usually has a short prognosis. Alternatively, pain may evolve as a separate problem when malignant processes are controlled or cured by systemic anti-cancer treatments. Patients commonly experience both courses of chronic cancer pain throughout the course of their cancer.

Assessment of chronic cancer pain

The assessment of cancer pain should follow the general principles described earlier in this chapter. Improved control of cancer-associated pain has been demonstrated with use of the Edinburgh Pain Assessment and management Tool (EPAT), which uses a simple screening question about worst pain on a scale of 0–10 in the last 24 hours, followed by questions to identify specific pain(s) in addition to exploring distress. The identified pains are linked to management algorithms. Continuing review of pain and any opioid side-effects is key (see 'Further information').

9.6 Examples of cancer-related pain – diagnosis to end of life

Source of pain	Acute pain*	Chronic pain*
Diagnostic procedures	Lymph node, skin or organ biopsy Pleurocentesis	Uncommon
Surgical treatment	Surgical wound pain Drain insertion Dressing changes	Post-surgical scar pain Post-mastectomy pain Phantom limb pain post amputation, e.g. for sarcoma in lower limb
Chemotherapy	Mucositis or ulceration of the gastrointestinal tract Skin reactions Arthralgia	Chemotherapy-induced peripheral neuropathy (CIPN)
Immunotherapy or targeted therapies	Skin reactions – localised or generalised Myositis or arthralgia	Peripheral neuropathy, e.g. bortezomib – multiple myeloma Arthritis
Hormonal therapy	N/A	Arthralgia related to tamoxifen or aromatase inhibitors
Radiotherapy	Mucositis, cystitis and enteritis Skin reaction in area treated	Post-radiotherapy plexopathy, e.g. brachial plexus pain Late skin reactions
Primary cancer and metastatic disease	Pathological bone fracture Malignant spinal cord compression	Paraneoplastic peripheral neuropathy Cancer-induced bone pain Raised intracranial pressure Visceral, peritoneal or pleural invasion Fungating skin tumours
Complications of cancer	Pulmonary embolus	Deep vein thrombosis Cancer cachexia – immobility, falls, joint laxity
Underlying comorbidities	Angina, gout, migraine etc.	Primary chronic pain, e.g. fibromyalgia Diabetic peripheral neuropathy

*Many acute cancer pains evolve into chronic pain experiences.

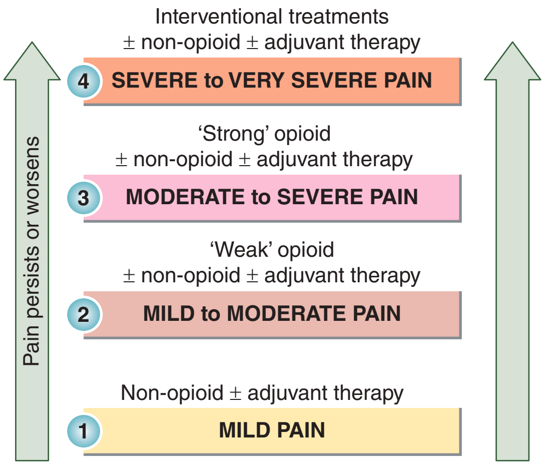
Management of chronic cancer pain

Pharmacological treatments are the mainstay of management; however, they must be underpinned by regular holistic assessment of pain and associated symptoms. Non-pharmacological and oncological treatments should run in parallel with each stage of prescribing for pain control. The non-pharmacological approaches described earlier in this chapter (p. 197) should be explored for all patients with chronic cancer pain.

The WHO analgesic ladder approach

The World Health Organization (WHO) analgesic three-step ladder formed the basis of managing cancer pain after its introduction in 1986. This remains a useful educational tool, but is not a strict protocol for management of cancer pain. The subsequent addition of a fourth step is now incorporated, which recognises the important role of interventional cancer pain management in patients who have ongoing pain despite pharmacological intervention, as shown in Figure 9.8.

Using the WHO ladder approach, the initial analgesic regimen prescribed is determined by the severity of pain reported. Those with mild pain are started on a non-opioid analgesic drug (step 1). If the patient fails to respond adequately or develops moderate pain, a weak opioid, such as codeine or tramadol, is added (step 2). If pain relief is still not achieved or the patient develops severe pain, a strong opioid is substituted for the weak opioid (step 3). If cancer pain is severe at the outset, a jump straight to prescribing step 3 strong opioids can be undertaken and titrated according to the patient's response. There is increasing evidence



Interventional treatments
± non-opioid ± adjuvant therapy
4 SEVERE to VERY SEVERE PAIN
'Strong' opioid
± non-opioid ± adjuvant therapy
3 MODERATE to SEVERE PAIN
'Weak' opioid
± non-opioid ± adjuvant therapy
2 MILD to MODERATE PAIN
Non-opioid ± adjuvant therapy
1 MILD PAIN
Pain persists or worsens

Fig. 9.8 Updated four-step version of the original WHO analgesic ladder.

that the use of a low dose of a step 3 opioid like morphine rather than a traditional step 2 opioid such as codeine is safe and effective. This approach is also cheaper, which is of great importance in low- and middle-income countries (LMICs), where step 2 drugs are usually much more expensive than morphine.

The ladder should be viewed as bidirectional, and regular review of pain can identify patients who can attempt a step-down if their pain has improved.

Adjuvant analgesics

A number of other medications, termed adjuvants, can be introduced alongside the primary medication of each analgesic ladder step. An adjuvant analgesic is a drug that has a primary indication other than pain, but which provides benefit in some painful conditions and may enhance the effect of other analgesics. Adjuvant analgesics used in the management of chronic cancer pain are summarised in Box 9.7. It is important to monitor for the specific side-effects of adjuvant drugs. The use of adjuvant analgesic can enhance the sedative effects of opioids as pain arousal falls, meaning opioid dose reductions may be required soon after commencing adjuvants.

Opioids in chronic cancer pain

Cancer pain responds more effectively to opioids than chronic pain secondary to non-cancer causes. Oral administration is effective, and morphine should be first choice whenever possible, although there is no good evidence that one opioid is superior to others for managing cancer pain.

Oral morphine comes in immediate-release and modified-release preparations. Immediate-release morphine takes around 30–45 minutes to produce pain relief, which peaks around 1 hour and lasts for up to 4 hours. Modified-release preparations have a slower onset of 1–2 hours for pain relief for up to 8–12 hours. Patients with chronic cancer pain can be initiated on regular morphine using either type of preparation, depending on the pattern of pain and patient preferences. Typical initial morphine dosing regimens are shown in Box 9.8. This regular use of morphine provides relief from background pain over each 24-hour period. Additional doses of immediate-release morphine should be prescribed as required for the treatment of pain that is not controlled by the regular background administration. Such transient severe increases in pain are called breakthrough pain. As a general rule, opioid breakthrough doses are one-sixth of the total 24-hour background dose of opioid, although this is sometimes adjusted on an individual basis. The time interval between doses and maximum number of daily breakthrough doses should be clearly prescribed. The patient or carer should note the timing of any breakthrough doses and the reason for them. This should be reviewed daily when first initiating morphine. It is normal for patients to still require 1–2 breakthrough doses on average each day, even when pain is well managed. When pain remains problematic, and morphine is well tolerated, the total of the breakthrough doses required over the previous 24 hours is calculated and regular background dose increased accordingly. Patients initially commenced on immediate-release morphine for background pain will usually have this converted to 12-hourly modified-release morphine once pain is well controlled. This approach of adjusting opioids based on requirement is known as opioid titration. Short-acting opioid analgesia used to treat movement-related pain, known as incident pain, is generally not included in background opioid dose titration, as this can lead to overdosing and opioid-related side-effects.

i 9.7 Adjuvant analgesics used in the management of chronic cancer pain

Adjuvant drug	Indications	Mode of action
Glucocorticoids	Raised intracranial pressure Malignant spinal cord compression Cancer-induced bone pain	Reduce prostaglandins production, oedema and inflammation
Hyoscine butylbromide	Intestinal colic Bladder spasms	Smooth muscle relaxation Inhibition of acetylcholine binding to muscarinic M_3 receptors
NSAIDs	Cancer-induced bone pain Inflammatory pain	Reduce prostaglandin synthesis via inhibition of COX enzymes
Methadone	Severe cancer pain not responding to opioid + adjuvants	NMDA receptor antagonist NA and 5-HT reuptake inhibition Opioid receptor agonist
Ketamine	Severe cancer pain with allodynia/ hyperalgesia	NMDA receptor antagonist
Clonidine/ dexmedetomidine	Severe cancer pain Poor opioid responsive pain Pain with agitation	Alpha-2 adrenergic agonists Enhance descending pain inhibition Reduce pain transmission in spinal cord
Duloxetine **Gabapentin** **Pregabalin** **Amitriptyline**	Neuropathic pain – see Box 9.1	

(5-HT = 5 hydroxytryptamine (serotonin); NA = noradrenaline (norepinephrine); NMDA = *N*-methyl-D-aspartate; NSAIDs = non-steroidal anti-inflammatory drugs)

i 9.8 Approaches to starting oral morphine for treating cancer pain

Using immediate-release preparations

- Usual adult dosing: commence 5 mg every 4 hours plus 5 mg up to every 2 hours for breakthrough pain
- If elderly or frail: commence 2 mg every 4 hours plus 2 mg up to every 2 hours for breakthrough pain

Using modified-release preparations

- Usual adult dosing: commence 10–15 mg every 12 hours plus 5 mg immediate-release morphine up to every 2 hours for breakthrough pain
- If elderly or frail: commence 5 mg every 12 hours plus 2 mg immediate-release morphine up to every 2 hours for breakthrough pain.

Use immediate-release preparations for initiation when possible

Choice of opioid

Renal failure Systemic clearance of active morphine metabolites occurs mostly via renal excretion (> 90%). Renal impairment can lead to accumulation of these active compounds, which eventually produces worsening side-effects and opioid toxicity. Oxycodone and hydromorphone clearance relies less on renal excretion, but accumulation can occur with repeated use. A reduction in the dose and frequency of administration for all three of these drugs is recommended in mild to moderate renal impairment (estimated glomerular filtration rate (eGFR) 30–59 mL/min). Use in severe (eGFR 15–29 mL/min) or end-stage renal failure (eGFR < 15 mL/min) is not recommended, and an alternative opioid should be used when possible.

Fentanyl, alfentanil, buprenorphine and methadone are less likely to accumulate in renal failure, although the prescribing of each of these drugs should only be undertaken by a cancer pain specialist.

Liver failure The risk of accumulation increases with most opioids in patients with severe hepatic impairment. Reduced first pass metabolism increases opioid oral bioavailability (fraction of opioid dose ingested that reaches the circulation); with morphine this increases from around 40% to nearly 100%. Reduced inactivation of opioids such as alfentanil and oxycodone via cytochrome P450 enzymes can significantly increase their effects. Fentanyl is considered the opioid of choice in liver failure, although low-dose immediate-release oral morphine is commonly used in practice.

Route of administration

The oral route is first choice for opioid administration whenever possible. Alternative routes are required for patients unable to swallow due to dysphagia, vomiting or reduced consciousness and those who have significant issues with drug absorption.

Transdermal patches, which provide controlled release of fentanyl or buprenorphine, can be used to manage pain in people who have stable chronic cancer pain (Box 9.9). These preparations are not suitable for people who have pain that is poorly controlled, as changes in the patch dosage can take days to take effect. Specialist advice is required when starting transdermal opioid patches especially in those who are not already established on another regular strong opioid (opioid naïve).

Delivery of several opioids via mucosal surfaces (transmucosal absorption) is also possible. Transmucosal fentanyl products are available, which can be administered sublingually, buccally or transnasally. These rapidly acting opioid preparations produce pain relief faster than oral immediate-release morphine and should only be prescribed by a specialist.

9.9 Transdermal opioid patches used in management of cancer pain

Medication	Clinical use and doses	Cautions*
Fentanyl	Used for severe but stable chronic cancer pain Patches are changed every 72 hours 10%–15% of people require 48-hourly patch changes Analgesic effects may take 48–72 hours to peak	Avoid use in patients who are not already taking strong opioids (opioid naïve)
Buprenorphine	Used for severe but stable chronic cancer pain Patches changed every 4 days (Transtec) or every 7 days (BuTrans) Analgesic effects may take up to 3 days to peak	The 5 μg/hour strength patch can be used with caution in patients who are opioid naïve. Stronger patches must not be used

*Fever, high ambient temperature and direct heat sources applied to transdermal patches (hot water bottle, electric blanket) increase the rate of drug absorption.

Patients with advanced cancer and those near the end of life are commonly administered opioid via subcutaneous injection or continuous infusion. Compared with intravenous administration, this route requires less training to use, is less painful and can be used in the community. A continuous subcutaneous infusion over 24 hours of opioid using a syringe driver can provide highly effective background pain relief, mimicking pain control produced by taking modified-release opioid. Breakthrough pain is then managed using bolus subcutaneous opioid injections, which work faster than oral immediate-release opioid.

Opioid switching

The practice of substituting one opioid for another is known as opioid switching and is commonly used in palliative medicine when the current opioid is ineffective or causing opioid toxicity. When performing a switch, an approximate starting dose of the new opioid is calculated using opioid equivalency formulae as presented in Figure 9.9. The new opioid dose regimen is usually reduced by 20%–30% to introduce an additional element of safety.

Opioid switching can involve changing the route of administration, as opioids such as diamorphine and alfentanil are normally given only via injection. Compared with oral opioids, approximately twice as much drug reaches the bloodstream when given via subcutaneous routes. The oral opioid dose is therefore halved to calculate an approximate subcutaneous dose, e.g. oral morphine 10 mg = subcutaneous morphine 5 mg.

Opioid-related adverse effects

Adverse effects are a common problem with opioids. The most common side-effects are nausea, drowsiness, constipation and dry mouth, as summarised in Box 9.10. Nausea, vomiting and drowsiness can occur at opioid initiation and dose increase. These usually settle within 7 days as tolerance to opioid effects develop in the affected neural areas. Tolerance does not develop in the salivary glands or colon, meaning dry mouth and constipation do not decrease with continued use.

Opioid-related constipation is a significant cause of suffering. Dietary measures and hydration may offer little benefit unlike other causes of constipation. In those who do not respond to first-line laxatives such as macrogol, consideration should be given to the use of a peripherally acting μ-opioid receptor antagonist (PAMORA), e.g. naldemedine. These drugs block opioid receptors on the bowel, but do not reduce pain relief in the CNS as they do not cross the blood–brain barrier.

Opioid toxicity and respiratory depression

Neurotoxicity occurs when opioids or their active metabolites reach a high enough level in the CNS. This presents as persisting drowsiness, visual hallucinations (often a sense of movement at the periphery of vision), delirium and myoclonic jerks. Pin-point pupils (miosis) are not a reliable sign of opioid toxicity. Opioid toxicity requires urgent assessment because if it is not managed, the patient may develop seizures, respiratory depression or coma. If pain is well controlled, then the current opioid dose should be reduced; if pain is not controlled, then an opioid switch is required. Good practice includes excluding renal impairment causing opioid accumulation or hypercalcaemia, which can mimic opioid toxicity.

Respiratory depression can occur with acute dosing, but is rare in patients on regular opioids or those starting on small, regular doses with appropriate titration. Opioid reversal using naloxone in patients with cancer pain needs careful assessment and should only be considered in life-threatening situations, as unnecessary use of naloxone will unmask cancer pain and cause acute opioid withdrawal.

Barriers to opioid prescribing

Some patients may have concerns about using opioids, and it is vital this is explored. Fear of addiction is common, and patients should be reassured that psychological dependence is rare when opioids are used for cancer pain. Media coverage of the opioid epidemic crisis in USA and Canada has increased fear and stigma worldwide. Unfamiliarity and concerns around prescribing opioids also exist among some health-care

When calculating doses for a switch to transdermal opioids (e.g. fentanyl, buprenorphine) always seek specialist advice.

Fig. 9.9 Approximate opioid equivalency formulae used when switching opioids. The calculated dose of the new opioid should then be reduced by 20%–30% to allow for individual differences in opioid tolerance. The opioid switching calculations provided are a basic guide only. Practice varies across the world. Clinicians should consult local guidelines and seek specialist advice if in any doubt. *Adapted from Laird BJA, Fallon MT. Palliative care in the elderly breast cancer patient. Clin Oncol. 2009;21:131–139.*

i 9.10 Opioid side-effects

Common side-effects	Clinical management
Constipation	Regular laxative – stimulant such as senna or bisacodyl, or macrogol PAMORA if first-line laxatives not effective (avoid in bowel obstruction)
Dry mouth	Sugar-free chewing gum Sips of water Artificial saliva sprays (many contain animal products)
Nausea/vomiting	Commonly resolves after a few days when starting opioid or increasing dose. If persisting: opioid switch and/or antiemetic, e.g. metoclopramide
Sedation	Often passes after a few days when starting opioid or increasing dose Avoid other sedating medication where possible Opioid switch
Itch	Opioid switch Antihistamines are rarely effective
Opioid-induced hyperalgesia	Paradoxical increase in pain when opioid dose increased Adjuvants and non-pharmacological measures – reduce opioid use Opioid switch Ketamine in select patients
Side-effects associated with long-term opioid use	
Opioid use disorder Immunosuppression Osteoporosis Hypogonadism Hypoadrenalism	

(PAMORA = peripherally acting μ-opioid receptor antagonist (see main text))

professionals. An opioid shortage crisis also exists. Many parts of the world have limited or no access to morphine for cancer pain relief. In 2018 the International Narcotics Control Board reported that 87% of the total amount of morphine used for pain relief is used in countries with only 21% of the world's population (mainly Europe, America, Australia and New Zealand). Cancer patients from many LMICs still suffer inadequate pain control due to restrictive government policies and a reliance on expensive opioids from step 2 of the WHO analgesic ladder.

Cancer-induced bone pain (CIBP)

The presenting features and assessment of bone metastases are covered in Chapter 8. Vertebrae, pelvic and long bones are the most commonly affected sites. Primary bone tumours such as osteosarcoma can also cause significant pain. CIBP occurs in response to mediators released by cancer cells, which lead to local changes in bone architecture via stimulation of osteoclasts and osteoblasts, increased nerve growth and the production of highly acidic local environment.

Weakening of bone may lead to pathological fractures (see Fig. 9.7), which can precipitate pain due to compression of peripheral nerves, cauda equina or spinal cord. The risk of long bone fracture due to a cancer deposit can be assessed using Mirel's criteria, and those at increased risk should be considered for prophylactic orthopaedic fixation or joint replacement (Box 9.11).

CIBP has both nociceptive and neuropathic elements. Opioids are normally required but pain relief is often unsatisfactory even with high doses. NSAIDs or dexamethasone are helpful in some individuals, but in general there is a lack of evidence to support the use of most adjuvant analgesics in CIBP. Immediate-release morphine or transmucosal fentanyl taken around 30 minutes before movement may offer some relief of activity-related pain.

Radiotherapy is the gold standard for managing CIBP with 60%–80% experiencing significant pain relief and 30% gaining complete relief. A single treatment (fraction) or short course of daily treatments is used. An

9.11 Mirel's criteria for assessing risk of future long bone fracture

Score	1	2	3
Site	Upper limb	Lower limb	Peritrochanteric
Pain	Mild	Moderate	Functional
Lesion	Blastic	Mixed	Lytic
Size	< 1/3	1/3 to 2/3	> 2/3

A score of 8 = ~15% fracture risk and 9 = ~33% fracture risk. Lesions with a score > 8 should be considered for prophylactic fixation.

9.12 Management of cancer-induced bone pain (CIBP)

Treatment	Clinical use
External beam radiotherapy	Gold standard for CIBP Can be repeated in some instances if effective
Intravenous bisphosphonates	Reduce bone breakdown by inhibiting osteoclast activity Zoledronic acid – first choice and given every 4–12 weeks Pamidronate may be used if eGFR < 30 mL/min Correct vitamin D deficiency before infusions – risk of hypocalcaemia Flu-like symptoms post infusion – paracetamol often effective
Denosumab	IgG monoclonal antibody that prevents osteoclast activation by binding to RANK Subcutaneous injection every 4 weeks Correct vitamin D deficiency before initiation Less nephrotoxic than bisphosphonates
Intravenous radioisotopes	Alpha particle emitting isotopes that bind to bone Reduce tumour damage and pain Radium-223 (^{223}Ra) – metastatic prostate cancer Side-effects: myelosuppression, nausea and fatigue
Vertebroplasty	Injection of acrylic cement into vertebral body of the spine affected by cancer Under video fluoroscopic guidance Cement leakage – serious complication that can cause neurological compromise

(eGFR = estimated glomerular filtration rate; RANK = receptor activator of nuclear factor κB)

initial pain flare can occur in the 24–48 hours after radiotherapy, which is managed using a short course of glucocorticoids. 50% of patients have a response within 2 weeks, but pain relief usually evolves over 4–6 weeks. An overview of managing CIBP is presented in Box 9.12.

Cancer-related neuropathic pain (CRNP)

Nerve damage can result from cancer infiltration, radiotherapy and chemotherapy. Addressing the underlying cause whenever possible should be the first goal of management. This can be difficult for patients with chemotherapy-induced peripheral neuropathy (CIPN), where the cause may simultaneously offer survival benefit. Pharmacological management follows the same principles as for chronic neuropathic pain secondary to other causes (see Box 9.5). It is important to remember that most cancer pain is mixed (nociceptive and neuropathic), and a trial of opioid will often provide pain relief in this group of patients.

Duloxetine is recommended first line for managing CIPN, and the use of 5% menthol in aqueous cream topically may provide some local relief. Topical lidocaine 5% patches can also be helpful in focal neuropathic pain. Methadone and ketamine may produce benefit in a subset of patients who have evidence of allodynia and hyperalgesia; both require specialist supervision for initiation and monitoring.

Interventional cancer pain techniques

The use of systemic analgesics to manage cancer pain can fail to bring sufficient relief for some patients, and many struggle with the impact of side-effects. Therapeutic techniques that block or reduce pain signals can be carried out by anaesthetists. If these are being considered, they should form part of a multidisciplinary management plan.

Nerve blocks and neurolysis

Local anaesthetic injections or infusions via nerve catheters can be used to provide temporary relief of cancer pain, which may allow other treatments to be undertaken, such as physiotherapy or lymphoedema care. The use of radiofrequency ablation, cryoablation or the injection of chemicals (phenol or alcohol) to cause targeted destruction of nerves (neurolysis) may be considered in selected patients, usually those with a short prognosis due to the potential for worsening pain as nerves regrow.

Coeliac plexus neurolysis (CPN) can be helpful for visceral pain associated with pancreatic or upper gastrointestinal cancers. CPN can be performed under CT guidance, but is increasingly performed using transoesophageal ultrasound guidance during endoscopy. Up to 80% of patients will gain pain relief from CPN, although pain often recurs after several months, which may lead to discussion about repeating the procedure.

Lateral cordotomy involves CT-guided radiofrequency ablation of one side of the spinothalamic tract at the level of the cervical spinal cord. This results in unilateral pain relief on the contralateral side of the body below the dermatomal level of C5. Cordotomy is commonly used to manage unilateral chest wall pain in patients with mesothelioma.

Neuraxial cancer pain interventions

The delivery of local anaesthetic, opioid and clonidine via the intrathecal route (see spinal anaesthesia above) is preferred to the epidural route in patients experiencing intractable cancer pain who have a longer prognosis. Intrathecal drug infusion is initially trialled using an external pump to achieve an acceptable balance between analgesia and lower limb motor function. If successful, then the pump is implanted into an abdominal subcutaneous pocket, with the drug delivery lines tunnelled internally to the spine. Intrathecal drug delivery can be used for months to years, with scheduled pump drug refills taking place every few weeks via an injection port accessed superficially through the skin.

Radiotherapy and chemotherapy

Radiotherapy is the treatment of choice for CIBP but can also be considered to reduce involvement at other sites. Chemotherapy and other systemic anti-cancer drugs that reduce cancer size will often reduce pain by relieving existing pressure on nerves, bones and other structures.

The evolution of managing cancer pain

The fundamentals of managing cancer pain were largely developed during the early hospice movement at a time when patient prognoses were frequently short (weeks to a short number of months). Although there was recognition of immediate and short-term opioid side-effects, the impacts of opioid-related harms from prolonged use were not factored into emerging practice. The traditional palliative care management of cancer pain typically involved upward titration of opioid doses with the addition of other analgesic medications as reflected in the original 1986 WHO analgesic ladder model, which was unidirectional. In general, those with unremitting progressive cancer pain are managed by palliative care teams. The management of chronic cancer pain in people with longer prognoses is not as clearly defined. Advances in surgical and oncology treatments over the past two decades have improved the prognosis for an ever-growing population of patients.

Supportive oncology

Many patients are now living longer with incurable but treatable cancer. There is also an increasing cohort of people who have survived cancer (survivorship). These patients can experience chronic pain that is not due to progressive or persistent tissue destruction, and many will already be taking opioids as well as other analgesics. Traditional palliative care prescribing and the WHO analgesic ladder cannot be universally transposed to manage such patients with complex cancer pain, who often have a prognosis of many years. Longer-term use of opioids and adjuvant analgesics in this patient population requires careful assessment and regular, long-term follow-up.

Monitoring is vital for medication-related harm, such as iatrogenic addiction and opioid-induced hyperalgesia, which compound the psychological and emotional distress typical of chronic pain. Multidisciplinary assessment for the potential role of cancer pain interventions needs to be considered, but availability of these services is variable. In the UK many of these patients are currently cared for by a combination of general practice, oncology, chronic pain and palliative care teams, who may not have the specific training or resources to fully meet their needs.

The specialty of supportive oncology is growing in response to the evolving need to optimise management for such patients. These specialist doctors and nurses provide integrated care alongside oncology teams to manage symptoms resulting from cancer and its treatments, including long-term sequelae like chemotherapy-induced neuropathy and other chronic pains.

Symptom management

The WHO defines palliative care as an approach that improves the quality of life of patients and their families who are facing problems associated with life-threatening illness. It prevents and relieves suffering through the early identification, holistic assessment and treatment of pain and other problems, whether physical, psychosocial, or spiritual. As the beneficial effects from medical treatment diminish in advanced disease, there should be a gradual transition to focusing on optimising symptom control and quality of life. The second part of this chapter covers a selection of presentations common in palliative care settings, including caring for the dying patient.

Cachexia

Overview

Cachexia is a multifaceted syndrome characterised by severe malnutrition, muscle wasting and weight loss, commonly associated with chronic illnesses such as heart failure, chronic obstructive pulmonary disease (COPD) and cancer. The presence of malnutrition in these chronic conditions significantly impacts patients, their families and their overall quality of life.

Defining cachexia and its spectrum

Cachexia is a condition where terminology can be confusing and often misused; therefore, defining key terms is important and the Global Leadership Initiative on Malnutrition (GLIM) criteria are recommended here:

- *Sarcopenia* is a condition characterised by loss of skeletal muscle quantity and therefore strength. It usually affects older adults due to ageing but can occur at any age due to other factors, including physical inactivity or acute illness. Set criteria can be used to define sarcopenia based on skeletal muscle index (quantity of muscle) and skeletal muscle density (quality of muscle). In the clinic, sarcopenia is not routinely assessed, but this is changing as it can be measured using computer-based body composition via a CT scan.
- *Malnutrition* is characterised by reduced dietary intake leading to weight loss. The GLIM criteria state that for malnutrition to be present, certain criteria need to be present (Fig. 9.10).
- *Cachexia*. When sarcopenia and malnutrition coexist with systemic inflammation, this is termed *cachexia*. This syndrome is prevalent in many chronic diseases, particularly in cancer, with its occurrence varying widely across different types. For example, it affects up to 80% of patients with certain cancers, being more frequent in lung and gastrointestinal cancers and less so in breast and prostate cancers.

Pathophysiology of cachexia

The pathophysiology of cachexia is intricate and involves a dynamic interaction between the disease and the patient (host). This interaction triggers a cascade of metabolic changes primarily driven by the release of pro-inflammatory cytokines. These cytokines induce a state of bioamplification through hepatic mediation, affecting both central (appetite and energy centres in the brain) and peripheral (muscle, liver, heart, gastrointestinal system) systems. The resulting metabolic disturbances lead to the clinical manifestations of cachexia (Fig. 9.11).

Clinical presentation

Clinically, cachexia manifests as significant weight loss, predominantly of muscle mass, with or without accompanying fat loss, reduced appetite, and diminished physical activity. Weight loss is often the most noticeable clinical feature, but the underlying biological changes begin much earlier. Cachexia can be present even before noticeable weight loss, a stage referred to as pre-cachexia (see Fig. 9.11).

Stages of cachexia

Cachexia is not a static condition but progresses through various stages:

- *Pre-cachexia*: Early metabolic disturbances without significant weight loss

- *Cachexia*: Noticeable weight loss and muscle wasting
- *Refractory cachexia*: Advanced stage where interventions become less effective

Historically, treatment has often been delayed until the later stages of cachexia, particularly refractory cachexia. However, this approach is increasingly recognised as inadequate. Early identification and intervention are crucial, with the goal of preventing or delaying the progression of cachexia.

Early identification and intervention

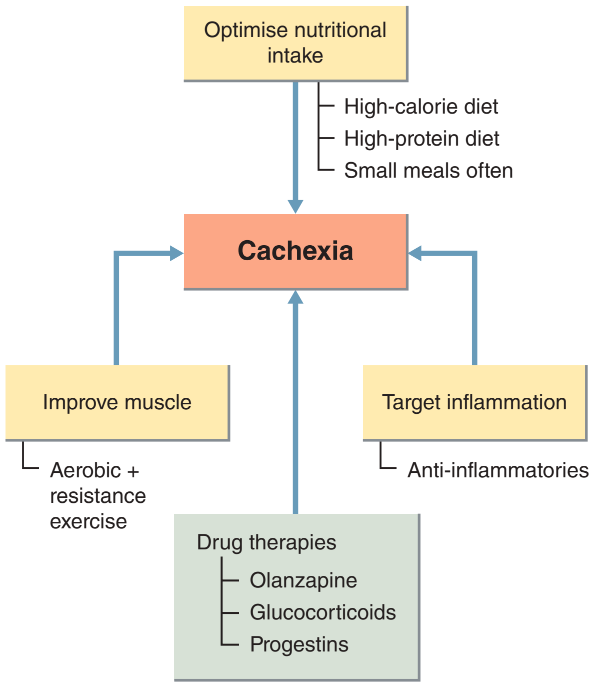
Modern medical practice emphasises the importance of recognising cachexia in its early stages, even before significant weight loss occurs. By identifying metabolic disturbances early, health-care providers can implement strategies to mitigate the progression of cachexia. These strategies may include nutritional support, anti-inflammatory treatments, and physical rehabilitation programs aimed at preserving muscle mass and overall functionality.

Comprehensive management of cachexia in cancer patients

The European Society for Clinical Nutrition and Metabolism (ESPEN) guidelines on clinical nutrition in cancer highlight several key areas for consideration, including regular dietary intake, exercise and the use of nutritional supplements (Fig. 9.12).

Basic cachexia care

Effective management of cachexia targets its complex pathophysiology through a multifaceted approach:



Optimise nutritional intake
High-calorie diet
High-protein diet
Small meals often
Cachexia
Improve muscle
Aerobic + resistance exercise
Target inflammation
Anti-inflammatories
Drug therapies
Olanzapine
Glucocorticoids
Progestins

Fig. 9.12 **Approach to managing cancer cachexia.**

- Optimising nutrition
  - Encourage energy-dense (high-calorie, small-volume) foods.
  - Recommend frequent small meals throughout the day rather than large meals, aiming for 25–30 kcal/kg/day.
  - Consider oral nutritional supplements if regular dietary intake is insufficient.

- Preventing sarcopenia and building muscle
  - Engage patients in aerobic and resistance exercises (30 minutes, three to four times a week) to improve muscle mass and physical function.
- Addressing inflammation
  - Although inflammation is a key component of cancer cachexia, there is insufficient evidence to recommend non-steroidal anti-inflammatory drugs (NSAIDs) for treatment.

Evidence-based multimodal therapy

The MENAC (Multimodal Exercise/Nutrition/Anti-inflammatory treatment for Cachexia) trial demonstrated that combining exercise, nutrition and anti-inflammatory treatments is more effective than standard care in stabilising weight and improving outcomes in patients with lung or pancreatic cancer receiving palliative therapy.

Specific drug therapies

- Olanzapine: Low-dose olanzapine (2.5 mg daily) can be used to improve appetite and reduce weight loss in patients with cancer cachexia.
- Glucocorticoids: These can be used to increase appetite in anorectic cancer patients with advanced disease for a restricted period (1–3 weeks). However, they come with side-effects such as muscle wasting, insulin resistance and increased risk of infections.
- Progestins: These can be considered to increase appetite in anorectic cancer patients with advanced disease but have potentially serious side-effects, including thromboembolism.

Emerging therapies

Several novel therapies are currently under investigation:

- Cannabinoids: Being studied for their potential to stimulate appetite and reduce weight loss.
- Anti-growth differentiation factor 15 (GDF15) antibodies: Targeting specific pathways involved in cachexia.

- S-pindolol: Under investigation for its potential benefits in treating cancer cachexia.

Delirium

Delirium is common, especially in palliative care settings. The point prevalence of delirium during the first palliative community visit is between 4% and 12%. In hospitals, the prevalence on the first palliative service review increases to 25%. Upon admission to inpatient palliative care units (IPCU), the prevalence is 32%, and the period prevalence in IPCU prior to death reaches 75%. Importantly, up to 50% of delirium cases may be reversible. Hypoactive delirium is the most common subtype in palliative care settings. This subtype carries an increased risk of being missed or misdiagnosed as fatigue, depression, dementia or impending death.

It is crucial to recognise and appropriately manage delirium to mitigate its impact on the quality of life for patients and the emotional well-being of their families.

Various factors can contribute to the onset of delirium and these are discussed, along with investigation and management, in Chapter 32. Cancer treatments such as cranial radiotherapy, along with the direct effects of cancer such as brain metastases and indirect effects like paraneoplastic syndromes, are additional factors to consider in patients with malignancy (Fig. 9.13).

Nausea and vomiting

Nausea and vomiting (emesis) are common in patients with cancer and can be caused by a variety of factors related to the disease itself, its treatment and other associated conditions. Nausea may occur without vomiting, while someone with small bowel obstruction may have severe vomiting with only transient nausea. Nausea is ranked as a more debilitating experience than pain by many patients. There are multiple causes, as detailed below, which can frequently co-exist:

- Cancer treatment
    - Chemotherapy: Many chemotherapy drugs trigger nausea and vomiting by directly stimulating the chemoreceptor trigger zone (CTZ) in the brainstem or indirectly by causing release of mediators from damaged cells, e.g. serotonin from enterochromaffin cells in the gastrointestinal tract (see Fig. 9.14).
    - Radiation therapy: Radiation, especially to the abdomen, chest, or brain, can irritate tissues and lead to nausea.
    - Immunotherapy: Some immunotherapy treatments can cause end-organ inflammation or other side-effects that result in nausea.
    - Surgery: Postoperative nausea is common after cancer surgeries, often due to anaesthesia, ileus or pain medications.
- Cancer
    - Tumour location: Tumours in the gastrointestinal tract, liver or brain can directly cause nausea due to obstruction, pressure or increased intracranial pressure.
    - Metabolic changes: Advanced cancer can lead to metabolic imbalances (e.g. hypercalcaemia, uraemia) that produce nausea via CTZ.
- Medications
    - Pain medications: Opioids, NSAIDs and antidepressants used for cancer pain commonly cause nausea as a side-effect.
    - Other drugs: Antibiotics, bisphosphonates, hormone therapies and many other medications taken during cancer treatment can produce nausea as a side-effect.
- Psychological factors
    - Anxiety and anticipation: The psychological stress of a cancer diagnosis and treatment can cause or exacerbate nausea. Anticipatory nausea is common in patients undergoing repeated chemotherapy.
- Infections
    - Infections: Cancer patients are often immunocompromised, making them more susceptible to infections and sepsis with associated nausea.
- Gastrointestinal issues
    - Gastrointestinal obstruction: Tumours or scar tissue in the gastrointestinal tract can obstruct normal digestion, leading to nausea and different patterns of vomiting depending on the level of obstruction.
    - Gastroparesis: Delayed gastric emptying due to autonomic neuropathy, tumour encroachment or opioids cause nausea, which is typically relieved after vomiting.
- Nutritional deficiencies
    - Malnutrition: Cancer and its treatment can lead to malabsorption and nutritional deficiencies such as hypomagnesaemia, which can result in nausea.

Managing nausea in cancer patients

Effectively managing nausea in cancer patients requires a thorough understanding of its underlying causes, as treatment strategies must

be tailored to address the specific factors contributing to the symptom (Fig. 9.14). Below is a detailed approach to managing nausea based on various potential causes.

Electrolyte disturbance

Abnormal levels of electrolytes, such as sodium, potassium, calcium or urea, can significantly contribute to nausea. It is essential to regularly monitor these levels in cancer patients, particularly those undergoing intensive treatments. Correction of these imbalances through appropriate supplementation or medication adjustments is crucial. For example, hypercalcaemia is often treated with intravenous fluids, bisphosphonates or denosumab, while hyponatraemia may require fluid restriction or saline administration.

Drug-induced nausea

A comprehensive review of the patient's medication regimen is essential. If a particular drug is identified as the cause, options include dose reduction, switching to an alternative medication or discontinuing the drug if possible. Opioid analgesics, for example, often cause nausea when first initiated, but this side-effect usually subsides within 1–2 weeks. If persistent, antiemetics or alternative pain management strategies may be necessary. Around 10% of patients may continue to experience opioid-induced nausea in the long term, requiring ongoing management.

Constipation

Constipation, even if distal, can lead to symptoms such as abdominal fullness, bloating and nausea. This is particularly common in cancer patients due to factors like reduced mobility, dietary changes and opioid use. Effective management includes the proactive use of laxatives, stool softeners or enemas to maintain regular bowel movements. Ensuring adequate hydration and encouraging physical activity, where possible, can also help alleviate constipation-related nausea. A PAMORA should be considered in those with opioid-related constipation.

Raised intracranial pressure

Elevated intracranial pressure (ICP), often resulting from brain metastases, can cause significant nausea and vomiting. Management typically includes the use of glucocorticoids, such as dexamethasone, to reduce inflammation and oedema. In some cases, radiotherapy may be indicated to shrink metastatic lesions and further alleviate pressure. Early intervention is critical to prevent worsening symptoms and improve the patient's quality of life.

Gastric irritation

Gastric irritation, which can occur due to direct effects of the cancer or as a side-effect of treatment, often leads to nausea. Proton-pump inhibitors (PPIs), such as omeprazole or pantoprazole, can be effective in reducing gastric acid production and irritation. This treatment is particularly important in patients receiving medications known to irritate the stomach lining, such as NSAIDs or certain chemotherapy agents.

Pharmacological management of nausea: a stepwise approach

Effective pharmacological management of nausea, particularly in cancer patients, often requires a stepwise approach based on the level of evidence supporting the use of different medications.

First-line treatments

- Metoclopramide is widely regarded as a first-line treatment for nausea, particularly when associated with gastrointestinal dysmotility.
- Haloperidol, traditionally used as an antipsychotic, has been found to be effective in treating nausea, particularly when other treatments are ineffective or contraindicated.

Second-line treatments

- Methotrimeprazine, also known as levomepromazine, is considered a second-line treatment option.

- Olanzapine, an atypical antipsychotic, has shown promise in treating chemotherapy-induced nausea and vomiting (CINV) and other refractory cases.

Bowel obstruction in advanced disease

Bowel obstruction is a significant and distressing complication in patients with advanced disease, particularly in the presence of autonomic neuropathy or intra-abdominal carcinomatosis. The obstruction may be partial or complete, with clinical manifestations varying depending on the level, type and duration of the obstruction.

Types and clinical features

Partial obstruction (sub-acute obstruction)

Partial obstruction presents with reduced bowel sounds and often no colic. Symptoms include constipation, faecal incontinence, intermittent nausea and vomiting (which may provide some relief). As the obstruction progresses, intermittent colicky pain and nausea worsen, while vomiting can become feculent due to the colonisation of small bowel contents by colonic bacteria. Abdominal distension is common, though it may be absent in cases of gastroduodenal obstruction or extensive peritoneal involvement.

Complete obstruction

Complete obstruction is characterised by the absence of flatus per rectum. Patients often experience continuous pain, which may be due to tumour or nerve infiltration, along with colic and altered bowel sounds.

Management approach

The management of bowel obstruction requires a multidisciplinary approach involving surgical, oncological and palliative care teams. Treatment decisions should be guided by the patient's clinical condition, the likely benefits and risks of intervention, and patient preferences.

Initial assessment and conservative management

Exclude faecal impaction, which can complicate or mimic bowel obstruction. For localised obstructions, surgical intervention may be considered, though other interventional palliative treatments like stenting (for gastric outlet, proximal small bowel or colon) or laser therapy may be appropriate. In cases of gastroduodenal or jejunal obstruction, a venting gastrostomy can provide relief.

Conservative management

In the acute phase (2–3 days), conservative management may include resting the bowel, keeping the patient nil by mouth (NBM), and possibly using a nasogastric (NG) tube. Encourage a low-fibre diet and consider additional hydration via subcutaneous or intravenous routes. Given that oral absorption is often unreliable, most patients will require subcutaneous infusion of medications.

Symptom management

The use of prokinetic agents such as metoclopramide may relieve partial obstruction, often temporarily. This is usually given in conjunction with subcutaneous dexamethasone 8 mg/day for 4–7 days, which can reduce gut wall oedema. If colicky abdominal pain occurs while using metoclopramide, this should be stopped, as this indicates progression towards complete obstruction. Other symptomatic interventions include:

- Pain management: Use opioids to control pain.
- Colic: Hyoscine butylbromide (Buscopan) can be effective.
- Nausea: First-line treatment includes cyclizine or hyoscine butylbromide, with levomepromazine as a second-line option.
- Vomiting: Hyoscine butylbromide or octreotide may be used; the latter is particularly effective in reducing the volume of vomit.

Supportive care

Frequent mouth care is essential, especially as patients may be NBM. Hyoscine butylbromide and opioids both cause dry mouth. Ensure ongoing communication with the patient and family, addressing concerns and preferences as part of a comprehensive care plan. Overall, the management of bowel obstruction in advanced disease is complex and should be tailored to the individual patient's needs, focusing on symptom control and quality of life.

Breathlessness in advanced disease

Breathlessness, also known as dyspnoea, is a common and distressing symptom in patients with advanced malignancies, affecting between 29% and 74% of these individuals. It is particularly prevalent in those with lung cancer, where breathlessness can occur in the presence of normal oxygen saturations due to abnormal stimulation of airway and chest wall mechanoreceptors.

Aetiology of breathlessness

Breathlessness in patients with advanced disease can arise from various causes:

- Direct tumour effects:
  - Pleural effusion: Accumulation of fluid in the pleural space, reducing lung capacity.
  - Bronchial obstruction: Tumour growth can obstruct airways, leading to reduced airflow and lobar collapse.
  - Lung replacement by tumour: Tumour infiltration reduces effective gas exchange.
  - Lymphangitis carcinomatosis: Spread of cancer through the lymphatic system in the lungs.
  - Superior vena cava obstruction: Compression or invasion of the superior vena cava, leading to venous congestion, reduced cardiac pre-load and bronchial/tracheal compression.
  - Pericardial effusion: Fluid accumulation around the heart, compromising cardiac function.
  - Massive ascites and abdominal distension: Increased intra-abdominal pressure affecting diaphragmatic movement.
- Treatment-induced causes:
  - Surgical procedures: Pneumonectomy or lobectomy will reduce lung capacity.
  - Radiation therapy: Can lead to fibrosis and reduced lung compliance.
  - Chemotherapy: Drugs such as doxorubicin and bleomycin can cause pulmonary toxicity.
- Debility-related causes:
  - Anaemia: Reduced oxygen-carrying capacity of the blood.
  - Atelectasis: Collapse of lung tissue, reducing ventilation.
  - Pulmonary embolism: Obstruction of pulmonary arteries, reducing blood flow to the lungs.
  - Pneumonia and empyema: Infection and pus accumulation in the pleural space, compromising lung function.
- Concurrent diseases:
  - Asthma
  - COPD
  - Congestive cardiac failure
  - Interstitial lung disease.

Principles of management of breathlessness

Effective management of breathlessness requires a comprehensive approach that includes both non-pharmacological and pharmacological strategies.

Patient and family support

Reassurance and clear explanations of the disease process help reduce anxiety; relaxation techniques may be beneficial. Physiotherapy can assist with positioning and techniques to control hyperventilation. Creating a stream of cool air onto the nose and mouth with a fan or open window can provide relief. Practical aids and adaptations for daily living can improve the patient's quality of life.

Oxygen therapy

Oxygen (provided in cylinders or via a concentrator device) can reverse hypoxia and give symptomatic relief to some patients (although some of the perceived benefit may be a placebo effect). It can also provide important reassurance to the patient and their family. However, it can lead to dependence, tying the patient to an oxygen source. It also can cause dry mouth and difficulties with communication. Oxygen therapy is expensive if used in the long term and cannot be given to patients who smoke (or where there is another smoker in the accommodation).

Drug management

- Opioids: Low-dose oral opioids may effectively reduce the sensation of breathlessness, although strong evidence to support this is lacking. Starting with morphine 2 mg every 4 hours, doses can be titrated up as needed. If the patient is already on opioids, the dose may be increased by 33%–50%. There is no strong evidence supporting the use of nebulised opioids, which can actually cause bronchospasm.
- Bronchodilators: These are useful in patients with reversible airway obstruction, such as those with asthma or COPD.

Specific treatments

- Pleural effusion: Management includes draining the effusion, considering surgical pleurodesis, or placing a pleuro-peritoneal shunt. Indwelling pleural catheters, which can be used to drain fluid regularly, are a suitable option for some with recurrent effusions.
- Endobronchial obstruction: High-dose glucocorticoids, radiotherapy, CO_2 laser bronchoscopy or the placement of bronchial stents may be effective in relieving obstruction and improving airflow.
- Blood transfusion to treat anaemia may be appropriate in some situations.

Cough

Coughing is a vital protective mechanism designed to clear foreign materials and excess mucus from the bronchial tree, helping to maintain airway patency and respiratory health.

Cough management depends on whether the cough is dry (non-productive) or wet (productive).

Dry cough

The primary approach is to treat the underlying cause, whether it be infection, reflux or another condition. Symptomatic interventions include:

- Demulcents, such as simple linctus, soothe the throat and reduce irritation.
- Cough suppressants: Codeine or pholcodine linctus can be used to reduce the frequency of coughing.
- Opioids: Morphine liquid can be prescribed, with the dose increased if the patient is already on regular opioid therapy. Methadone linctus is another option. It is important to note that there is no strong evidence supporting the use of nebulised agents for dry cough, except for saline and bronchodilators.

Wet cough

The goal is to encourage the expulsion of mucus and to treat the underlying cause, such as infection or chronic lung disease.

- Expectoration: Encouraging patients to cough effectively can help clear the mucus from their airways.
- Physiotherapy: Techniques such as chest percussion or postural drainage can be beneficial.
- Nebulised saline: Helps to thin mucus, making it easier to cough up.
- Mucolytics: Medications like carbocisteine can reduce the viscosity of mucus, aiding in its clearance from the lungs.

Death and dying

Future care planning

Medical treatments have advanced significantly even in the past decade. Despite these advances, the inescapable fact remains that everyone will die at some time. Radiological investigations, invasive medical treatments and hospital admissions remain high in the last year of people's lives.

For many people with advanced illness, hospital admission or dying in hospital is completely appropriate. However, when death is foreseeable, a hospital admission can cause undue distress, with an increasing number of people expressing a wish to die at home. Hospice admission is another option, but may be limited by the small number of inpatient units available. Dying at home can often be well supported, but gaps in health and social care exist, which can make optimal symptom control and family support challenging. It is important to have an honest discussion with people about the support available in their local area.

The Supportive and Palliative Care Indicators Tool (SPICT) can help identify people with advancing illness that would benefit from a process known as future care planning (also known as advance care planning), which involves discussions between health-care professionals, the patient and their family or legal proxy. Through open, honest exchanges of information over time, the patient is assisted to have their preferences around medical care documented in advance of changes in their health. This process is dynamic, and patient views on interventions frequently change over time.

It is important to distinguish between interventions that will not provide clinical benefit (a medical decision) and those that may not confer sufficient benefit to be worthwhile (a decision that can only be made with the patient's involvement).

Recognising dying

The Australia-modified Karnofsky Performance Status (AKPS) is routinely used to guide patient prognosis in palliative care (Box 9.13). The rate at which performance status falls can give an indication of how long they have to live, e.g. someone with a score of 50% falling steadily week by week to 20% may have a short number of weeks to live. When patients with cancer or other conditions become bed-bound, semi-comatose, are unable to take tablets and only able to take sips of water, with no reversible cause (AKPS 10%), they are likely to be in their last few days of life. Signs that someone is close to death include skin mottling, movement of the jaw with breathing, audible respiratory secretions and changes in breathing such as Cheyne–Stokes respiration. It is important for health-care professionals to make the assessment that someone is dying as a multidisciplinary team.

Management of symptoms at end of life

For most people, dying is a gentle and peaceful process that needs very minimal medical input. It is vital that patients who do develop distressing symptoms at end of life have these managed promptly and effectively. Oral medications can often be used until close to end of life, but it is important to carry out a regular medication review with the patient. Drugs such as statins, vitamins, bisphosphonates and antihypertensives can usually be stopped in the last weeks of life to reduce the burden of taking pills.

9.13 The Australia-modified Karnofsky Performance Status (AKPS)

AKPS score	Description of performance status
100%	Normal, no complaints, no evidence of disease
90%	Able to carry on normal activity, minor signs or symptoms of disease
80%	Normal activity with effort, some signs or symptoms of disease
70%	Cares for self, but unable to carry on normal activity or to do active work
60%	Able to care for most needs, but requires occasional assistance
50%	Considerable assistance and frequent medical care required
40%	In bed more than 50% of the time
30%	Almost completely bedfast
20%	Totally bedfast and requiring extensive nursing care by professionals and/or family
10%	Comatose or barely arousable, unable to care for self, requires equivalent of institutional or hospital care, disease may be progressing rapidly
0%	Dead

Syringe drivers

A continuous subcutaneous infusion (CSCI) of medication can be used to provide symptom control for people near end of life who can no longer swallow medications. Opioids may be required for pain or breathlessness, midazolam can be used to manage agitation or seizures, hyoscine butylbromide (anti-cholinergic) is used to reduce respiratory secretions and haloperidol or levomepromazine is used to manage both nausea and agitation. Anti-epileptics, NSAIDs, tranexamic acid and a range of other drugs can also be given via this route. Some of these drugs can be mixed together in the same syringe; guidance is available on compatible mixtures.

Anticipatory medications

It is good practice to have a selection of ‘as required’ symptom control medications prescribed for patients who are approaching end of life. These medications are usually administered as subcutaneous injections but can be given via transmucosal routes if appropriate. Should a patient develop symptoms, then pre-prescribed medication can be given by nursing staff without delay, e.g. waiting for a doctor to come and prescribe. A similar supply of injectable medication can also be stored in a patient’s house or care home to be administered by district nurses or trained informal carers. The medication dose, indication, minimum dose interval and maximum 24-hour dose should be clear on the prescription.

The common medications prescribed (UK) are as follows:

- an opioid medication for managing pain or breathlessness, e.g. morphine sulphate injection 2 mg up to 1 hourly – max 6 doses in 24 hours
- a benzodiazepine for managing breathlessness or agitation, e.g. midazolam injection 2 mg up to 1 hourly – max 6 doses in 24 hours
- an antiemetic for managing nausea, e.g. levomepromazine 2.5 mg up to 8 hourly – max 3 doses in 24 hours
- an anti-secretory medication to reduce audible respiratory secretions, e.g. hyoscine butylbromide 20 mg up to 2 hourly – max 6 doses in 24 hours

For those at risk of seizures, bleeding or airway compromise, a higher dose of midazolam may be prescribed to use only in an emergency.

Supportive care at end of life

The following elements of care are essential in the care of the dying person:

- Mouth care: Dry mouth, ulcers and candidiasis can all cause pain. Oral fluids should be provided to relieve thirst while the patient is able to drink. Small sips of fluid or a water spray may still be soothing near end of life. A soft toothbrush can be used to cleanse the teeth and tongue. Foam mouth swabs or sponges should be avoided due to the risk of choking.
- Skin care: Pressure area protection using positional changes and pressure-relieving mattresses.
- Bowel care: Constipation can cause agitation. Use of suppositories may be needed.
- Bladder care: Urinary retention due to opioids or hyoscine can occur. Urethral catheterisation can help preserve skin integrity, save energy and produce dignity for the patient.

Communication with the patient and family should occur with all aspects of care. Explaining what medication or nursing care is being given and why is important. Involvement of family in the practical care of their loved ones should be explored, remembering that family are usually the main carers when people are dying at home.

Multiple Choice Questions

9.1. A 68-year-old patient with advanced pancreatic cancer is receiving long-term opioid therapy for pain management. He presents with persistent constipation despite taking regular senna for the past week. His bowel movements are infrequent and difficult, and he denies any recent dietary changes or signs of bowel obstruction. What is the most appropriate next step in managing his constipation?

A. Increase the dose of senna
B. Add docusate sodium
C. Initiate a peripherally acting μ-opioid receptor antagonist (PAMORA)
D. Recommend increased fluid intake and dietary fibre
E. Perform a manual disimpaction

Answer: C.

This patient has clear signs of opioid-induced constipation (OIC) that has not responded to a first-line laxative (senna). When a patient with OIC fails to respond to conventional laxatives, current guidelines recommend initiating a PAMORA such as naloxegol, methylnaltrexone, or naldemedine. These agents target the underlying mechanism by antagonising opioid receptors in the gut without affecting analgesia. Increasing senna or adding docusate is unlikely to resolve refractory OIC, and dietary measures alone are inadequate in this context. Manual disimpaction is only indicated in cases of faecal impaction, which is not evident here.

9.2. A 45-year-old woman consults her GP with gradually worsening low back pain that started over 2 years ago. There is no radiation, nor any red flags. She cannot take non-steroidal anti-inflammatory drugs (NSAIDs) due to gastrointestinal upset. She takes co-codamol 30/500, at a dose of 8 tablets per day, with limited benefit. She works as a cleaner in the local school and is a single parent, with three children ranging in age from 7 to 18. She has been off work for the last 6 months after a flare-up that has not settled, and is worried about her job and her finances. Her mother lives nearby and is very supportive, helping out with child care and shopping. She saw a physiotherapist for one session, but did not go back as she felt the exercises were too hard and made the pain worse. She worries that if the pain gets worse she must be damaging her back, and she spends much of her time in bed or lying on the couch. What management approach should be used to increase her physical activity?

A. Refer back to the physiotherapist for more effective exercises
B. Switch co-codamol to oral morphine to control the pain better and thus allow her to do more
C. Assess what barriers there are to increasing her physical activity before agreeing on management
D. Refer for further investigations, such as X-ray or magnetic resonance imaging (MRI), of her lumbar spine to exclude any sinister causes, such as malignancy, or to identify any surgical target
E. Add in diazepam to help with muscle spasm and reduce her anxiety about the impact of the pain

Answer: C.

There is good evidence that increasing physical activity is an effective way to manage chronic pain, but it is acknowledged that there may be a number of barriers preventing people who live with chronic pain from doing this successfully. These can include fear avoidance, not pacing activities well, depression, financial problems or other commitments that prevent their ability to attend appointments or go to a leisure centre. Advice alone is not enough and personal preference/previous experience will impact on patient engagement. There is no one type of exercise that will work for everyone. Opioids are not recommended for long-term use in chronic pain, and combining these with other sedative drugs may be harmful. Ongoing review of the benefits versus risks of continuing co-codamol at the current dose should be undertaken. Review for potential opioid side-effects such as somnolence or constipation from her current co-codamol therapy is important to make sure these are not impacting her quality of life. There is no good evidence that benzodiazepines are helpful in chronic low back pain. Continued investigation in the absence of specific concerns is not recommended.

9.3. A 65-year-old woman with breast cancer and known bone metastases is admitted to hospital with worsening thoracic back pain. She undergoes an MRI, which demonstrates new metastases in her T4 and T5 vertebral bodies with no involvement of her spinal cord. She is commenced on dexamethasone 6 mg/day and regular immediate-release oral morphine 5 mg four times daily with the option of further 5 mg immediate-release morphine doses as required up to 4 hourly as well. She uses three extra doses of morphine in the first 24 hours and finds these give some extra relief for around 2 hours. She does not feel sleepy with morphine and there are no signs of toxicity evident. The day after admission, her pain is still described as 'severe', and she is due to undergo palliative radiotherapy to her spine later that day. What approach should be taken to manage her analgesia in the coming days?

A. Commence a non-steroidal anti-inflammatory drug (NSAID) such as ibuprofen 400 mg three times a day
B. Add in pregabalin 100 mg twice daily as an adjuvant for cancer bone pain
C. Commence a continuous infusion via syringe driver of morphine 15 mg over 24 hours with immediate-release morphine 5 mg as required 4 hourly
D. Increase immediate-release morphine doses to 10 mg four times per day and 10 mg as required 1 hourly. Review twice daily for benefit/side-effects
E. Switch morphine to oxycodone to provide better pain relief with less risk of causing opioid toxicity

Answer: D.

This patient has uncontrolled cancer-related bone pain. Radiotherapy is the treatment of choice for improving pain and will be effective in around 50% of people in the first 2 weeks. An increase in pain can occur in the first 24–48 hours after radiotherapy for bone metastases, known as a pain flare; the risk of this can be reduced by prescribing dexamethasone 4–6 mg/day, which this patient is already taking. This patient requires an immediate increase in her morphine to manage her current pain levels. Morphine has been giving some analgesic benefit and has been well tolerated so far, meaning there is no indication to switch to oxycodone. An increase from 5 mg to 10 mg per morphine dose would be appropriate in the first instance, with ongoing review over the day. She may also require a further dose adjustment in the coming days should her pain flare with radiotherapy. It will be important to subsequently reduce her opioid dose should she experience good pain relief from her radiotherapy over the coming weeks. Failure to adjust doses in this reactive manner could result in distressing pain acutely and opioid toxicity over time. Using regular and as-required immediate-release (short-acting) morphine to provide this flexibility in the first few days will allow more refined dose adjustment. The option to have immediate-release morphine as required up to 1 hourly rather than 4 hourly will reduce the chance of the patient waiting for analgesia while in pain and allow recognition of acutely worsening pain. Introducing modified-release morphine would be a potential option once the 24-hour morphine dose requirement becomes clearer in due course. Although using a continuous infusion of morphine may give some flexibility to adjust the dose over the coming days, the patient can currently take oral medications, so this is not indicated. Consideration of an adjuvant such as pregabalin is not currently indicated and may complicate opioid titration due to side-effects from the combination. The combination of NSAID and dexamethasone can increase the risk of gastrointestinal bleeding; analgesic benefit is unlikely to be superior to opioids in this scenario.

9.4. John is a 73-year-old retired joiner with a 3-month history of right-sided chest pain and cough. He has been receiving palliative radiotherapy for right-sided Pancoast tumour. He lives with his wife, and his family are not nearby.

Timeline:

1. John was reviewed during radiotherapy because of pain in his right shoulder and arm. He experiences constant severe background pain, rated as 9/10. He also experiences intermittent, excruciating shooting pain associated with pins and needles and a tight sensation, rated as 10/10.
2. John is unable to sleep. He says he feels miserable and hopeless, and that he 'doesn't look forward to anything, each day is a challenge'. He has also lost weight and has a poor appetite.
3. His medication is:
   Co-codamol (30/500 mg) 2 tablets 4 times a day
   Laxidol (laxative) 1 sachet daily
4. He was able to give a clear history that a codeine and paracetamol combination worked within 40 minutes, but lasted for just an hour, reducing background pain from 10/10 to 8/10. John has normal biochemistry.

Which of the following did John's doctor suggest?

A. Stop co-codamol and start titration with a strong opioid to 5 mg of normal release morphine orally 6 times daily, with the same dose provided for breakthrough analgesia (1/6 of the total 24-hour dose). Advice with regard to continuing with the laxative and a metoclopramide made available in case of nausea. Arranged a review in 48 hours
B. As in answer A, but also continue with co-codamol
C. His doctor was concerned about commencing a strong opioid too soon, as John was not yet actively dying. So, he decided to try tramadol instead of co-codamol
D. In view of John's mood and inability to sleep, analgesia should be left unchanged; however, night sedation and an antidepressant can be introduced
E. The doctor knew it was important to control John's pain as quickly as possible, therefore slow-release morphine 60 mg 2 times daily was commenced

Answer: A.

Pain affects, and is affected by, many other symptoms and aspects of daily living. Time spent on the initial detailed assessment of all aspects of the patient is key to successful management. For John, rapid proposed solutions to his myriad of problems would only lead to therapeutic chaos. The key decision is what is the greatest driver of the symptoms and how does this potentially interact with other symptoms and distress.

Our patient had very severe pain with a strong neuropathic component, as would be expected from pressure on and/or invasion of the brachial plexus by the tumour. It is not surprising that he was not sleeping because of this extremely severe pain, and felt thoroughly miserable and hopeless. His poor appetite and weight loss could be a result of the uncontrolled pain; however, it could also be the result of the cancer process via a cachexia mechanism. It is important to recognise that neuropathic pain is particularly associated with mood disturbances.

When assessing complexities, it is important to ground decisions on information obtained directly from the patient. John was able to give a clear history that a codeine and paracetamol combination worked within 40 minutes but lasted for just an hour, and the clue here is that his pain was at least partially opioid responsive. It is critical not to move sideways on an analgesic ladder, and if maximum dose of codeine is not effective, the patient should move to a strong opioid, such as morphine. The usual starting dose in this situation of normal renal function and such severe pain should be 5 mg of normal release morphine orally 6 times daily. If starting modified-release morphine, the dose is 10–15 mg 2 times daily. For breakthrough analgesia, the dose is usually 1/6 of the total 24-hour dose, so 5 mg in this case. The patient should be advised that if breakthrough pain relief is required, it will take 30 minutes to start having an effect. The patient should be instructed to take a careful note of duration onset and duration of effect of the regular dose, and frequency of onset and duration and effect of the breakthrough dose.

9.5. John's analgesia was further titrated over the coming weeks to modified-release morphine 40 mg twice daily found that his background pain reduced from 10/10 to 6/10. He occasionally felt tired after taking immediate-release morphine but had no other significant side-effects. He was now increasingly troubled by pain related to anything touching the skin surface or movement of his right arm. Overnight this was also accompanied by a deep-seated burning pain in his right shoulder, which did not respond in any way to the last increase in his morphine doses. He was unable to sleep due to the pain and worsening anxiety around his deteriorating health, describing lying in bed with his thoughts racing.

What did John's doctor decide to do next?

A. Switch from morphine to oxycodone as morphine does not seem to work for John's pain
B. Continue with morphine at current doses and add in pregabalin 50 mg at night
C. Increase modified-release morphine dose to 60 mg twice daily
D. Commence ketamine for neuropathic pain
E. No changes to opioid regimen but add dexamethasone 8 mg/day for brachial plexus pressure

Answer: B.

There is a strong ongoing neuropathic element to John's pain. He likely has mixed cancer pain (somatic and neuropathic) with a partial response evident to adequately titrated morphine. There does not appear to be much benefit in further increasing his morphine given the last dose increment offered no subjective benefit for John. There is no evidence to support that oxycodone is any better for management of neuropathic cancer pain than morphine. At this point it would be acceptable to try adding an adjuvant analgesic to his established morphine regimen. It is important when considering an adjuvant analgesic to consider the potential side-effects of the drug itself and how it might interact with currently prescribed medications. Although adding dexamethasone may produce some analgesic benefit if there is nerve compression, it can interfere with people's ability to sleep and may exacerbate John's anxiety and racing thoughts. Ketamine is usually only considered for neuropathic pain once more commonly used adjuvants have been tried. Pregabalin has been shown to improve neuropathic pain in some individuals and also has anxiolytic calming properties which would potentially offer some relief from John's distress overnight. The combination of pregabalin and morphine can increase the risk of daytime somnolence, confusion and falls, so patient counselling, careful dose titration and review is essential.

9.6. A 45-year-old woman with metastatic colon cancer had her first cycle of chemotherapy 2 weeks ago and is due to attend again tomorrow for her next treatment. She was prescribed dexamethasone 4 mg twice daily for 3 days with her last cycle of chemotherapy to reduce the risks of nausea and vomiting. She has also been taking ondansetron 4 mg three times daily for the past 2 weeks. She developed severe nausea and vomiting after her first cycle, which resolved fully after 72 hours. She found this very distressing and required IV fluids to manage dehydration. When attending the oncology ward for pre-chemotherapy bloods this week, she became acutely nauseous on arrival but reports this settled once she got home. She has phoned the oncology department today to say she is nervous about coming to the hospital tomorrow and has developed worsening nausea again today. She has taken her prescribed ondansetron and a pre-chemo dose of dexamethasone 4 mg this morning. Her chemotherapy regimen for her upcoming 2nd cycle has been altered by her consultant to reduce the risk of nausea and vomiting.

What action did the oncology doctor take?

A. Instructed the patient to increase her dexamethasone dose to 8 mg twice daily to manage her nausea
B. Added regular metoclopramide 10 mg three times daily to the current ondansetron regimen
C. Prescribed omeprazole 20 mg twice daily
D. Prescribed lorazepam 1 mg to be taken the evening before chemotherapy and on the way to the hospital for treatment
E. Instructed the patient to increase her ondansetron dose to 8 mg three times daily

Answer: D.

The most likely cause of this patient's symptoms is anticipatory nausea and vomiting. Her first chemotherapy session led to severe nausea and vomiting, which caused her significant distress. That experience has led to a learned association between being in the hospital ward and feeling nauseous. This was evident when she attended for her blood tests and became nauseous, which has further reinforced this anxiety response to the location. She is now feeling nauseous even when thinking about attending the ward, which is closely tied in with her anxieties about further treatment. Anticipatory nausea and vomiting is mediated primarily by the neurotransmitter GABA (gamma-aminobutyric acid), and therefore using a benzodiazepine such as lorazepam may offer relief of symptoms.

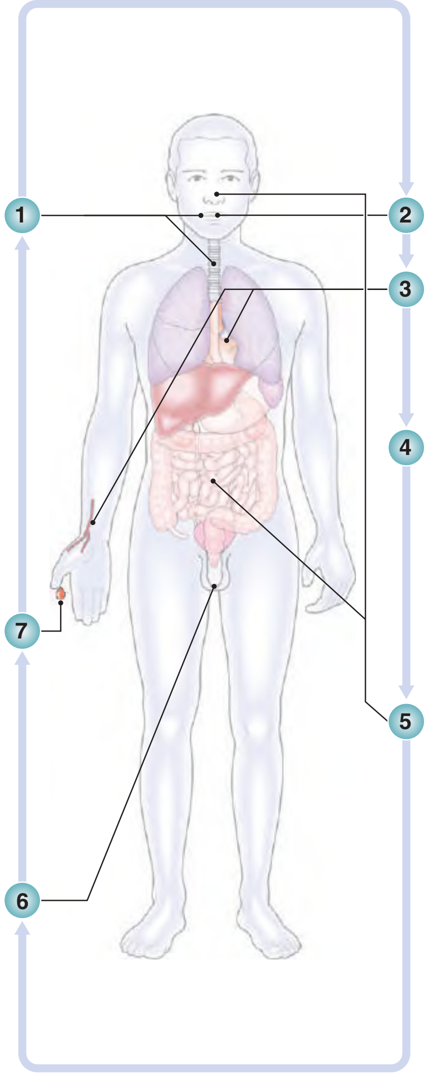
Clinical examination in critical care

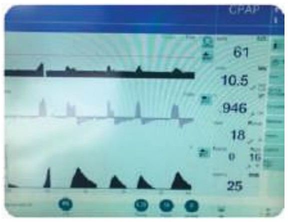


1 Airway

Is the airway patent?
Is the end-tidal CO_2 trace normal?
Are there any signs of airway obstruction?

2 Breathing

Is the physiology normal (SpO_2, respiratory rate, tidal volume)?
What is the level of support?
Are there any abnormal signs on chest examination?
Review the ventilator settings, arterial blood gases and recent chest X-ray



3 Circulation

Is the physiology normal (heart rate, blood pressure, peripheral temperature, lactate, urine output)?
How much support is required (inotrope, vasopressor)?

Normal
Bronchospasm
Partial obstruction/displacement of airway device
No ventilation (from any cause)

Electrocardiography
Heart rate, rhythm and QRS morphology

Arterial line trace
Size of the area under the curve is proportional to stroke volume
Narrow peaks suggest low stroke volume as shown here

Oxygen saturation
Saturation of haemoglobin measured by plethysmography (SpO_2). Gives an indication of adequacy of oxygenation, and the quality of tissue perfusion can also be inferred – a flat trace suggests poor peripheral perfusion

Central venous pressure trace
A non-specific guide to volume status and right ventricular function. Increased values in fluid overload and right ventricular failure

Capnography
Numerical value of end-tidal CO_2 ($ETCO_2$) is less than arterial PCO_2 ($PaCO_2$) by a variable amount. Shape of trace can signify airway displacement/obstruction, bronchospasm or a low cardiac output (as shown below)

Bedside physiological data commonly monitored in an intensive care unit setting.

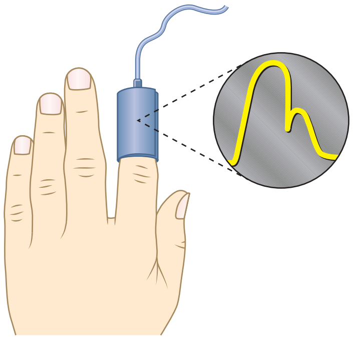
i Pulse oximetry (SpO_2)

Basic principles

- Uses the different red and infrared absorption profiles of oxyhaemoglobin and deoxyhaemoglobin to estimate arterial oxyhaemoglobin saturation (SaO_2)
- Only pulsatile absorption is measured
- A poor trace correlates with poor perfusion

Sources of error

- Race – SpO_2 (vs SaO_2) is overestimated in patients with darker skin. This is more pronounced at lower saturation levels. Desaturation can be under-estimated in patients with darker skin
- Carboxyhaemoglobin – absorption profile is the same as oxyhaemoglobin: falsely elevated SpO_2
- Methaemoglobinaemia – SpO_2 will tend towards 85% regardless of oxygen content
- Ambient light/poor application of probe/severe tricuspid regurgitation (pulsatile venous flow): falsely depressed SpO_2
- Reduced accuracy below 80% saturation
- Hyperbilirubinaemia does not affect SpO_2



Hospital medicine is becoming ever-more specialised and people are living longer while accruing increasing numbers of chronic disease diagnoses. Rather than diminishing the role of the generalist, these factors paradoxically create a need for experts in the undifferentiated presentation. In the UK such physicians are known as 'general physicians', while in the United States they are referred to as 'hospitalists'.

Acute illness can present in a large variety of ways, depending on the nature of the illness, the underlying health of the individual, and their cultural and religious background. The skills of prompt diagnosis formation and provision of appropriate treatment rely on the integration of information from all the available sources, along with careful consideration of underlying chronic health problems.

Patients who deteriorate while in hospital make up a small but important cohort. If they are well managed, in-hospital cardiac arrest rates will be low. This can be achieved through the combined effects of prompt resuscitation and appropriate end-of-life decision-making. Early recognition of deterioration by ward teams and initial management by healthcare professionals operating within a functioning rapid response system are the central tenets of any system designed to improve the outcomes of deteriorating ward patients.

Intensive care medicine has developed into a prominent specialty, central to the safe functioning of a modern acute hospital. Scientific endeavour has resulted in a much better understanding of the molecular pathophysiology of processes such as sepsis and acute respiratory distress syndrome, which account for much premature death worldwide.

Acute medicine

Acute medicine is the part of general medicine that is concerned with the immediate and early management of medical patients who require urgent care. As a specialty, it is closely aligned with emergency medicine and intensive care medicine, but is firmly rooted within general medicine. Acute physicians manage the adult medical take and lead the development of acute care pathways that aim to reduce variability, improve care and cut down hospital admissions. In order to achieve these aims, acute physicians must use their knowledge, combined with high-level clinical reasoning and decision-making skills, to minimise both diagnostic error and the risks of over-investigation. These concepts are explained more fully in Chapter 1.

The decision to admit to hospital

Every patient presenting to hospital should be assessed by a clinician who is able to determine whether or not admission is required. The requirement for admission is determined by many factors, including the severity of illness, the patient's physiological reserve, the need for urgent investigations, the nature of proposed treatments and the patient's social circumstances. In many cases, it is clear early in the assessment process that a patient requires admission. In such cases, a move into a medical receiving unit – often termed a medical admissions unit (MAU) or acute medical unit (AMU) – should be facilitated as soon as the initial assessment has been completed and urgent investigations and/or treatments have been instigated. In hospitals where such units do not exist, patients will need to be moved to a downstream ward once treatment has been commenced and they have been deemed sufficiently stable. In suspected cases of airborne-transmissible infectious diseases, patients should be isolated initially and may require cohorting in specific areas of the hospital once diagnoses have been confirmed. Following the initial assessment, it may be possible to discharge stable patients home with a plan for early follow-up (such as a rapid-access specialist clinic appointment).

Ambulatory care

In some hospitals, it is increasingly possible for patient care to be coordinated in an ambulatory setting, negating the need for a patient to remain in hospital overnight. In the context of acute medicine, ambulatory care can be employed for conditions that are perceived by either the patient or the referring practitioner as requiring prompt clinical assessment by a competent decision-maker with access to appropriate diagnostic resources. The patient may return on several occasions for investigation, observation, consultation or treatment. Some presentations, such as a unilateral swollen leg (p. 224), lend themselves to this type of management (Box 10.1). If indicated, a Doppler ultrasound can be arranged, and patients with confirmed deep vein thrombosis can be anticoagulated on an outpatient basis. Successful ambulatory care requires careful patient selection; while many patients may cherish the opportunity to sleep at home, others may find frequent trips to hospital or clinic too difficult due to frailty, poor mobility or transport difficulties.

Presenting problems in acute medicine

This section details some of the most common presentations to acute medicine. However, many people present to hospital with physical complaints that do not appear to be the symptoms of a medical condition, referred to as 'medically unexplained' or 'functional' symptoms (see Chs 22, 27 and 29). It is thought that such symptoms may account for up to half of all new visits to hospital in the UK. Rather than providing reassurance, a lack of understanding of the cause of the symptoms can result in more distress for patients. When the unexplained symptoms relate to the nervous system (such as limb weakness, numbness, shaking or blackouts), the term 'functional neurological disorder' is used (see p. 1183). Medically unexplained symptoms are more common in women, younger people, those who have previously suffered from depression or anxiety, recently bereaved people and those recovering from a recent physical illness. For every acute medical presentation, there will be a cohort of patients for whom the diagnosis remains elusive. In such circumstances, consideration should be given to the potential harm of over-investigation and the alternative approaches required to manage medically unexplained symptoms.

10.1 Groups of patients who are potentially suitable for ambulatory care

Group	Example(s)	Quality and safety issues
Diagnostic exclusion group	Chest pain – possible myocardial infarction; breathlessness – possible pulmonary embolism	Even when a specific condition has been excluded, there is still a need to explain the patient's symptoms through the diagnostic process
Low-risk stratification group	Non-variceal upper gastrointestinal bleed with low Blatchford score (Box 22.17); community-acquired pneumonia with low CURB-65 score (see Fig. 17.32)	Appropriate treatment plans should be in place
Specific procedure group	Replacement of percutaneous endoscopic gastrostomy (PEG) tube; drainage of pleural effusion/ascites	The key to implementation is how ambulatory care for this group of patients can be delivered when they present out of hours
Outpatient group with supporting infrastructure	Deep vein thrombosis (DVT); cellulitis	These are distinct from the conditions listed above because the infrastructure required to manage them is quite different

Chest pain

Chest pain is a common symptom in patients presenting to hospital. The differential diagnosis is wide (Box 10.2), and a detailed history and thorough clinical examination are paramount to ensure that the subsequent investigative pathway is appropriate.

Presentation

Chest 'pain' is clearly a subjective phenomenon and may be described by patients in a variety of different ways. Whether the patient describes 'pain', 'discomfort' or 'pressure' in the chest, there are some key features that must be elicited from the history.

Site and radiation

Pain secondary to myocardial ischaemia is typically located in the centre of the chest. It may radiate to the neck, jaw and upper or even lower arms. Occasionally, it may be experienced only at the sites of radiation or in the back. The pain of myocarditis or pericarditis is characteristically felt retrosternally, to the left of the sternum, or in the left or right shoulder. The severe pain of aortic dissection is typically central with radiation through to the back. Central chest pain may also occur with tumours affecting the mediastinum, oesophageal disease (p. 824) or disease of the thoracic aorta (p. 479). Pain situated over the left anterior chest and radiating laterally is unlikely to be due to cardiac ischaemia and may have many causes, including pleural or lung disorders, musculoskeletal problems or anxiety. Rarely, sharp, left-sided chest pain that is suggestive of a musculoskeletal problem may be a feature of mitral valve prolapse (p. 491).

10.2 Differential diagnosis of chest pain

Central

Cardiac

- Myocardial ischaemia (angina)
- Myocardial infarction
- Myocarditis
- Pericarditis
- Mitral valve prolapse syndrome

Aortic

- Aortic dissection
- Aortic aneurysm

Oesophageal

- Oesophagitis
- Oesophageal spasm
- Mallory–Weiss syndrome
- Oesophageal perforation (Boerhaave syndrome)

Pulmonary embolus

Mediastinal

- Malignancy

Anxiety/emotion[1]

Peripheral

Lungs/pleura

- Pulmonary infarct
- Pneumonia
- Pneumothorax
- Malignancy
- Tuberculosis
- Connective tissue disorders

Musculoskeletal[2]

- Osteoarthritis
- Rib fracture/injury
- Acute vertebral fracture
- Costochondritis (Tietze syndrome)
- Intercostal muscle injury
- Epidemic myalgia (Bornholm disease)

Neurological

- Prolapsed intervertebral disc
- Herpes zoster

[1] May also cause peripheral chest pain.
[2] Can sometimes cause central chest pain.

Characteristics

Pleurisy, a sharp or 'catching' chest pain aggravated by deep breathing or coughing, is indicative of respiratory pathology, particularly pulmonary infection or infarction. However, the pain associated with myocarditis or pericarditis is often also described as 'sharp' and may 'catch' during inspiration, coughing or lying flat. It typically varies in intensity with movement and the phase of respiration. A malignant tumour invading the chest wall or ribs can cause gnawing, continuous local pain. The pain of myocardial ischaemia is typically dull, constricting, choking or 'heavy', and is usually described as squeezing, crushing, burning or aching. Patients often emphasise that it is a discomfort rather than a pain. Angina occurs during (not after) exertion and is promptly relieved (in less than 5 minutes) by rest. It may also be precipitated or exacerbated by emotion but tends to occur more readily during exertion, after a large meal or in a cold wind. In crescendo or unstable angina, similar pain may be precipitated by minimal exertion or at rest. The increase in venous return or preload induced by lying down may also be sufficient to provoke pain in vulnerable patients (decubitus angina). Patients with reversible airways obstruction, such as asthma, may also describe exertional chest tightness that is relieved by rest. This may be difficult to distinguish from myocardial ischaemia. Bronchospasm may be associated with wheeze, atopy and cough (p. 537). Musculoskeletal chest pain is variable in site and intensity but does not usually fall into any of the patterns described above. The pain may vary with posture or movement of the upper body, or be associated with a specific movement (bending, stretching, turning). Many minor soft tissue injuries are related to everyday activities, such as driving, manual work and sport.

Onset

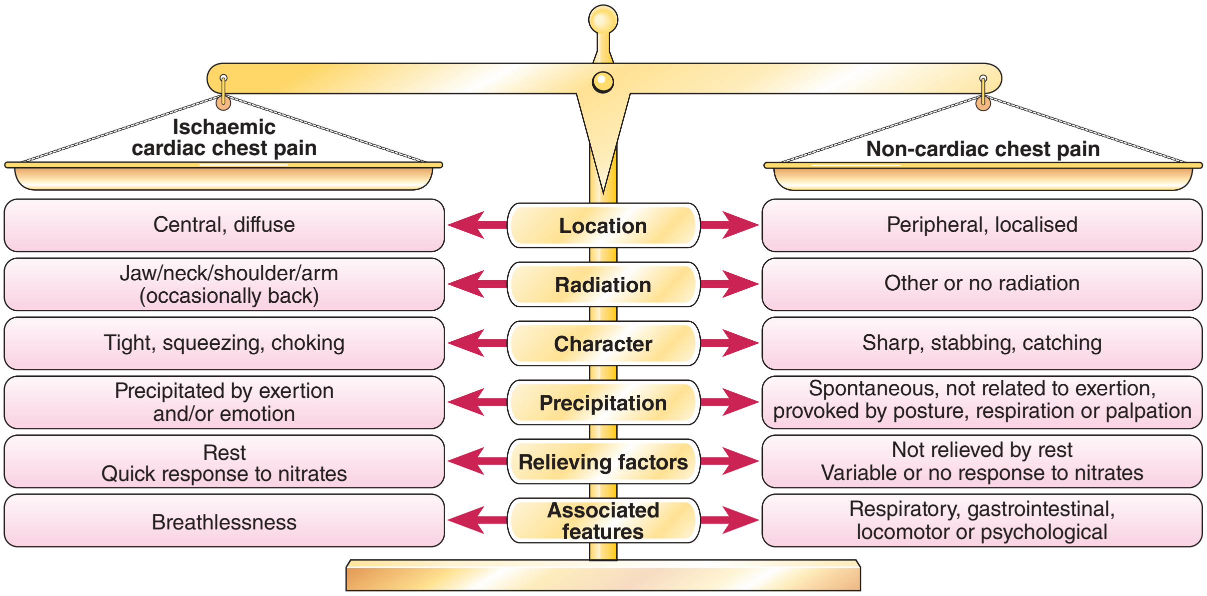
The pain associated with myocardial infarction (MI) typically takes several minutes or even longer to develop to its maximal intensity; similarly, angina builds up gradually in proportion to the intensity of exertion. Pain that occurs after, rather than during, exertion is usually musculoskeletal or psychological in origin. The pain of aortic dissection (severe and 'tearing'), massive pulmonary embolism (PE) or pneumothorax is usually very sudden in onset. Other causes of chest pain tend to develop more gradually, over hours or even days.

Associated features

The pain of MI, massive PE or aortic dissection is often accompanied by autonomic disturbance, including sweating, nausea and vomiting. Some patients describe a feeling of impending death, referred to as 'angor animi'. Breathlessness, due to pulmonary congestion arising from transient ischaemic left ventricular dysfunction, is often a prominent feature of myocardial ischaemia. Breathlessness may also accompany any of the respiratory causes of chest pain and can be associated with cough, wheeze or other respiratory symptoms. Patients with myocarditis or pericarditis may describe a prodromal viral illness. Gastrointestinal disorders, such as gastro-oesophageal reflux or peptic ulceration, may present with chest pain that is hard to distinguish from myocardial ischaemia; it may even be precipitated by exercise and be relieved by nitrates. However, it is usually possible to elicit a history relating chest pain to supine posture or eating, drinking or oesophageal reflux. The pain of gastro-oesophageal reflux often radiates to the interscapular region and dysphagia may be present. Severe chest pain arising after retching or vomiting, or following oesophageal instrumentation, should raise the possibility of oesophageal perforation.

Anxiety-induced chest pain may be associated with breathlessness (without hypoxaemia), throat tightness, perioral tingling and other evidence of emotional distress. It is important to remember, however, that chest pain itself can be an extremely frightening experience, and so psychological and organic features often coexist. Anxiety may amplify the effects of organic disease and a confusing clinical picture may result.

A detailed and clear history is key to narrowing the differential diagnosis of chest pain. Figure. 10.1 shows how certain features of the history, particularly when combined, can tip the balance of evidence towards or away from ischaemic cardiac chest pain.



Ischaemic cardiac chest pain
Non-cardiac chest pain
Central, diffuse
Location
Peripheral, localised
Jaw/neck/shoulder/arm (occasionally back)
Radiation
Other or no radiation
Tight, squeezing, choking
Character
Sharp, stabbing, catching
Precipitated by exertion and/or emotion
Precipitation
Spontaneous, not related to exertion, provoked by posture, respiration or palpation
Rest
Quick response to nitrates
Relieving factors
Not relieved by rest
Variable or no response to nitrates
Breathlessness
Associated features
Respiratory, gastrointestinal, locomotor or psychological

Fig. 10.1 **Identifying ischaemic cardiac pain: the 'balance' of evidence.**

Clinical assessment

Cardiorespiratory examination may detect clinical signs that help guide ongoing investigation. Patients with a history compatible with myocardial ischaemia should have a 12-lead electrocardiogram (ECG) performed while clinical examination proceeds. Ongoing chest pain with clinical features of shock or pulmonary oedema, or ECG evidence of ventricular arrhythmia or complete heart block, should prompt urgent cardiology review and referral to a higher level of care.

Chest pain that is accompanied by clinical evidence of increased intracardiac pressure (especially a raised jugular venous pressure) increases the likelihood of myocardial ischaemia or massive PE. The legs should be examined for clinical evidence of deep vein thrombosis.

A large pneumothorax should be evident on clinical examination, with absent breath sounds and a hyper-resonant percussion note on the affected side. Other unilateral chest signs, such as bronchial breathing or crackles, are most likely to indicate a respiratory tract infection, and a chest X-ray should be expedited.

Pericarditis may be accompanied by a pericardial friction rub. In aortic dissection, syncope or neurological deficit may occur. Examination may reveal asymmetrical pulses, features of undiagnosed Marfan syndrome (p. 481) or a new early diastolic murmur representing aortic regurgitation.

Any disease process involving the pleura may restrict rib movement and a pleural rub may be audible on the affected side. Local tenderness of the chest wall is likely to indicate musculoskeletal pain but can also be found in pulmonary infarction.

Subdiaphragmatic inflammatory pathology, such as a liver abscess, cholecystitis or ascending cholangitis, can mimic pneumonia by causing fever, pleuritic chest pain and a small sympathetic pleural effusion, usually on the right. Likewise, acute pancreatitis can present with thoracic symptoms, and an amylase or lipase level should be requested where appropriate. It is imperative that the abdomen is examined routinely in all patients presenting with pleuritic chest pain.

Initial investigations

Chest X-ray, ECG and biomarkers (e.g. troponin, D-dimer) play a pivotal role in the evaluation of chest pain. However, indiscriminate ordering of such investigations may result in diagnostic confusion and over-investigation. The choice of investigation(s) is intimately linked to the history and examination findings. A chest X-ray and 12-lead ECG should be performed in the vast majority of patients presenting to hospital with chest pain. Pregnancy is not a contraindication to chest X-ray, but particular consideration should be given to whether the additional diagnostic information justifies breast irradiation.

The chest X-ray may confirm the suspected diagnosis, particularly in the case of pneumonia. Small pneumothoraces are easily missed, as are rib fractures or small metastatic deposits, and all should be considered individually during chest X-ray review. A widened mediastinum suggests acute aortic dissection, but a normal chest X-ray does not exclude the diagnosis. Provided it has been more than 1 hour since the onset of pain, chest X-ray in oesophageal rupture may reveal subcutaneous emphysema, pneumomediastinum or a pleural effusion.

Patients with a history compatible with myocardial ischaemia require an urgent 12-lead ECG. Acute chest pain with ECG changes indicating an ST segment elevation myocardial infarction (STEMI) suggests that the patient is likely to benefit from immediate reperfusion therapy. Specific information relating to cocaine or amphetamine use should be sought, particularly in younger patients. In the context of a compatible history, an ECG showing ischaemic changes that do not meet STEMI criteria should prompt regular repeat ECGs and treatment for non-ST segment elevation myocardial infarction (NSTEMI)/unstable angina. Measurement of serum troponin concentration on admission is often helpful in cases where there is diagnostic doubt, but a negative result should always prompt a repeat sample 6–12 hours after maximal pain. Acute coronary syndrome may be diagnosed with confidence in patients with a convincing history of ischaemic pain (see Fig. 10.1) and either ECG evidence of ischaemia or an elevated serum troponin. If an elevated serum troponin is found in a patient who has an atypical history or is at low risk of ischaemic heart disease, then alternative causes of raised troponin should be considered (Box 10.3). Further management of acute coronary syndromes is discussed on page 468.

In the absence of convincing ECG evidence of myocardial ischaemia, other life-threatening causes of chest pain, such as aortic dissection, massive PE and oesophageal rupture, should be considered. Suspicion of aortic dissection (background of hypertension, trauma, pregnancy or previous aortic surgery) should prompt urgent thoracic computed tomography (CT) or transoesophageal echocardiography. An ECG in the context of massive PE most commonly reveals only a sinus tachycardia, but may show new right axis deviation, right bundle branch block or a dominant R wave in V_1. The classical finding of $S_1Q_3T_3$ (a deep S wave in lead I, with a Q wave and T wave inversion in lead III) is rare. If massive PE is suspected and the patient is haemodynamically unstable, a transthoracic echocardiogram, to seek evidence of right heart strain and exclude alternative diagnoses such as tamponade, is extremely useful.

i 10.3 Causes of elevated serum troponin other than acute coronary syndrome

Cardiorespiratory causes

- Pulmonary embolism
- Acute pulmonary oedema
- Tachyarrhythmias
- Myocarditis/myopericarditis
- Aortic dissection
- Cardiac trauma
- Cardiac surgery/ablation

Non-cardiorespiratory causes

- Prolonged hypotension
- Severe sepsis
- Severe burns
- Stroke
- Subarachnoid haemorrhage
- End-stage renal failure

If the patient is deemed to be at low risk of PE, a D-dimer test can be informative, as a negative result effectively excludes the diagnosis. The D-dimer test should be performed only if there is clinical suspicion of PE, as false-positive results can lead to unnecessary investigations. If the D-dimer is positive, there is high clinical suspicion, or there is other convincing evidence of PE (such as features of right heart strain on the ECG), prompt imaging should be arranged (p. 586 and Fig. 17.66).

Acute breathlessness

In acute breathlessness, the history, along with a rapid but careful examination, will usually suggest a diagnosis that can be confirmed by routine investigations including chest X-ray, 12-lead ECG and arterial blood gas (ABG) sampling.

Presentation

A key feature of the history is the speed of onset of breathlessness. Acute severe breathlessness (over minutes or hours) has a distinct differential diagnosis list to chronic exertional breathlessness. The presence of associated cardiovascular (chest pain, palpitations, sweating and nausea) or respiratory (cough, wheeze, haemoptysis, stridor) symptoms can narrow the differential diagnosis yet further. A previous history of left ventricular dysfunction, asthma or exacerbations of chronic obstructive pulmonary disease (COPD) is important. A high temperature, cough (productive or non-productive) and/or viral prodrome may indicate respiratory infection and, if so, relevant infection control precautions should be taken from initial assessment. In the severely ill patient, it may be necessary to obtain the history from accompanying witnesses. In children, the possibility of inhalation of a foreign body (Fig. 10.2) or acute epiglottitis should always be considered. There is often more than one underlying diagnosis; a thorough assessment should continue, even after a possible diagnosis has been reached, particularly if the severity of symptoms does not seem to be adequately explained. The causes of acute severe breathlessness are covered here; chronic exertional dyspnoea is discussed further on page 528.

Clinical assessment

Airway obstruction, anaphylaxis and tension pneumothorax require immediate identification and treatment. If any of these is suspected, treatment should not be delayed while additional investigations are performed, and anaesthetic support is likely to be required. In the absence of an immediately life-threatening cause, the following should be assessed and documented:

- level of consciousness
- degree of central cyanosis
- work of breathing (rate, depth, pattern, use of accessory muscles)
- adequacy of oxygenation (SpO_2)
- ability to speak (in single words or sentences)
- cardiovascular status (heart rate and rhythm, blood pressure (BP) and peripheral perfusion).

Pulmonary oedema is suggested by a raised jugular venous pressure and bi-basal crackles or diffuse wheeze, while asthma or COPD is characterised by wheeze and prolonged expiration. A hyper-resonant hemithorax with absent breath sounds raises the possibility of pneumothorax, while severe breathlessness with normal breath sounds may indicate PE. Leg swelling may suggest cardiac failure or, if asymmetrical, venous thrombosis.

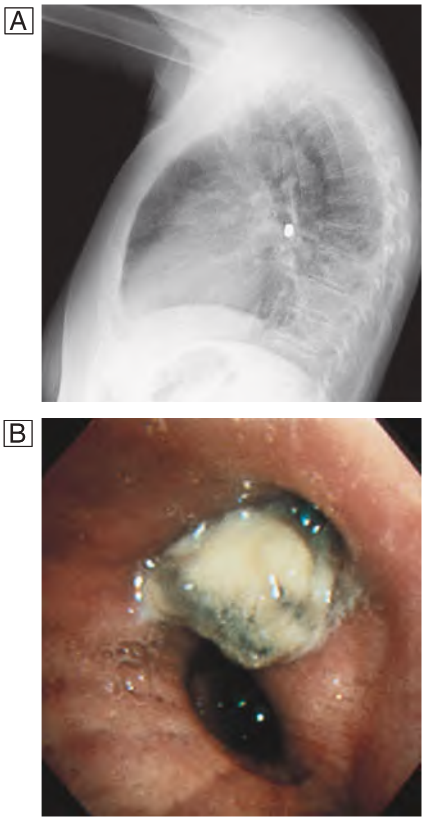


Fig. 10.2 Inhaled foreign body. **A** Chest X-ray showing a tooth lodged in a main bronchus. **B** Bronchoscopic appearance of inhaled foreign body (tooth) with a covering mucous film.

The presence of wheeze is not always indicative of bronchospasm. In acute left heart failure, an increase in the left ventricular diastolic pressure causes the pressure in the left atrium, pulmonary veins and pulmonary capillaries to rise. When the hydrostatic pressure of the pulmonary capillaries exceeds the oncotic pressure of plasma (about 25–30 mmHg), fluid moves from the capillaries into the interstitium. This stimulates respiration through a series of autonomic reflexes, producing rapid respiration, and congestion of the bronchial mucosa may cause wheeze (sometimes known as cardiac asthma). Sitting upright or standing may provide some relief by helping to reduce congestion at the apices of the lungs. The patient may be unable to speak and is typically distressed, agitated, sweaty and pale. Respiration is rapid, with recruitment of accessory muscles, coughing and wheezing. Sputum may be profuse, frothy and blood-streaked or pink. Extensive crepitations and rhonchi are usually audible in the chest, and there may also be signs of right heart failure.

Any arrhythmia may cause breathlessness, but usually does so only if the heart is structurally abnormal, such as with the onset of atrial fibrillation in a patient with mitral stenosis. In such cases, the classic mid-diastolic rumbling murmur may be heard. Patients sometimes describe chest tightness as 'breathlessness'. However, myocardial ischaemia may also induce true breathlessness by provoking transient left ventricular dysfunction. When breathlessness is the dominant or sole feature of myocardial ischaemia, it is known as 'angina equivalent'. A history of chest tightness or close correlation with exercise should be sought.

Initial investigations

As shown in Box 10.4, amalgamation of a clear history and thorough clinical examination with chest X-ray, ECG and ABG findings

i 10.4 Clinical features in acute breathlessness

Condition	History	Signs	Chest X-ray	ABG	ECG
Pulmonary oedema	Chest pain, palpitations, orthopnoea, cardiac history*	Central cyanosis, ↑JVP, sweating, cool extremities, basal crackles*	Cardiomegaly, oedema/pleural effusions*	$\downarrow PaO_2 \downarrow PaCO_2$	Sinus tachycardia, ischaemia*, arrhythmia
Massive pulmonary embolus	Risk factors, chest pain, pleurisy, syncope*, dizziness*	Central cyanosis, ↑JVP*, absence of signs in the lung*, shock (tachycardia, hypotension)	Often normal Prominent hilar vessels, oligaemic lung fields*	$\downarrow PaO_2$ $\downarrow PaCO_2$	Sinus tachycardia, RBBB, $S_1Q_3T_3$ pattern $\uparrow T(V_1–V_4)$
Acute severe asthma	History of asthma, asthma medications, wheeze*	Tachycardia, pulsus paradoxus, cyanosis (late), silent chest/cyanosis (late)*, ↓peak flow, wheeze*	Hyperinflation only (unless complicated by pneumothorax)*	$\downarrow PaO_2$ Normal $PaCO_2$ ($\uparrow PaCO_2$ in extremis)	Sinus tachycardia (bradycardia in extremis)
Acute exacerbation of COPD	Previous episodes*, smoker. If in type II respiratory failure, may be drowsy	Cyanosis, hyperinflation*, signs of CO_2 retention (flapping tremor, bounding pulses)*	Hyperinflation*, bullae, complicating pneumothorax	or $\downarrow\downarrow PaO_2$ $\uparrow PaCO_2$ in type II failure $\pm \uparrow H^+$, $\uparrow HCO_3^-$ in chronic type II failure	Normal, or signs of right ventricular strain
Pneumonia/lower respiratory tract infection	Prodromal illness*, fever*, rigors*, pleurisy*	Fever, delirium, pleural rub*, consolidation*, cyanosis (if severe)	Pneumonic consolidation*	$\downarrow PaO_2$ $\downarrow PaCO_2$ (↑ in extremis)	Tachycardia
Metabolic acidosis	Evidence of diabetes mellitus or renal disease, aspirin or ethylene glycol overdose	Fetor (ketones), hyperventilation without heart or lung signs*, dehydration*, air hunger	Normal	PaO_2 normal $\downarrow\downarrow PaCO_2$, $\uparrow H^+$ $\downarrow HCO_3^-$	
Psychogenic	Previous episodes, digital or perioral dysaesthesia	No cyanosis, no heart or lung signs, carpopedal spasm	Normal	PaO_2 normal* $\downarrow\downarrow PaCO_2$, $\downarrow H^+$*	

*Valuable discriminatory feature.
(ABG = arterial blood gas; COPD = chronic obstructive pulmonary disease; JVP = jugular venous pressure; RBBB = right bundle branch block)

will usually indicate the primary cause of breathlessness. In cases of suspected infection, a viral throat swab should be obtained early in the course of the assessment; increasingly, point-of-care testing of viral throat swabs is available, providing important and rapid diagnostic information. If available, sputum should be sent for culture. If bronchospasm is suspected, measurement of peak expiratory flow will assist in the assessment of severity and should be performed whenever possible.

An ABG will often provide additional information to SpO_2 measurement alone, particularly if there is clinical evidence (drowsiness, delirium, asterixis) or a strong likelihood of hypercapnia. An acute rise in $PaCO_2$ will increase the HCO_3^- by only a small amount, resulting in inadequate buffering and acidaemia. Renal compensation and a large rise in HCO_3^- will take at least 12 hours. In acute type II respiratory failure (p. 535), the rate of rise of $PaCO_2$ is a better indicator of severity than the absolute value. An ABG can also give a carboxyhaemoglobin level after smoke inhalation (although this can also be measured on a venous sample), and is central to the identification of metabolic acidosis or the diagnosis of psychogenic hyperventilation (see Box 10.4).

If pulmonary embolism is suspected, calculating pre-test probability (see Ch. 1) is key. In a patient with a pre-test probability of less than 15%, the pulmonary embolism rule-out criteria (PERC) can exclude pulmonary embolism clinically, negating the need for further imaging, if none of the criteria listed in Box 10.5 are met. Further detail on the investigation and management of pulmonary embolus is given on page 586.

Procalcitonin (PCT) and N-terminal pro-hormone brain natriuretic protein (NT-proBNP) can be measured in venous blood. While these biomarkers can give an indication of aetiology in shortness of breath, they are probably of more value in tracking clinical progression and response to treatment. Elevated PCT is a biomarker for bacterial infection and may be useful, in addition to clinical assessment, in helping decide the need for and duration of antibiotic therapy in patients with confirmed viral respiratory disease (such as COVID-19) who may have additional bacterial super-infection. Elevated NT-proBNP is suggestive of underlying left ventricular failure (p. 429), although it can be elevated in other conditions such as renal failure, COPD, pulmonary hypertension and pulmonary embolism. Measurement of NT-proBNP may be considered if there is no clear-cut evidence of pulmonary oedema on a chest X-ray and can be particularly useful as a 'rule-out' test, as a normal NT-proBNP has high negative predictive value for heart failure. Individuals with suspected heart failure should undergo early echocardiography.

CT imaging (with or without pulmonary angiography) is a useful investigation in many respiratory conditions as interstitial changes, tumours or consolidation may not be evident on chest X-ray. If breathlessness is suspected to be an 'angina equivalent', objective evidence of myocardial ischaemia from stress testing may help to establish the diagnosis, although coronary artery angiography (either by CT or cardiac catheterisation) is often performed early in the investigation pathway.

i 10.5 PERC rule for pulmonary embolism

Rules out PE if none of the eight criteria is present and pre-test probability is less than or equal to 15%*

- Age ≥ 50
- Heart rate ≥ 100
- Oxygen saturation on room air < 95%
- Unilateral leg swelling
- Haemoptysis
- Recent surgery or trauma (≤ 4 weeks ago requiring hospitalisation)
- Prior venous thromboembolism (VTE)
- Hormone use (oral contraceptives), hormone replacement or oestrogenic hormone use in male or female patients

*A false-negative level of <1.8% was chosen as the point of equipoise between the benefits and risks of further investigations for PE, and the benefits and risks of not investigating further.

Anaphylaxis

Anaphylaxis is a potentially life-threatening, systemic allergic reaction characterised by a variable combination of circulatory collapse, bronchospasm, laryngeal stridor, angioedema and urticaria. The risk of death is increased in patients with pre-existing asthma, particularly if this is poorly controlled, and in situations where treatment with adrenaline (epinephrine) is delayed.

Presentation

Anaphylaxis occurs when an allergen binds to and cross-links membrane-bound IgE on mast cells in a susceptible individual, causing release of histamine, tryptase and other vasoactive mediators from mast cells. These mediators have a variety of effects, including vasodilatation, increased capillary permeability leading to hypotension, and bronchoconstriction. It can be difficult to distinguish IgE-mediated anaphylaxis clinically from non-specific degranulation of mast cells on exposure to drugs, chemicals or other triggers where IgE is not involved, previously known as anaphylactoid reactions.

Clinical assessment

The clinical features of anaphylaxis are summarised in Figure 10.3. Several other conditions can mimic anaphylaxis and these are listed in Box 10.6.

It is important to assess the severity of the reaction, and the time between allergen exposure and onset of symptoms provides a guide. Enquiry should be made about potential triggers. If a trigger is immediately obvious, a detailed history of the previous 24 hours may be helpful. The most common triggers of anaphylaxis are foods, latex, insect venom and drugs. A history of previous local allergic responses to the offending agent is common. The route of allergen exposure may influence the principal clinical features of a reaction; for example, if an allergen is inhaled, the major symptom is frequently wheezing. Features of anaphylaxis may overlap with the direct toxic effects of drugs and venoms (Chs 11 and 12). Potentiating factors, such as exercise, alcohol, nonsteroidal anti-inflammatory medications or fatigue, can lower the threshold for an anaphylactic event. It is important to identify precipitating factors so that appropriate avoidance measures may be taken in the longer term.

Investigations and management

Measurement of serum mast cell tryptase concentrations is useful to confirm the diagnosis. It is important to measure tryptase in serial tests to demonstrate the temporal relationship to the triggering event. Specific IgE tests may be useful in confirming hypersensitivity and may be preferable to skin-prick tests when investigating patients with a history of anaphylaxis. The cornerstone of management of a severe case is the early administration of adrenaline (epinephrine), which supports the cardiovascular system, reduces bronchospasm and has some disease-modifying effects. Secondary management depends upon which organs are most affected. The emergency management of anaphylaxis is summarised in Box 10.7. If present, angioedema of the orofacial area requires careful observation and timely intervention, possibly with endotracheal intubation. The investigation and management of angioedema is discussed further on page 81.

Individuals who have recovered from an anaphylactic event should be referred for specialist assessment. The aims are to identify the trigger, educate the patient regarding avoidance and management of subsequent episodes, and to establish whether specific treatment, such as immunotherapy, is indicated. If the trigger factor cannot be identified or avoided, recurrence is common. Patients who have previously experienced an anaphylactic event should be prescribed self-injectable

10.6 Differential diagnosis of anaphylaxis

Causes of hypotension

- Vasovagal syncope
- Cardiac arrhythmia
- Cardiogenic shock

Causes of respiratory distress

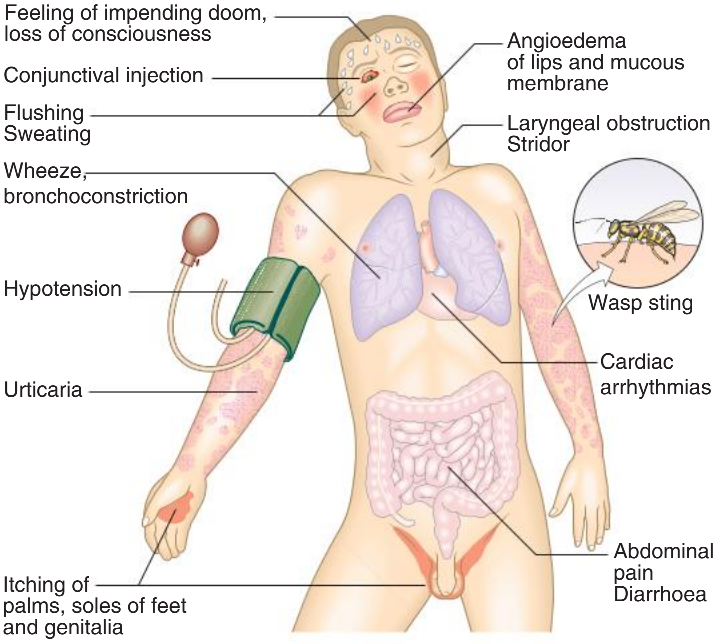
- Status asthmaticus
- Pulmonary embolus

Causes of laryngeal obstruction

- C1 inhibitor deficiency
- Idiopathic angioedema

Causes of generalised flushing

- Systemic mastocytosis
- Carcinoid syndrome



Feeling of impending doom, loss of consciousness
Conjunctival injection
Flushing
Sweating
Wheeze, bronchoconstriction
Hypotension
Urticaria
Itching of palms, soles of feet and genitalia
Angioedema of lips and mucous membrane
Laryngeal obstruction
Stridor
Wasp sting
Cardiac arrhythmias
Abdominal pain
Diarrhoea

Fig. 10.3 Clinical manifestations of anaphylaxis. In this example, the response is to an insect sting containing venom to which the patient is allergic. This causes release of histamine and other vasoactive mediators, which lead to the characteristic features of anaphylaxis that are illustrated.

10.7 Emergency management of anaphylaxis in adults

Treatment	Comment
Prevent further contact with allergen	Prevents ongoing mast cell activation
Ensure airway patency	Prevents hypoxia
Administer adrenaline (epinephrine) promptly: 0.5 mL 1 : 1000 solution IM (0.5 mg)	Intramuscular route important because of peripheral vasoconstriction Acts within minutes Increases blood pressure Reverses bronchospasm
If initial response is inadequate after 5 minutes, administer:	
Further IM bolus of 0.5 mg adrenaline (epinephrine)	
500–1000 mL IV crystalloid	Restores plasma volume
Provide supportive treatment:	
Nebulised adrenaline (epinephrine) (e.g. 3 mg)	Reduces airway oedema
Nebulised β_2-agonists (e.g. salbutamol 5 mg)	Reverses bronchospasm
Oxygen	Reverses hypoxia

In refractory cases, early expert help and critical care support are vital. IM adrenaline (epinephrine) should be given every 5 minutes; a low dose IV infusion may be needed. Further boluses of IV crystalloid may also be needed.
(IM = intramuscular; IV = intravenous)

adrenaline (epinephrine) and they and their families or carers should be instructed in its use (Box 10.8). The use of a MedicAlert (or similar) bracelet will increase the likelihood of the injector being administered in an emergency. There is an important role for a specialist dietitian when a food trigger is the suspected allergen. Allergy in adolescence requires additional consideration and management, as set out in Box 10.9.

Syncope/presyncope

The term ‘syncope’ refers to sudden loss of consciousness due to reduced cerebral perfusion. ‘Presyncope’ refers to lightheadedness, in which the individual thinks they may ‘black out’. Dizziness and presyncope are particularly common in old age (Box 10.10). Symptoms are disabling, undermine confidence and independence, and can affect a person’s ability to work or to drive.

There are three principal mechanisms that underlie recurrent presyncope or syncope:

- *cardiac syncope* due to mechanical cardiac dysfunction or arrhythmia
- *neurocardiogenic syncope (also known as vasovagal or reflex syncope)*, in which an abnormal autonomic reflex causes bradycardia and/or hypotension
- *postural hypotension*, in which physiological peripheral vasoconstriction on standing is impaired, leading to hypotension.

There are, however, other causes of loss of consciousness, and differentiating syncope from seizure is a particular challenge. Psychogenic blackouts (also known as psychogenic non-epileptiform seizures, or dissociative disorder) also need to be considered in the differential diagnosis.

10.8 How to prescribe self-injectable adrenaline (epinephrine)

Prescription (normally initiated by an immunologist or allergist)

- Specify the brand of autoinjector, as they have different triggering mechanisms
- Prescribe two devices

Indications

- Anaphylaxis to allergens that are difficult to avoid:
  - Insect venom
  - Foods
- Idiopathic anaphylactic reactions
- History of severe localised reactions with high risk of future anaphylaxis:
  - Reaction to trace allergen
  - Likely repeated exposure to allergen
- History of severe localised reactions with high risk of adverse outcome:
  - Poorly controlled asthma
  - Lack of access to emergency care

Patient and family education

- Know when and how to use the device
- Carry the device at all times
- Seek medical assistance immediately after use
- Wear an alert bracelet or necklace
- Include the school in education for young patients

Other considerations

- Caution with β-adrenoceptor antagonists (β-blockers) in patients with anaphylaxis as they may increase the severity of an anaphylactic reaction and reduce the response to adrenaline (epinephrine)

10.9 Allergy in adolescence

- **Resolution of childhood allergy**: most children affected by allergy to milk, egg, soybean or wheat will grow out of their food allergies by adolescence, but allergies to peanuts, tree nuts, fish and shellfish are frequently life-long.
- **Risk-taking behaviour and fatal anaphylaxis**: serious allergy is increasingly common in adolescents and this is the highest risk group for fatal, food-induced anaphylaxis. This is associated with increased risk-taking behaviour, and food-allergic adolescents are more likely than adults to eat unsafe foods, deny reaction symptoms and delay emergency treatment.
- **Emotional impact of food allergies**: some adolescents may neglect to carry a prescribed adrenaline (epinephrine) autoinjector because of the associated nuisance and/or stigma. Surveys of food-allergic teenagers reveal that many take risks because they feel socially isolated by their allergy.

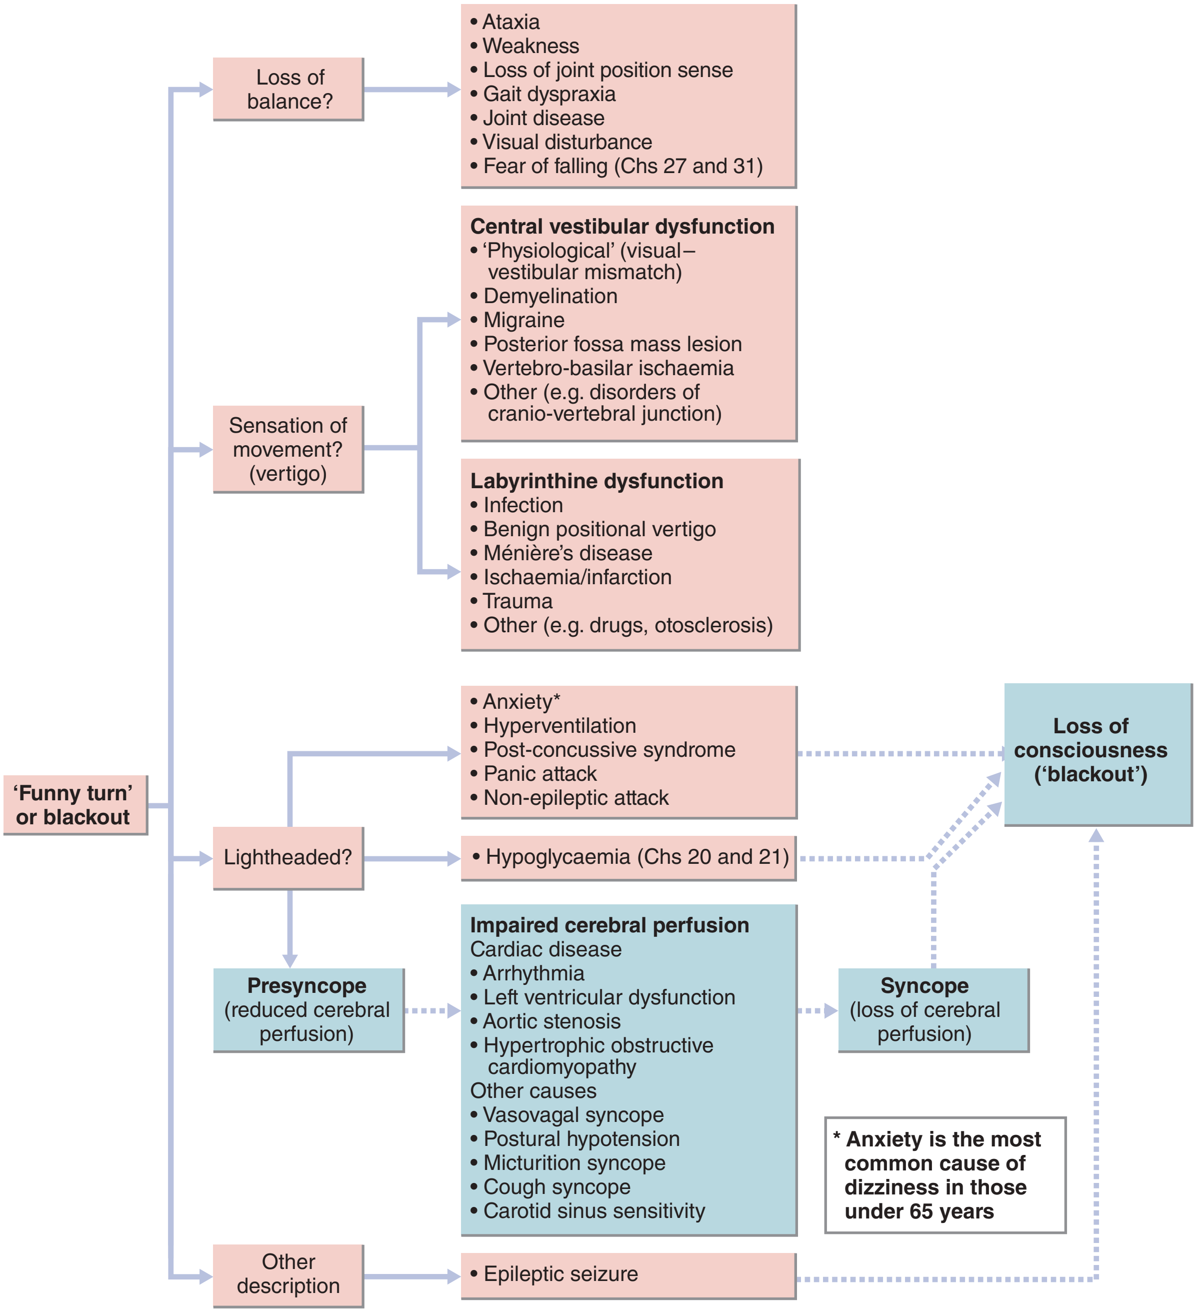
10.10 Dizziness in old age

- **Prevalence**: common, affecting up to 30% of people aged > 65 years.
- **Symptoms**: most frequently described as a combination of unsteadiness and lightheadedness.
- **Most common causes**: postural hypotension and cardiovascular disease. Many patients have more than one underlying cause.
- **Arrhythmia**: can present with lightheadedness either at rest or on activity.
- **Anxiety**: frequently associated with dizziness but rarely the only cause.
- **Falls**: multidisciplinary workup is required if dizziness is associated with falls.

Presentation

The history from the patient *and* a witness is the key to establishing a diagnosis. The terms used for describing the symptoms associated with syncope vary so much among patients that they should not be taken for granted. Some patients use the term ‘blackout’ to describe a purely visual symptom, rather than loss of consciousness. Some may understand ‘dizziness’ to mean an abnormal perception of movement (vertigo), some will consider this a feeling of faintness, and others will regard it as unsteadiness. The clinician thus needs to elucidate the exact nature of the symptoms that the patient experiences. The potential differential diagnosis of syncope and presyncope, on the basis of the symptoms described, is shown in Figure 10.4.

The history should always be supplemented by a direct eye-witness account if available. Careful history with corroboration will usually establish whether there has been full consciousness, altered consciousness, vertigo, transient amnesia or something else. Attention should be paid to potential triggers (e.g. medication, micturition, exertion, prolonged standing), the patient’s appearance (e.g. colour, seizure activity), the duration of the episode, and the speed of recovery (Box 10.11). Cardiac syncope is usually sudden, but can be associated with premonitory



'Funny turn' or blackout
Loss of balance?
• Ataxia
• Weakness
• Loss of joint position sense
• Gait dyspraxia
• Joint disease
• Visual disturbance
• Fear of falling (Chs 27 and 31)
Sensation of movement? (vertigo)
Central vestibular dysfunction
• 'Physiological' (visual–vestibular mismatch)
• Demyelination
• Migraine
• Posterior fossa mass lesion
• Vertebro-basilar ischaemia
• Other (e.g. disorders of cranio-vertebral junction)
Labyrinthine dysfunction
• Infection
• Benign positional vertigo
• Ménière's disease
• Ischaemia/infarction
• Trauma
• Other (e.g. drugs, otosclerosis)
Lightheaded?
• Anxiety*
• Hyperventilation
• Post-concussive syndrome
• Panic attack
• Non-epileptic attack
• Hypoglycaemia (Chs 20 and 21)
Loss of consciousness ('blackout')
Presyncope (reduced cerebral perfusion)
Impaired cerebral perfusion
Cardiac disease
• Arrhythmia
• Left ventricular dysfunction
• Aortic stenosis
• Hypertrophic obstructive cardiomyopathy
Other causes
• Vasovagal syncope
• Postural hypotension
• Micturition syncope
• Cough syncope
• Carotid sinus sensitivity
Syncope (loss of cerebral perfusion)
* Anxiety is the most common cause of dizziness in those under 65 years
Other description
• Epileptic seizure

Fig. 10.4 The differential diagnosis of syncope and presyncope.

lightheadedness, palpitation or chest discomfort. The blackout is usually brief and recovery rapid. Exercise-induced syncope can be the presenting feature of a number of serious pathologies (such as hypertrophic obstructive cardiomyopathy or exercise-induced arrhythmia) and always requires further investigation. Neurocardiogenic syncope will often be associated with a situational trigger (such as pain or emotion), and the patient may experience flushing, nausea, malaise and clamminess for several minutes afterwards. Recovery is usually quick and without subsequent delirium, provided the patient has assumed a supine position. There is often some brief stiffening and limb-twitching, which requires differentiation from seizure-like movements. It is rare for syncope to cause injury or to cause amnesia after regaining awareness. Patients with seizures do not exhibit pallor, may have abnormal movements, usually take more than 5 minutes to recover and are often confused. Aspects of the history that can help to differentiate seizure from syncope are shown in Box 10.12.

A diagnosis of psychogenic blackout (also known as non-epileptic seizure, pseudoseizure or psychogenic seizure) may be suggested by specific emotional triggers, dramatic movements or vocalisation, or by very prolonged duration (hours). A history of rotational vertigo is suggestive of a labyrinthine or vestibular disorder (p. 1174). Postural hypotension is normally obvious from the history, with presyncope or, less commonly, syncope occurring within a few seconds of standing. The history should include enquiry about predisposing medications (diuretics, vasodilators, antidepressants) and conditions (such as diabetes mellitus and Parkinson disease).

Clinical assessment

Examination of the patient may be entirely normal, but may reveal clinical signs that favour one form of syncope. The systolic murmurs of aortic stenosis or hypertrophic obstructive cardiomyopathy are important findings, particularly if paired with a history of lightheadedness or syncope

10.11 Typical features of cardiac syncope, neurocardiogenic syncope and seizures

	Cardiac syncope	Neurocardiogenic syncope	Seizures
Premonitory symptoms	Often none Lightheadedness Palpitation Chest pain Breathlessness	Nausea Lightheadedness Sweating	Delirium Hyperexcitability Olfactory hallucinations 'Aura'
Unconscious period	Extreme 'death-like' pallor	Pallor	Prolonged (> 1 min) unconsciousness Motor seizure activity* Tongue-biting Urinary incontinence
Recovery	Rapid (< 1 min) Flushing	Rapid Nausea Lightheadedness	Prolonged delirium (> 5 mins) Headache Focal neurological signs

*N.B. Cardiac syncope can also cause convulsions by inducing cerebral anoxia.

10.12 How to differentiate seizures from syncope

	Seizure	Syncope
Aura (e.g. olfactory)	+	−
Cyanosis	+	−
Lateral tongue-biting	+	−/+
Post-ictal delirium	+	−
Post-ictal amnesia	+	−
Post-ictal headache	+	−
Rapid recovery	−	+

on exertion. BP taken when supine and then after 1 and 3 minutes of standing may, when combined with symptoms, provide robust evidence of symptomatic postural hypotension.

Clinical suspicion of hypersensitive carotid sinus syndrome (sensitivity of carotid baroreceptors to external pressure such as a tight collar) should prompt monitoring of the ECG and BP during carotid sinus pressure, provided there is no carotid bruit or history of cerebrovascular disease. A positive cardio-inhibitory response is defined as a sinus pause of 3 seconds or more; a positive vasodepressor response is defined as a fall in systolic BP of more than 50 mmHg. Carotid sinus pressure will produce positive findings in about 10% of older adults, but fewer than 25% of these experience spontaneous syncope. Symptoms should not, therefore, be attributed to hypersensitive carotid sinus syndrome unless they are reproduced by carotid sinus pressure.

Initial investigations

A 12-lead ECG is essential in all patients presenting with syncope or presyncope. Lightheadedness may occur with many arrhythmias, but blackouts (Stokes–Adams attacks) are usually due to profound bradycardia or malignant ventricular tachyarrhythmias. The ECG may show evidence of conducting system disease (e.g. sinus bradycardia, atrioventricular block, bundle branch block), which would predispose a patient to bradycardia, but the key to establishing a diagnosis is to obtain an ECG recording *while symptoms are present*. Since minor rhythm disturbances are common, especially in older adults, symptoms must occur at the same time as a recorded arrhythmia before a diagnosis can be made. Ambulatory ECG recordings are helpful only if symptoms occur several times per week. Patient-activated ECG recorders are useful for examining the rhythm in patients with recurrent dizziness, but are not helpful in assessing sudden blackouts. When these investigations fail to establish a cause in patients with presyncope or syncope, an implantable ECG recorder can be sited subcutaneously over the upper left chest. This device continuously records the cardiac rhythm and will activate automatically if extreme bradycardia or tachycardia occurs. The ECG memory can also be tagged by the patient, using a hand-held activator as a form of 'symptom diary'. Stored ECGs can be accessed by the implanting centre, using a telemetry device in a clinic, or using a home monitoring system via an online link.

Head-up tilt-table testing is a provocation test used to establish the diagnosis of vasovagal syncope. It involves positioning the patient supine on a padded table that is then tilted to an angle of 60–70° for up to 45 minutes, while the ECG and BP responses are monitored. A positive test is characterised by bradycardia (cardio-inhibitory response) and/or hypotension (vasodepressor response), associated with typical symptoms.

Headache

Headache is common and causes considerable worry amongst both patients and clinicians, but rarely represents sinister disease. The causes may be divided into primary or secondary, with primary headache syndromes being vastly more common (Box 10.13).

Presentation

The primary purpose of the history and clinical examination in patients presenting with headache is to identify the small minority of patients with serious underlying pathology. Key features of the history include the temporal evolution of a headache; a headache that reached maximal intensity immediately or within 5 minutes of onset requires rapid assessment for possible subarachnoid haemorrhage. Other 'red flag' symptoms are shown in Box 10.14.

It is important to establish whether the headache comes and goes, with periods of no headache in between (usually migraine), or whether it is present all or almost all of the time. Associated features, such as preceding visual symptoms, nausea/vomiting or photophobia/phonophobia, may support a diagnosis of migraine, but others, such as progressive focal symptoms or constitutional upset like weight loss, may suggest a more sinister cause. The headache of cerebral venous thrombosis may be 'throbbing' or 'band-like' and associated with nausea, vomiting or hemiparesis. Raised intracranial pressure (ICP) headache tends to be worse in the morning and when lying flat or coughing, and is associated with nausea and/or vomiting.

A description of neck stiffness along with headache and photophobia should raise the suspicion of meningitis (Box 10.15), although this may

10.13 Primary and secondary headache syndromes

Primary headache syndromes

- Migraine (with or without aura)
- Tension-type headache
- Trigeminal autonomic cephalalgia (including cluster headache)
- Primary stabbing/coughing/exertional/sex-related headache
- Thunderclap headache
- New daily persistent headache syndrome

Secondary causes of headache

- Medication overuse headache (chronic daily headache)
- Intracranial bleeding (subdural haematoma, subarachnoid or intracerebral haemorrhage)
- Raised intracranial pressure (brain tumour, idiopathic intracranial hypertension)
- Infection (meningitis, encephalitis, brain abscess)
- Inflammatory disease (temporal arteritis, other vasculitis, arthritis)
- Referred pain from other structures (orbit, temporomandibular joint, neck)

10.14 'Red flag' symptoms in headache

Symptom	Possible explanation
Sudden onset (maximal immediately or within 5 min)	Subarachnoid haemorrhage Cerebral venous sinus thrombosis Pituitary apoplexy Meningitis (onset over hours)
Focal neurological symptoms (other than for typically migrainous)	Intracranial mass lesion: Vascular Neoplastic Infection
Constitutional symptoms: Weight loss General malaise Pyrexia Meningism Rash	Meningitis Encephalitis Neoplasm (lymphoma or metastases) Inflammation (vasculitis)
Raised intracranial pressure (worse on waking/lying down, associated vomiting)	Intracranial mass lesion
New-onset aged > 60 years	Temporal arteritis

10.15 Identification of bacterial meningitis

In patients presenting with headache, identification of those with bacterial meningitis is a top priority to facilitate rapid antibiotic treatment. In almost all cases there will be one of the following features:

- meningism (neck stiffness, photophobia, positive Kernig sign)
- fever > 38°C
- signs of shock (tachycardia, hypotension, elevated serum lactate)
- rash (not always petechial)

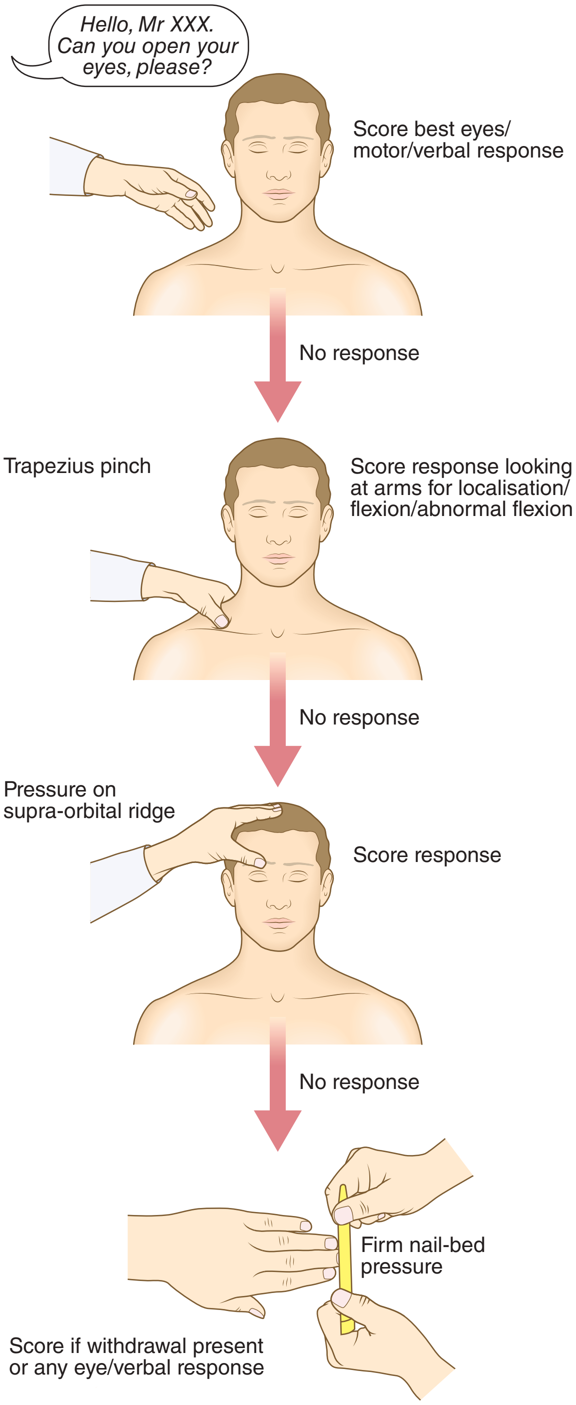
present in atypical ways in immunosuppressed, alcoholic or pregnant patients. The behaviour of the patient during headache is often instructive; migraine patients typically retire to bed to sleep in a dark room, whereas cluster headache often induces agitated and restless behaviour. The pain of a subarachnoid haemorrhage frequently causes significant distress.

Headache duration is also important to elicit; headaches that have been present for months or years are almost never sinister, whereas new-onset headache, especially in older adults, is more of a concern. In a patient over 60 years with head pain localised to one or both temples, scalp tenderness or jaw claudication, temporal arteritis (Ch. 25) should be considered.

Clinical assessment

An assessment of conscious level (using the Glasgow Coma Scale (GCS); Fig. 10.5) should be performed early and constantly reassessed. A decreased conscious level suggests raised ICP, and urgent CT scanning (with airway protection if necessary) is indicated. A full neurological examination may provide clues as to the pathology involved; for example, brainstem signs in the context of acute-onset occipital headache may indicate vertebrobasilar dissection. Neurological signs may, however, be 'falsely localising', as in large subarachnoid haemorrhage or bacterial meningitis. Care should be taken to examine for other evidence of meningitis such as a rash (not always petechial), fever or signs of shock.

Unilateral headache with agitation, ipsilateral lacrimation, facial sweating and conjunctival injection is typical of cluster headache. Conjunctival injection may also be seen in acute glaucoma, accompanied by peri- or retro-orbital pain, clouding of the cornea, decreased visual acuity and, often, systemic upset. Temporal headaches in patients over 60 should prompt examination for enlarged or tender temporal arteries and palpation of temporal pulses (often absent in temporal arteritis). Visual acuity should be assessed promptly, as visual loss is an important complication of temporal arteritis.



Hello, Mr XXX. Can you open your eyes, please?
Score best eyes/ motor/verbal response

Score response
No response
Firm nail-bed pressure
Score if withdrawal present or any eye/verbal response

Fig. 10.5 Assessment of the Glasgow Coma Scale (GCS) score in an obtunded patient. Avoid using a sternal rub, as it causes bruising.

Initial investigations

If there is any alteration of conscious level, focal neurological signs, new-onset seizures or a history of head injury, then CT scanning of the head is indicated. The urgency of scanning will depend on the clinical picture and trajectory but in many circumstances will be immediately required. Intracranial haemorrhage or a space-occupying lesion with mass effect should prompt urgent neurosurgical referral. If bacterial meningitis is suspected (see Box 10.15), cerebrospinal fluid (CSF) analysis is required to make a definite diagnosis. Antibiotics should not be delayed for lumbar puncture (LP), which needs to be preceded by CT scanning only if raised ICP is suspected. In cases of thunderclap headache (peak

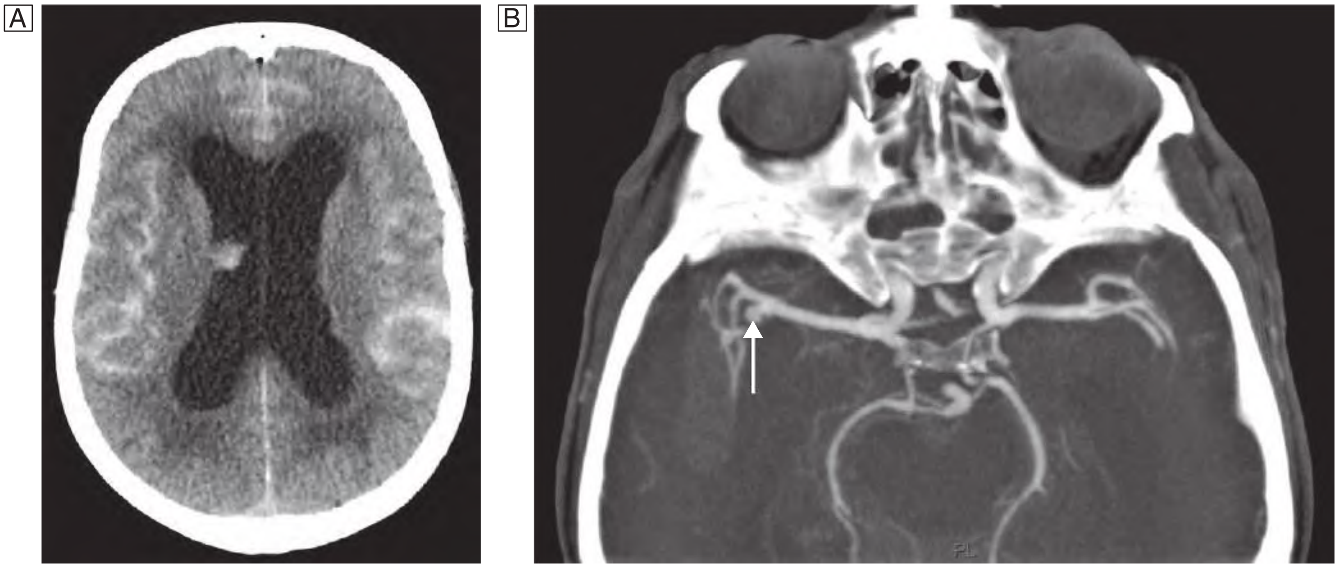

Fig. 10.6 A CT head demonstrating acute subarachnoid haemorrhage within the cortical sulci of both cerebral hemispheres. B CT angiogram demonstrating the culprit right middle cerebral artery aneurysm (arrow).

intensity within 5 minutes and lasting over an hour), a normal CT scan should be followed by an LP performed more than 12 hours after headache onset, to look for evidence of xanthochromia. A negative CT scan within 6 hours of headache onset has a high degree of sensitivity for detecting subarachnoid blood. In such cases, a discussion of risks and benefits with the patient may conclude that an LP is not necessary to exclude subarachnoid haemorrhage. A CT angiogram may be considered to exclude other pathology, such as arterial dissection, and will be required in those with a confirmed subarachnoid haemorrhage to help identify the source (Fig. 10.6). Many headaches require prompt involvement of specialists. Features of acute glaucoma, for example, require immediate ophthalmological review for measurement of intraocular pressures. Suspected temporal arteritis with an erythrocyte sedimentation rate (ESR) of > 50 mm/hr should prompt immediate glucocorticoid therapy and rheumatological referral (see Ch. 25 for management). Features of raised ICP in the absence of a mass lesion on neuroimaging may indicate idiopathic intracranial hypertension; CSF opening pressure is likely to be informative.

Confusion

When a patient presents with confusion, it is imperative to establish if the confusion is acute or acute on chronic. Acute or chronic confusion in a patient with diagnosed or suspected dementia (p. 1293) strongly suggests delirium with a ‘vulnerable brain’, which is more susceptible to developing confusion from systemic causes. The differential diagnoses will depend on both the chronicity of confusion and the demographics of the patient, with certain causes being more common in particular age groups (like illicit drug use in younger patients) and geographical location (such as some infectious causes). Delirium (p. 1346) will account for the majority of cases in elderly patients, but clinical assessment should aim to identify the minority of patients with a specific neurological cause and potential underlying medical or pharmacological causes of delirium.

Clinical assessment

History taking can be challenging if there is ongoing confusion. A collateral history from a relative, carer or friend can assist with establishing the key facts: Was there an acute onset? Has there been any confusion in the past? How long has the confusional state lasted? Are there any potential contributing causes such as alcohol or drugs? Is there a diurnal variation? Are there any associated features such as rigors, fever, or organ-specific symptoms and signs such as dysuria, malodorous urine, cough, breathlessness? Have there been any other neurological symptoms and signs such as headache, seizures or focal weakness?

Clinical examination should focus on identifying any systemic signs of infection, signs of chronic liver disease (as confusion can be a presentation of decompensated liver disease), and focal neurological deficits. In patients with confusion, it is also important to examine comprehensively for any concealed stigmata such as injection sites, unusual sources of infection (such as retained sanitary products in women) and for secondary injuries such as pressure areas and swollen compartments. In-dwelling devices such as urinary catheters should be closely examined and changed if appropriate.

Initial investigations

The blood panel will assist with assessment. Attention should be paid to inflammatory markers, liver function (noting that some patients with chronic liver disease will have normal liver function tests), glucose (severe hyperglycaemia or hypoglycaemia), renal function and electrolytes (disorders of sodium and renal failure). Urine should be analysed for infection and, if relevant, for toxicology.

Further testing will depend upon the results of the initial assessment. A CT head scan should be performed if the clinician suspects a primary neurological cause. Acute pathology on the CT scan such as ischaemia, hemorrhage, abscess, tumour, oedema or hydrocephalus will require specialist management. Further imaging such as MRI or EEG may be indicated. Lumbar puncture may be required if CNS infection is suspected. Additional blood tests such as ammonia (if a liver or metabolic cause is suspected) may be indicated.

Very occasionally there are no clear causes and a diagnosis of transient global amnesia (p. 1169) is suspected. This is a rare presentation which requires specific management, and specialist input should be sought after the above initial investigations have excluded alternative diagnoses.

Unilateral leg swelling

Most leg swelling is caused by oedema, the accumulation of fluid within the interstitial space. There are three explanatory mechanisms for development of oedema, which are described in Box 10.16. Unilateral swelling usually indicates a localised pathology in either the venous or the lymphatic system, while bilateral oedema often represents generalised fluid overload combined with the effects of gravity. However, all causes of unilateral leg swelling may present bilaterally, and generalised fluid overload

i 10.16 Mechanisms of oedema

There are three explanatory mechanisms for the development of oedema that may occur in isolation or combination:

- increased hydrostatic pressure in the venous system due to increased intravascular volume or venous obstruction
- decreased oncotic pressure secondary to a decrease in the plasma proteins that retain fluid within the circulation
- obstruction to lymphatic drainage ('lymphoedema').

10.17 Identification of compartment syndrome

- Compartment syndrome classically occurs following extrinsic compression of a limb due to trauma or reduced conscious level (especially when caused by drugs or alcohol).
- It usually presents with a tense, firm and exquisitely painful limb.
- The pain is characteristically exacerbated by passive muscle stretching or squeezing the compartment.
- Altered sensation may be evident distally.
- Absent peripheral pulses are a late sign and their presence does not exclude the diagnosis.
- Clinical suspicion of compartment syndrome should prompt measurement of creatine kinase and urgent surgical review.

may present with asymmetrical (and therefore apparently unilateral) oedema. Fluid overload may be the result of cardiac failure, pulmonary hypertension (even in the absence of right ventricular failure), renal failure, hypoalbuminaemia or drugs (calcium channel blockers, glucocorticoids, mineralocorticoids, non-steroidal anti-inflammatory drugs (NSAIDs) and others); see Box 16.14 for other causes. The remainder of this section focuses on the causes of 'unilateral' oedema.

Presentation

Any patient who presents with unilateral leg swelling should be assessed with the possibility of deep vein thrombosis (DVT) in mind. The pain and swelling of a DVT is often fairly gradual in onset, over hours or even days. Sudden-onset pain in the posterior aspect of the leg is more consistent with gastrocnemius muscle tear (which may be traumatic or spontaneous) or a ruptured Baker cyst. Leg swelling and pain associated with paraesthesia or paresis, or in the context of lower limb injury or reduced conscious level, should always prompt concern regarding the possibility of compartment syndrome (Box 10.17).

Clinical assessment

Lower limb DVT characteristically starts in the distal veins, causing an increase in temperature of the limb and dilatation of the superficial veins. Often, however, symptoms and signs are minimal.

Cellulitis is usually characterised by erythema and skin warmth localised to a well-demarcated area of the leg and may be associated with an obvious source of entry of infection (e.g. leg ulcer or insect bite). The patient may be febrile and systemically unwell. Superficial thrombophlebitis is more localised; erythema and tenderness occur along the course of a firm, palpable vein.

Examination of any patient presenting with leg swelling should include assessment for malignancy (evidence of weight loss, a palpable mass or lymphadenopathy). Malignancy is a risk factor for DVT, but pelvic or lower abdominal masses can also produce leg swelling by compressing the pelvic veins or lymphatics. Early lymphoedema is indistinguishable from other causes of oedema. More chronic lymphoedema is firm and non-pitting, often with thickening of the overlying skin, which may develop a 'cobblestone' appearance.

Chronic venous insufficiency is a cause of long-standing oedema that, particularly when combined with another cause of leg swelling, may acutely worsen. Characteristic skin changes (haemosiderin deposition, hair loss, varicose eczema, ulceration) and prominent varicosities are common, and sometimes cause diagnostic confusion with cellulitis. See Box 10.17 for the examination findings associated with compartment syndrome.

i 10.18 Predicting the pre-test probability of deep vein thrombosis (DVT) using the Wells score*

Clinical characteristic	Score
Previous documented DVT	1
Active cancer (patient receiving treatment for cancer within previous 6 months or currently receiving palliative treatment)	1
Paralysis, paresis or recent plaster immobilisation of lower extremities	1
Recently bedridden for ≥ 3 days, or major surgery within previous 12 weeks	1
Localised tenderness along distribution of deep venous system	1
Entire leg swollen	1
Calf swelling at least 3 cm larger than that on asymptomatic side (measured 10 cm below tibial tuberosity)	1
Pitting oedema confined to symptomatic leg	1
Collateral superficial veins (non-varicose)	1
Alternative diagnosis at least as likely as DVT	−2
Clinical probability	**Total score**
DVT low probability	< 1
DVT moderate probability	1–2
DVT high probability	> 2

*A dichotomised revised Wells score, which classifies patients as 'unlikely' or 'likely', may also be used.

Initial investigations

Factors predisposing to venous thromboembolism are covered in detail in Chapter 24. Clinical criteria can be used to rank patients according to their likelihood of DVT, by using scoring systems that determine pre-test probability (see Ch. 1), such as the Wells score (Box 10.18). Figure 10.7 gives an algorithm for investigation of suspected DVT based on initial Wells score. In patients with a low ('unlikely') pre-test probability of DVT, D-dimer levels can be measured; if these are normal, further

10.19 D-dimer

- D-dimers are specific cross-linked fibrin degradation products which are small protein fragments present in blood after a blood clot is degraded by fibrinolysis.
- D-dimers are present in human blood when the coagulation system has been activated, usually because of the presence of thrombosis, disseminated intravascular coagulation or venom-induced consumptive coagulopathy.
- As the sensitivity of D-dimer decreases with time, it should not be used in the assessment of patients who present with symptoms for 7 days or more.
- D-dimer increases with age; for patients aged over 50 years with suspected venous thromboembolism (VTE), a cut-off equal to the patient's age in years × 10 µg/L (or × 0.056 nmol/L) has therefore been proposed.
- Although their safety is still being evaluated, age-adjusted D-dimers appear to decrease the false-positive rate without substantially increasing the false-negative rate.

10.20 Swollen legs in pregnancy

- **Benign swollen legs**: common in pregnancy; this is usually benign.
- **DVT**: pregnancy is a significant risk factor; however, D-dimer should not be measured in pregnancy; it has not been validated in this group.
- **Imaging**: should be arranged on the basis of clinical suspicion alone, and the threshold for undertaking a definite diagnostic test should be low.

investigation for DVT is unnecessary. Further information on the interpretation of D-dimer is given in Box 10.19. In those with a moderate or high ('likely') probability of DVT or with elevated D-dimer levels, objective diagnosis of DVT should be obtained using appropriate imaging, usually a Doppler ultrasound scan. Therefore, in the same way as for pulmonary embolism, the investigative pathway for DVT differs according to the pre-test probability of DVT. For low-probability DVT, the negative predictive value of the D-dimer test (the most important parameter in this context) is over 99%; if the test is negative, the clinician can discharge the patient with confidence. In patients with a high probability of DVT, the negative predictive value of a D-dimer test falls to somewhere in the region of 97%–98%. While this may initially appear to be a high figure, to discharge 2 or 3 patients in every 100 incorrectly would generally be considered an unacceptable error rate. Hence, with the exception of pregnancy (Box 10.20), a combination of clinical probability and blood test results should be used in the diagnosis of DVT.

If cellulitis is suspected, serum inflammatory markers, skin swabs and blood cultures should be sent, ideally before antibiotics are given. Ruptured Baker cyst and calf muscle tear can both be readily diagnosed on ultrasound. If pelvic or lower abdominal malignancy is suspected, a prostate-specific antigen (PSA) level should be measured in males and appropriate imaging with ultrasound (transabdominal or transvaginal) or CT should be undertaken.

Acute abdomen

The acute abdomen accounts for approximately 50% of all urgent admissions to general surgical units, but a significant proportion of patients present via acute medicine. Below is an overview: specific decision-making is guided by the surgical specialists.

Presentation

The acute abdomen is a consequence of one or more of the following pathological processes (Box 10.21):

- *Inflammation*. Pain develops gradually, usually over several hours. It is initially rather diffuse until the parietal peritoneum is involved, when it becomes localised. Movement exacerbates the pain; abdominal rigidity and guarding occur.
- *Perforation*. When a viscus perforates, pain often starts abruptly; it is severe and leads to generalised peritonitis.
- *Obstruction*. Pain is often colicky, with spasms that cause the patient to writhe around and double up. Colicky pain that does not disappear between spasms suggests complicating inflammation.
- *Ischaemia*. Signs are variable; pain may come on acutely or more gradually and the abdomen can be soft or rigid. A raised venous lactate is usually only a late sign once hepatic lactate clearance is overwhelmed (see Fig. 10.16).

10.21 Causes of acute abdominal pain

Inflammation

- Appendicitis
- Diverticulitis
- Cholecystitis
- Pelvic inflammatory disease
- Pancreatitis
- Pyelonephritis
- Intra-abdominal abscess

Perforation/rupture

- Peptic ulcer
- Diverticular disease
- Ovarian cyst
- Aortic aneurysm

Obstruction

- Intestinal obstruction
- Biliary colic
- Ureteric colic

Other (rare)

- See Box 22.23

Clinical assessment

If there are signs of peritonitis (guarding and rebound tenderness with rigidity), the patient should be resuscitated with titrated oxygen, intravenous fluids and antibiotics; urgent surgical input is required. In other circumstances, further investigations may be necessary, as detailed below (Fig. 10.8).

Initial investigations

Patients should have a full blood count, urea and electrolytes, glucose and amylase (or lipase) taken to look for evidence of dehydration, leucocytosis and pancreatitis. Urinalysis is useful in suspected renal colic and pyelonephritis. An erect chest X-ray may show air under the diaphragm, suggestive of perforation, and a plain abdominal film may show evidence of obstruction or ileus (see Fig. 22.11). An abdominal ultrasound may help in identifying gallstones, renal stones, free fluid or an intra-abdominal abscess. Abdominal CT scanning is the most useful investigation and is essential in differentiating pseudo-obstruction and mechanical large bowel obstruction. CT may also identify evidence of pancreatitis, retroperitoneal collections or masses, including aortic aneurysm (Fig. 10.9). Concerns regarding contrast-induced nephropathy should be secondary to the imperative to reach an early diagnosis.

Diagnostic laparotomy should be considered when the diagnosis has not been revealed by other investigations. All patients must be carefully and regularly reassessed (every 2–4 hours) so that any change in condition that might alter both the suspected diagnosis and clinical decision can be observed and acted on early.

Management

The general approach is to wash out, defunction and/or close, treat inflammatory conditions with antibiotics or resection, and relieve obstructions. Aspiration of gastric contents is a major risk in all acute abdominal conditions, especially intestinal obstruction. This occurs once the laryngeal reflexes are overwhelmed by the volume of regurgitated material, and is particularly common in frailer individuals or where there is a coexisting reduction in conscious level. The placement of a large-bore nasogastric tube should therefore be considered whenever bowel obstruction or ileus are suspected. The speed of intervention and the necessity for surgery depend upon various factors, of which the presence of peritonitis

is the most pertinent. A treatment summary of some of the more common surgical conditions follows:

- *Acute appendicitis:* This should be treated by early surgery, since there is a risk of perforation and recurrent attacks with non-operative treatment. The appendix can be removed through a conventional right iliac fossa skin crease incision or by laparoscopic techniques.
- *Acute cholecystitis*: Most cases will settle with intravenous antibiotics, and it is surgically preferable to perform a cholecystectomy after the inflammation has resolved. However, if there are complications such as cholangitis or a gallbladder perforation, then intervention may be required.
- *Acute diverticulitis*: Conservative therapy is standard, but if perforation has occurred, resection is advisable. Depending on peritoneal contamination and the degree of shock (risk of anastomotic leak correlates with severity of shock), primary anastomosis is preferable to a Hartmann procedure (oversew of rectal stump and end-colostomy).
- *Small bowel obstruction*: If the cause is obvious and surgery inevitable (such as with a strangulated hernia), an early operation is appropriate. If the suspected cause is adhesions from previous surgery, only those patients who do not resolve within the first 48 hours or who develop signs of strangulation (colicky pain becoming constant, peritonitis, tachycardia, fever, leucocytosis) should have surgery.
- *Large bowel obstruction:* Pseudo-obstruction should be treated non-operatively unless there is evidence of complications such as secondary bowel ischaemia. Some patients benefit from colonoscopic decompression, the passage of a flatus tube or the use of a neostigmine infusion. Cross-sectional imaging is useful to rule out a physical obstruction that may benefit from surgical decompression. A CT may reveal a transition point where distended bowel transitions to collapsed bowel, suggesting a physical obstruction that may be amenable to surgery.
- *Mesenteric ischaemia*: This can be due to an arterial or venous thrombosis, or a structural abnormality of the gut such as a volvulus. Early surgery can be successful in revascularisation of the gut

or removing ischaemic tissue, although acute mesenteric arterial thrombosis has a poor prognosis, especially when the diagnosis is delayed.

- *Acute pancreatitis*: CT scanning can be useful to rule out other pathologies that may be amenable to operative management (e.g. retroperitoneal perforation), but is not essential in the early management of the disease. Management is usually conservative and the majority of patients will improve. A minority will develop pancreatic necrosis that will require prolonged supportive care and organ support. Antibiotics are not usually indicated in the early phase of the disease.
- *Perforation of the gastrointestinal (GI) tract (stomach, duodenum or lower GI)*: It may not be possible to close a defect. The priority is decontamination, and in these patients the surgeon may perform a wash-out and 'omental patch' where the omentum is used to provide some degree of control to the defect. Some patients without generalised peritonitis can be treated non-operatively. This decision requires expert evaluation of the risks and benefits of surgery for that individual. Lower GI tract perforations are more commonly treated operatively, and resection of the diseased area is more straightforward than in the upper GI tract.

For a more detailed discussion of acute abdominal pain, the reader is referred to the companion volume of this text, *Principles and Practice of Surgery*.

Identification and assessment of deterioration

Early warning scores and the role of the medical emergency team

There are many systems that have been developed with the aim of rapidly identifying and managing physiological deterioration. These are referred to as 'rapid response systems'. One popular example of a rapid response system is a medical emergency team (MET). A MET system operates on the basis that when a patient meets certain physiological criteria, the team is alerted. The team is expected to make a rapid assessment and institute immediate management. This may include escalation to critical care or, following liaison with the parent clinical team, ongoing ward-based care.

The trigger for a 'MET' call may be a single parameter – such as a low BP or tachycardia – or may consist of a composite early warning score. Early warning score systems function by the observer allocating a value between 0 and 3 for abnormalities in respiratory rate, SpO_2, temperature, BP, heart rate and neurological response (Fig. 10.10). The values are summed and the composite score gives an indication of the severity of physiological derangement. Early warning systems can be automated into an electronic format that calculates the score and even alerts the responsible clinician(s) by email or text message.

There are advantages and disadvantages to having a separate MET system, compared with allowing the responsible clinical team to manage deterioration, and to having a composite score or a single parameter detection system. These are outlined in Box 10.22.

Immediate assessment of the deteriorating patient

An approach to assessment of the deteriorating patient can be summarised by the mnemonic 'C-A-B-C-D-E'.

C – Control of obvious problem

For example, if the patient has ventricular tachycardia on the monitor or significant blood loss is apparent, immediate action is required.

A and B – Airway and breathing

If the patient is talking in full sentences, then the airway is clear and breathing is adequate. A rapid history should be obtained while the initial assessment is undertaken. Breathing should be assessed with a focused respiratory examination. Oxygen saturations and ABGs should be checked early.

C – Circulation

A focused cardiovascular examination should include heart rate and rhythm, blood pressure, jugular venous pressure, evidence of bleeding, signs of shock and abnormal heart sounds. The carotid pulse should be palpated in the collapsed or unconscious patient, but peripheral pulses also should be checked in conscious patients. The radial, brachial, foot and femoral pulses may disappear as shock progresses, and this indicates the severity of circulatory compromise.

D – Disability

Conscious level should be assessed using the GCS (see Fig. 10.5 and Box 10.29). A brief neurological examination looking for focal signs should be performed. Capillary blood glucose should always be measured to exclude hypoglycaemia or severe hyperglycaemia.

E – Exposure and evidence

'Exposure' indicates the need for targeted clinical examination of the remaining body systems, particularly the abdomen and lower limbs. 'Evidence' may be gathered via a collateral history from other health-care professionals or family members, recent investigations, prescriptions or monitoring charts.

Selecting the appropriate location for ongoing management and anticipatory care planning

Two groups of patients frequently gain benefit from admission to critical care: those with organ dysfunction severe enough to require organ support and those in whom the disease process is clearly setting them on a downward trajectory and in whom early, aggressive management may alter the outcome. Whether an individual patient should be admitted to the intensive care or high-dependency unit (ICU/HDU) will depend on local arrangements. A useful tool to assist with the decision regarding location is the 'level of care' required (Box 10.23). Many intensive care units are a mix of level 2 and level 3 beds, which streamlines the admission process. When a patient requires admission with a suspected transmissible disease that poses a risk to other patients and staff, the patient should be admitted to an isolated room located within an appropriate area of the hospital that can provide an appropriate level of care.

Anticipatory care planning (ACP) refers to the process of decision-making relating to treatments or support that would be appropriate if a patient's condition was to deteriorate. Admission can be a valuable opportunity for discussion with the patient and family members/carers about the appropriate 'ceiling of care'; for example, would resuscitation in the event of a cardiac arrest and/or admission to a critical care area be appropriate. Such discussions may result in the placement of a 'do not resuscitate order' and a decision that 'ward-level' care may be the 'ceiling' for that individual. These are emotive decisions and must be made in conjunction with the patient and the next of kin. If it is not appropriate to discuss these matters, there is no consensus or there is uncertainty as to the potential benefits of an increase in intensity of care, then the patient should remain for full escalation. It is important that discussions and decisions are clearly documented in the patient record. Further details of ACP decision-making are found on page 243.

Common presentations of deterioration

As patients become critically unwell, they usually manifest physiological derangement. The principle underpinning critical care is the simultaneous assessment of illness severity and the stabilisation of life-threatening physiological abnormalities. The goal is to prevent deterioration and effect improvements as the diagnosis is established and treatment of the underlying disease process is initiated.

It can be useful to consider the physiological changes as a starting point to help delineate urgent investigations and supportive treatment, which should proceed alongside the search for a definitive diagnosis.

Tachypnoea

Pathophysiology

A raised respiratory rate (tachypnoea) is the earliest and most sensitive sign of clinical deterioration. Tachypnoea may be primary (i.e. a problem within the respiratory system) or secondary to pathology elsewhere in the body. Cardiopulmonary causes of tachypnoea have been covered on page 217. Secondary tachypnoea is usually due to a metabolic acidosis, commonly observed in the context of sepsis, haemorrhage, ketoacidosis or visceral ischaemia. More detailed information on metabolic acidosis can be found on page 673.

Assessment and management

A simple assessment of a patient's clinical status and basic physiology will usually indicate whether urgent intervention is required. In the examination, attention should be paid to the adequacy of chest expansion, air entry and the presence of added sounds such as wheeze.

Analysis of an arterial blood sample is especially helpful in narrowing the differential diagnosis and confirming clinical suspicion of severity. The 'base excess' provides rapid quantification of the component of disease that is metabolic in origin. A base excess lower than −2 mEq/L (or, put another way, a 'base deficit' of more than 2 mEq/L) is likely to represent a metabolic acidosis. A simple rule of thumb is that a lactate of more than 4 mmol/L (36 mg/dL) or a base deficit of more than 10 mEq/L should cause concern and trigger escalation to a higher level of care. In addition to clinical examination, chest radiography and bedside ultrasound can help to distinguish the cause of poor air entry; consolidation and effusion can be readily identified, and a significant pneumothorax can be excluded (as shown in Fig. 10.11).

Hypoxaemia

Pathophysiology

Low arterial partial pressure of oxygen (PaO_2) is termed hypoxaemia. It is a common presenting feature of deterioration. Hypoxia is defined as an inadequate amount of oxygen in tissues (or the inability of cells to use the available oxygen for cellular respiration). Hypoxia may be due to hypoxaemia, or may be secondary to impaired cardiac output, the presence of inadequate or dysfunctional haemoglobin, or intracellular dysfunction (such as in cyanide poisoning, where oxygen utilisation at the cellular level is impaired).

Over 97% of oxygen carried in the blood is bound to haemoglobin. The haemoglobin–oxygen dissociation curve delineates the relationship between the percentage saturation of haemoglobin with oxygen (SO_2) and the partial pressure (PO_2) of oxygen in the blood. A shift in the curve will influence the uptake and release of oxygen by the haemoglobin molecule. As capillary PCO_2 rises, the curve moves to the right, increasing the offloading of oxygen in the tissues (the Bohr effect). This increases capillary PO_2 and hence cellular oxygen supply. Shifts of the oxyhaemoglobin dissociation curve can have significant implications in certain disease processes (Fig. 10.12).

Due to the shape of the curve, a small drop in arterial PO_2 (PaO_2) below 8 kPa (60 mmHg) will cause a marked fall in SaO_2.

Relative hypoxaemia refers to the comparison between the observed PaO_2 and that which might be expected for a given fraction of inspired oxygen (FiO_2). With the patient breathing air, PaO_2 of 12–14 kPa (90–105 mmHg) would be expected; with the patient breathing 100% oxygen, a PaO_2 of > 60 kPa (450 mmHg) would be normal.

Assessment and management

Oxygen therapy should be titrated to avoid hyperoxia (too high a PaO_2; Box 10.24). Hyperoxia is theoretically harmful via a number of mechanisms. This has a clinically significant effect in patients with acute stroke, those with MI and those who chronically retain CO_2. Adverse effects of hyperoxia include:

- free radical–induced tissue damage
- less efficient buffering of carbon dioxide by oxyhaemoglobin (compared to deoxyhaemoglobin)
- less efficient ventilation–perfusion matching in lung units (due to loss of hypoxic vasoconstriction of under-ventilated lung units)
- decreased hypoxic respiratory drive in individuals with chronic hypercapnia.

When attempting to determine the cause of hypoxaemia, it is useful to consider whether the primary physiological mechanism is a type of shunt, or one of the many causes of ventilation–perfusion mismatch, such as alveolar or central hypoventilation (Fig. 10.13). A classification of common causes of hypoxaemia in hospitalised patients is shown in Box 10.25. In reality, the observed physiological abnormality may represent a combination of inter-related processes, such as severe pulmonary oedema leading to exhaustion, which in turn causes hypoventilation.

Evaluation of risk factors, history and examination will help to differentiate the likely aetiology and guide specific management. Further management of respiratory failure is discussed on page 244.

Tachycardia

Pathophysiology

A heart rate of > 110 beats/min in an adult should always be considered abnormal and not attributed to anxiety until other causes have been excluded. Intrinsic cardiac causes (atrial fibrillation (AF), atrial flutter, supraventricular tachycardia and ventricular dysrhythmias) are less common in the general inpatient population than secondary causes of tachycardia.

A cardiac monitor or 12-lead ECG early in the examination will help both determine severity (heart rate > 160 beats/min should prompt urgent escalation to a higher level of care) and narrow the differential diagnosis. AF with a rapid ventricular response should usually be regarded as secondary to another insult (most commonly, infection) until other diagnoses have been excluded. Hypovolaemia should not be missed. Concealed bleeding (e.g. into the pleura, gastrointestinal tract or retroperitoneum) may not be apparent initially, and assessment of haemoglobin in an acute haemorrhage, when < 30 mL/kg of fluid has been administered, can be misleadingly high. Sepsis and other hyper-metabolic conditions may present with a tachycardia that is accompanied by tachypnoea, peripheral vasodilatation and a raised temperature. Other organ dysfunction should be noted from a brief general examination and salient points from the history.

Assessment and management

The management of a tachycardic patient should focus on treating the cause. Treating the rate alone with β-blockade in an unwell or deteriorating patient should be done only under specialist guidance, in controlled conditions and when a clear evaluation of the risk–benefit ratio has been undertaken.

NEW score	Frequency of monitoring	Clinical response
0	Minimum 12 hourly	• Continue routine NEWS monitoring
Total 1–4	Minimum 4–6 hourly	• Inform registered nurse, who must assess the patient • Registered nurse decides whether increased frequency of monitoring and/or escalation of care is required
3 in single parameter	Minimum 1 hourly	• Registered nurse to inform medical team caring for the patient, who will review and decide whether escalation of care is necessary
Total 5 or more Urgent response threshold	Minimum 1 hourly	• Registered nurse to immediately inform the medical team caring for the patient • Registered nurse to request urgent assessment by a clinician or team with core competencies in the care of acutely ill patients • Provide clinical care in an environment with monitoring facilities
Total 7 or more Emergency response threshold	Continuous monitoring of vital signs	• Registered nurse to immediately inform the medical team caring for the patient – this should be at least at specialist registrar level • Emergency assessment by a team with critical care competencies, including practitioner(s) with advanced airway management skills • Consider transfer to a level 2 or 3 clinical care facility, i.e. higher-dependency unit or ICU • Clinical care in an environment with monitoring facilities

Fig. 10.10, cont'd

10.22 Advantages and disadvantages of different rapid response systems

System	Advantages	Disadvantages
Single parameter trigger	High sensitivity. Will probably pick up subclinical deterioration and allow optimisation	Low specificity. Much time will be spent with patients who are not deteriorating
Composite early warning scoring system, e.g. NEWS2	Combines good sensitivity with improved specificity	May miss single parameter deterioration that is still significant, e.g. a drop of 2 GCS points may not trigger an alert
MET system	Brings expertise in deteriorating patients immediately to the bedside	Expensive to have well-trained individuals who are free from other clinical duties. May de-skill the ward-based teams in acute care. May not have expertise in highly specific areas of medicine
Clinical team review	Patient is seen by clinicians familiar with the patient and condition	Clinical team may be busy with other urgent duties. There may not be expertise in acute care within the ward-based team

(GCS = Glasgow Coma Scale; MET = medical emergency team; NEWS2 = National Early Warning Score 2)

10.23 Levels of care and the corresponding admission criteria for intensive care unit (ICU) and high-dependency unit (HDU)

Level of care	Criteria	Appropriate location
3	Patients requiring/likely to require endotracheal intubation and invasive mechanical ventilatory support Patients requiring support of two or more organ systems (e.g. inotropes and renal support) Patients with chronic impairment of one or more organ systems (e.g. COPD or severe ischaemic heart disease) who require support for acute reversible failure of another organ	ICU
2	Patients requiring detailed observation or monitoring that cannot be provided at ward level: Direct arterial BP monitoring/management, e.g. IV vasodilators or low dose vasopressors Patients requiring support for a single failing organ system, excluding invasive ventilatory support (IPPV): Non-invasive respiratory support (p. 244) Renal replacement therapy in an otherwise stable patient Step-down from intensive care requiring additional monitoring or single organ support	HDU
1	Patients in whom frequent but intermittent observations and medical review are sufficient, e.g. intermittent neurological observation (GCS)	General ward setting with enhanced observation

(BP = blood pressure; COPD = chronic obstructive pulmonary disease; GCS = Glasgow Coma Scale; IPPV = intermittent positive pressure ventilation; IV = intravenous)

Abnormal (pneumothorax cannot be excluded)

Fig. 10.11 Using ultrasound to rule out an anterior pneumothorax. **A** Probe position and orientation. **B** and **C** Two-dimensional (2D) ultrasound images. **D** and **E** M-mode ultrasound images. Key: (1) Intercostal muscle. (2) Rib. (3) Normal bright pleural line – 'shimmering appearance' of sliding pleura. (4) Lung. (5) Absent 'shimmering' in pneumothorax and lung not visible. (6) Normal – 'sea shore' sign excludes pneumothorax at that location. The 'sea shore' is represented by the bright granular line with lung (sea) deeper to the bright line. (7) Absent granular pleural line and a repeating linear pattern or 'barcode' sign suggest the presence of pneumothorax.

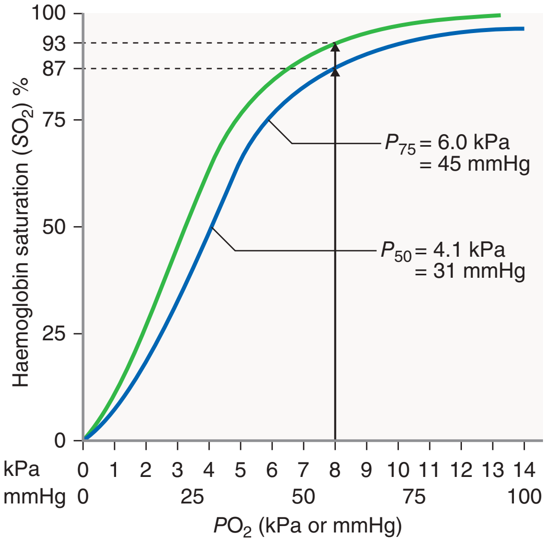

Fig. 10.12 The haemoglobin–oxygen dissociation curve and the effect of CO_2 on oxygen saturations. In pulmonary embolism, compensatory hyperventilation often occurs. $PaCO_2$ decreases, shifting the oxyhaemoglobin saturation curve to the left (green line). Therefore, despite a low PaO_2 (8 kPa/60 mmHg), the oxygen saturation reading is 93%.

10.24 Prescribing oxygen in critical illness

- Oxygen should be prescribed to achieve a target saturation of 94%–98% for most critically unwell patients.
- 88%–92% is a more appropriate target range for those at risk of hypercapnic respiratory failure.
- In patients with acute myocardial infarction or stroke, do not start oxygen unless SpO_2 is below 92%, as hyperoxia may be harmful.

The recognition and management of primary cardiac dysrhythmias are discussed on page 444. The most appropriate method of rate control in AF depends primarily on the degree of haemodynamic compromise. An intravenous loading dose of amiodarone is well tolerated and efficacious in most critically ill patients with AF and a very rapid ventricular rate. There are thromboembolic concerns regarding chemical cardioversion of AF of unknown duration. However, in deteriorating patients, the low incidence of embolic events makes this concern of secondary importance to achieving haemodynamic stability.

Digoxin continues to have a role in the treatment of AF in critically unwell, but haemodynamically stable, patients when its inotropic properties can be helpful. Electrical cardioversion is reserved for dysrhythmias with extremely high heart rates, following failure of pharmacological management, and/or for those of ventricular origin. It is rarely successful in dysrhythmias secondary to systemic illness.

Hypotension

Pathophysiology

Low BP (hypotension) should always be defined in relation to a patient's usual BP. The calculation of mean arterial pressure (MAP) is shown in Box 10.26; it unifies the systolic and diastolic BPs into a single reference value. A MAP of > 65 mmHg will maintain renal perfusion in most patients, although a MAP of up to 80 mmHg may be required in patients with chronic hypertension.

Assessment and management

The first stage of assessment is to decide if the hypotension is physiological or pathological. The MAP is useful as, despite low systolic pressures, it is rare to see a physiological MAP of < 65 mmHg. Urine output is particularly useful in the determination of the desirable MAP for an individual patient; oliguria suggests that measures to increase the MAP should be sought (p. 246). If the hypotension is pathological, an assessment of severity should look at whether it is causing physiological harm to the patient (i.e. the patient is shocked).

Shock

Shock means 'circulatory failure'. It can be defined as a level of oxygen delivery (DO) that fails to meet the metabolic requirements of the tissues (Box 10.27). Hypotension is a common presentation of shock but the terms are not synonymous. Patients can be hypotensive but not shocked, and oxygen delivery can be critically low in the context of a 'normal' BP. Along with the signs of low cardiac output (Box 10.28), objective markers of inadequate tissue oxygen delivery, such as increasing base deficit, elevated blood lactate and reduced urine output, can aid early identification. If shock is suspected, resuscitation should be commenced (p. 246).

Hypotensive patients who do not have any evidence of shock are still at significant risk of organ dysfunction. Hypotension should serve as a 'red flag' that there may be serious underlying pathology. Organ failure occurs despite normal or elevated oxygen delivery, so a full assessment of the patient is indicated. A review of the drug chart is essential, as many inpatients will be on antihypertensive medications that are contributing to hypotension. Non-cardiac medications may also have a negative influence on BP; for example, some drugs used for urine outflow tract obstruction, such as tamsulosin, have an α-adrenoceptor-blocking effect.

Fig. 10.13 Theoretical mechanisms of hypoxaemia. **A** Normal physiology. **B** Shunt caused by alveolar filling, e.g. in pneumonia or alveolar haemorrhage. The mixture of oxygenated and deoxygenated blood causes arterial desaturation. **C** Shunt caused by interstitial pathology, e.g. pulmonary oedema or fibrosis. Interstitial thickening causes inadequate transfer of oxygen from the alveolus to the blood, leading to shunting and arterial desaturation. Because minute volume is usually maintained, this causes type I respiratory failure. **D** Ventilation–perfusion ($\dot{V}/\dot{Q}$) mismatch caused by alveolar hypoventilation, e.g. in chronic obstructive pulmonary disease (COPD)/asthma. Alveoli are under-ventilated relative to perfusion. Alveolar PO_2 falls and PCO_2 rises, causing type II respiratory failure. **E** $\dot{V}/\dot{Q}$ mismatch caused by central hypoventilation, e.g. in neuromuscular disease or narcotic use. The alveoli are relatively over-perfused, causing type II respiratory failure. **F** $\dot{V}/\dot{Q}$ mismatch caused by a perfusion defect, e.g. a small pulmonary embolism. Pulmonary blood flow is diverted to other alveoli, causing them to be relatively over-perfused and thus reducing alveolar PO_2. Minute volume is increased, so PCO_2 is not elevated.

i 10.25 Common causes of hypoxaemia in hospitalised patients

Hypoxaemia due to shunt

- Lung collapse
- Consolidation/alveolar haemorrhage
- Interstitial oedema or interstitial infiltration (e.g. fibrosis)
- Silent aspiration of gastric contents

Hypoxaemia due to ventilation–perfusion mismatch

- Pulmonary embolism
- Acute exacerbation of asthma
- COPD (with high minute volume)

Hypoxaemia from hypoventilation

- Effects of opiates
- Severe COPD (with low minute volume)
- Neuromuscular disease/general weakness from other illness

(COPD = chronic obstructive pulmonary disease)

i 10.26 Calculation of mean arterial pressure (MAP)

$$\text{MAP} = \text{Diastolic blood pressure} + \frac{(\text{systolic} - \text{diastolic})}{3}$$

At normal heart rates, the heart, on average, spends two-thirds of the cycle in diastole. The MAP reflects this by weighting the value towards the diastolic blood pressure.

i 10.27 Oxygen content and delivery

- Oxygen content of blood = Haemoglobin concentration* × oxygen saturation × constant
- Cardiac output = Heart rate × stroke volume
- Stroke volume is dependent on cardiac filling (preload) and contractility.
- In shock, the most productive measures to improve oxygen delivery are optimising the haemoglobin level and the cardiac output.

*Oxygen is almost exclusively bound to haemoglobin; only tiny amounts are dissolved in blood at atmospheric pressure.

i 10.28 Hypotension in relation to cardiac output: clinical signs and possible causes

	High cardiac output	Low cardiac output
Signs	Warm hands Pulsatile head movement High-volume/strong pulse Low venous pressure	Cold/clammy peripheries Peripheral cyanosis Raised venous pressure (except in haemorrhage)
Causes	Sepsis Allergy Drug overdose (e.g. antihypertensive) Acidosis (e.g. diabetic ketoacidosis) Thyrotoxicosis Beri-beri	Bleeding Aortic stenosis and failed compensation Dysrhythmia Obstructive (pulmonary embolism/ tamponade/dynamic hyperinflation, as in severe asthma) Chronic heart failure

Hypertension

Pathophysiology

High BP (hypertension) is common and is usually benign in a critical care context. However, it can be the presenting feature of a number of serious disease processes. Furthermore, acute hypertension can result in an acute rise in vascular tone that increases left ventricular end-systolic pressure (afterload). The left ventricle may be unable to eject blood against the increased aortic pressure, and acute pulmonary oedema can result (referred to as 'flash' pulmonary oedema.)

Assessment and management

Before treating an acute rise in BP, it is worth considering a few important diagnoses that may impact on the immediate management:

- *Intracranial event*. Ischaemia of the brainstem (commonly via a pressure effect) will cause acute increases in BP. A neurological examination and CT scan of the head should be considered.
- *Fluid overload*. Once the capacity of the venous blood reservoir becomes saturated, increases in fluid volume will lead to increases in BP. This can occur in younger patients without the onset of peripheral oedema and originate from myocardial dysfunction or impaired renal clearance.
- *Underlying medical problems*. A brief search for a history of renal disease, spinal injury and less common metabolic causes such as phaeochromocytoma can be worthwhile. In women of child-bearing age, pregnancy-induced hypertension and pre-eclampsia must always be considered.
- *Primary cardiac problems*. Myocardial ischaemia, acute heart failure and aortic dissection can all present with hypertension.
- *Drug-related problems*. Most commonly, these involve a missed antihypertensive medication, but sympathomimetic drugs such as cocaine and amphetamines can be implicated.

The management of hypertension is discussed further on page 481.

Decreased conscious level

Assessment

A reduction in conscious level should prompt an urgent assessment of the patient, a search for the likely cause and an evaluation of the risk of airway loss. The GCS was developed to risk-stratify head injury, but it has become the most widely recognised assessment tool for conscious level (see Box 10.29 for a breakdown of GCS assessment, Box 10.30 for how to communicate the findings and Fig. 10.5 for how to assess GCS). While disorders that affect language or limb function (e.g. left hemisphere stroke, locked-in syndrome) may reduce its usefulness, evaluation of the GCS usually provides helpful prognostic information, and serial recordings can plot improvement or deterioration. It is not possible to define a total score below which a patient is unlikely to be able to protect the airway (from aspiration or obstruction), but a motor score of less than 5 would suggest significant risk.

Coma is defined as a persisting state of deep unconsciousness. In practice, this means a sustained GCS of 8 or less. There are many causes of coma (Box 10.31), including neurological (structural or non-structural brain disease) and non-neurological (e.g. type II respiratory failure) ones. The mode of onset of coma and any precipitating event is crucial to establishing the cause and should be obtained from witnesses. Failure to obtain an adequate history for patients in coma is a common cause of diagnostic delay.

Once the patient is stable from a cardiorespiratory perspective, examination should include accurate assessment of conscious level and a thorough general medical examination, looking for clues such as needle tracks indicating drug abuse, rashes, fever and focal signs of infection, including neck stiffness or evidence of head injury. Focal neurological signs may suggest a structural explanation (stroke or tumour) or may

10.29 Glasgow Coma Scale (GCS)*

Eye opening (E)

Best motor response (M)	
Obeys commands	6
Localises to painful stimulus	5
Flexion to painful stimulus or withdraws hand from pain	4
Abnormal flexion (internal rotation of shoulder, flexion of wrist)	3
Extensor response (external rotation of shoulder, extension of wrist)	2
Nil	1
Verbal response (V)	
Orientated	5
Confused conversation	4
Inappropriate words	3
Incomprehensible sounds	2
Nil	1
Coma score = E + M + V	
Always present GCS as breakdown, not a sum score (unless 3 or 15)	
Minimum sum	3
Maximum sum	15

*Record the best score observed. When the patient is intubated, there can be no verbal response. The suffix 'T' should replace the verbal component of the score, and the remainder of the score is therefore a maximum of 10.

10.30 How to communicate conscious level to other health-care professionals

- It is best to state the physical response along with the numerical score.
- For example, 'a patient who doesn't open his eyes, withdraws to pain and makes groaning noises, having a GCS of E1, M4, V2, making a total of 7' is preferable to 'a patient with a GCS of 7'.

10.31 Causes of coma

Metabolic disturbance

- Drug overdose
- Diabetes mellitus
    - Hypoglycaemia
    - Ketoacidosis
    - Hyperosmolar coma
- Hyponatraemia
- Uraemia
- Hepatic failure (hyperammonaemia)
- Inborn metabolic disorders causing hyperammonaemia
- Hyperammonaemia on refeeding following profound anorexia
- Respiratory failure
- Hypothermia
- Hypothyroidism

Trauma

- Cerebral contusion
- Extradural haematoma
- Subdural haematoma
- Diffuse axonal injury

Vascular disease

- Subarachnoid haemorrhage
- Brainstem infarction/haemorrhage
- Intracerebral haemorrhage
- Cerebral venous sinus thrombosis

Infections

- Meningitis
- Encephalitis
- Cerebral abscess
- Systemic sepsis

Others

- Epilepsy
- Brain tumour
- Functional ('pseudo-coma')

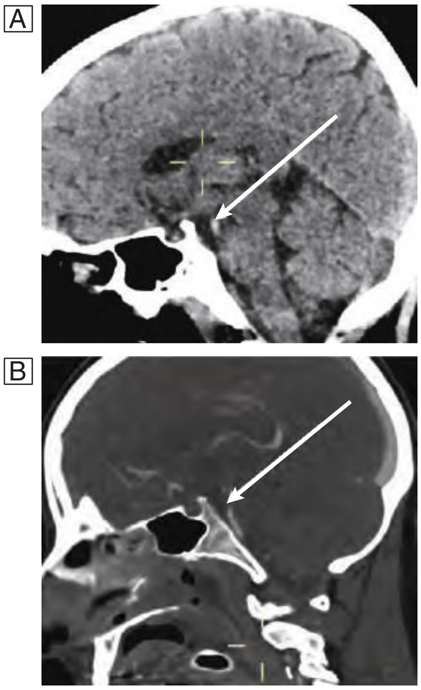

Fig. 10.14 **Hyperacute changes in conscious state are commonly of vascular origin.** CT of the brain is unlikely to identify many vascular causes but a CT angiogram of the circle of Willis is a high-yield investigation in this context. **A** Non-contrast CT of the head showing hyperdense thrombus in the basilar artery (arrow). This is a specific, but not sensitive, sign. **B** CT angiogram of the circle of Willis demonstrating thrombosis in the basilar artery (arrow). This has better sensitivity for acute vascular occlusion.

be falsely localising (for example, 6th nerve palsy can occur as a consequence of raised intracerebral pressure). It is vital to exclude non-neurological causes of coma. Sodium and glucose should be measured urgently as part of the initial assessment, as acute hyponatraemia (Ch. 19) and hypoglycaemia (see Box 21.17) are easily corrected and can cause irreversible brain injury if missed.

Further investigations should be guided by the clinical presentation and examination findings; a sudden onset suggests a vascular cause. An early CT scan of the brain may demonstrate any gross pathology, but if a brainstem stroke is suspected (Fig. 10.14), a CT angiogram of the circle of Willis will provide more useful information, as a non-contrast CT is frequently negative in this context. If there are features suggestive of cerebral venous thrombosis, such as thrombophilia or sinus infection, a CT venogram should be performed. Meningitis or encephalitis may be suggested by the history, signs of infection or subtle radiological findings. If these diagnoses are considered, it is best to commence treatment with broad-spectrum antibiotics and antivirals while awaiting more definitive diagnostic information.

Other drug, metabolic and hepatic causes of reduced conscious level are dealt with in the relevant chapters. An ammonia level (sent on ice) can narrow the differential diagnosis to a metabolic or hepatic cause if there is diagnostic doubt; levels > 140 μg/dL (100 μmol/L) are significantly abnormal. Psychiatric conditions such as catatonic depression or neurological conditions such as the autoimmune encephalitides can cause a reduced level of consciousness, but they are diagnoses of exclusion in the short term (as specific antibody titres can a take a long time to be reported) and will require specialist input.

Management

Moving an unconscious patient into the recovery position is best for airway protection while preparations are made for escalation to a higher level of care. The decision regarding intubation for airway protection is sometimes difficult. Length of stay in intensive care is significantly reduced if there is no secondary organ dysfunction. Therefore, early intubation and the prevention of lung injury constitute the safer option if there is any doubt about a patient's ability to protect the airway from obstruction or aspiration.

Decreased urine output/deteriorating renal function

Assessment

A urine output of 0.5 mL/kg/hr is a commonly quoted, though arbitrary target. Although some patients can produce urine volumes below this level with no change in their renal biochemistry, such low volumes should alert the clinician to the possibility of suboptimal renal perfusion.

Oliguria in association with hypotension or an increase in serum creatinine level (even if small) should prompt examination for the underlying cause. Pre-renal causes predominate in the general inpatient population, so optimising the MAP by administration of intravenous fluids (and possibly vasopressors) is the priority. In the majority of inpatients there is no role for high volumes (i.e. > 30 mL/kg) of intravenous fluid if the MAP is normal. Exceptions to this rule include patients with clinical dehydration or high fluid losses such as in burns, diabetes emergencies (see Ch. 21) and arginine vasopressin deficiency or resistance (diabetes insipidus) (Ch. 20), where fluid management should be guided by local protocols.

Diagnosis and management

Further assessment and management of oliguria are explained on page 607. Two other important causes of renal failure in the inpatient population are abdominal compartment syndrome and rhabdomyolysis.

Abdominal compartment syndrome

Abdominal compartment syndrome occurs when raised pressure within the abdomen reduces perfusion to the abdominal organs. It is most commonly seen in surgical patients, but can occur in medical conditions with extreme fluid retention such as liver cirrhosis. When it is suspected, intra-abdominal pressure can be monitored via a pressure transducer connected to a urinary catheter (following instillation of 25 mL of 0.9% saline into the bladder). Values over 20 mmHg suggest abdominal compartment syndrome is present. Urgent measures should be taken to reduce the pressure, such as decompression of the stomach, bladder and peritoneum if ascites is present. If conservative measures fail, a laparostomy can be considered.

Rhabdomyolysis

Rhabdomyolysis occurs when there is an injury to a large volume of skeletal muscle, usually because a single limb or muscle compartment has been ischaemic for a prolonged period. It can also occur following trauma and crush injury or after over-exertion of muscles. Over-exertion can occur after intense physical exercise or as part of a medical condition that causes widespread muscular activity, such as malignant hyperpyrexia or neuroleptic malignant syndrome. A creatine kinase (CK) level of > 1000 U/L is highly suggestive, although it can rise to tens of thousands in severe cases. Management should focus on identification and correction of the underlying cause and support for multi-organ dysfunction. Forced alkaline diuresis (using intravenous bicarbonate infusion and furosemide) can be used to maintain a good flow of less acidic fluid within the renal tubules and reduce myoglobin precipitation. However, this has not been demonstrated to be superior to standard care.

Disorders causing critical illness

Sepsis and the systemic inflammatory response

Sepsis is one of the most common causes of multi-organ failure. Sepsis requires the presence of infection with a resultant systemic inflammatory state; organ dysfunction occurs from a combination of the two processes. The definition of sepsis has undergone various iterations and

10.32 Definitions of sepsis and septic shock*

Sepsis

Patients with suspected infection who have two or more of:

- *Hypotension* – systolic blood pressure <100 mmHg
- *Altered mental status* – Glasgow Coma Scale score ≤ 14
- *Tachypnoea* – respiratory rate ≥ 22 breaths/min

Sepsis can also be diagnosed by suspected infection and an increase of ≥ 2 points on the Sequential Organ Failure Assessment (SOFA) score (see Box 10.54).

Septic shock

A subset of sepsis with underlying circulatory or cellular/metabolic abnormalities associated with a substantially increased mortality:

- Sepsis and both of (after fluid resuscitation):
  1. Persistent hypotension requiring vasopressors to maintain a MAP > 65 mmHg
  2. Serum lactate > 2 mmol/L (18 mg/dL)

(MAP = mean arterial pressure)

*From the Third International Consensus Definitions for Sepsis and Septic Shock (Sepsis-3).

there is still a lack of consensus as to the exact wording that best reflects this complex, multisystem process (Box 10.32).

Aetiology and pathogenesis

To understand how an infection can lead to progressive multi-organ failure, it is essential to understand the pathophysiology.

Initiation of the inflammatory response

The process begins with infection in one part of the body that triggers a localised inflammatory response. Appropriate source control and a competent immune system will, in most cases, contain the infection at this stage. However, if certain factors are present, the infection may become systemic. The causative factors are not fully elucidated, but probably include:

- a genetic predisposition to sepsis
- a large microbiological load
- high virulence of the organism
- delay in source control (either surgical or antimicrobial)
- resistance of the organism to treatment
- patient factors (immune status, nutrition, frailty).

Mediators are released from damaged cells (called ‘alarmins’) and these, coupled with direct stimulation of immune cells by the molecular patterns of the microorganism, trigger the inflammatory response. An example of such direct stimulation is that of lipopolysaccharide, which is found on the surface of gram-negative bacteria. It strongly stimulates an immune response and is commonly used in research settings to initiate a septic cascade.

Viral and fungal infections can cause a syndrome that is clinically indistinguishable from bacterial sepsis. Likewise, numerous non-infective processes, such as pancreatitis, burns, trauma, major surgery and drug reactions, can cause alarmins to be released and initiate the process of systemic inflammation.

Propagation of the inflammatory response

Once activated, immune cells such as macrophages release the inflammatory cytokines interleukin-2 (IL-2), IL-6 and tumour necrosis factor alpha, which, in turn, activate neutrophils. Activated neutrophils express adhesion factors and release various other inflammatory and toxic substances; the net effects are vasodilatation (via activation of inducible nitric oxide synthase enzymes) and damage to the endothelium. Neutrophils migrate into the interstitial space; fluid and plasma proteins will also leak through the damaged endothelium, leading to oedema and intravascular fluid depletion.

Activation of the coagulation system

Damaged endothelium triggers the coagulation cascade (via tissue factor, factor VII, and reduced activity of proteins C and S) and thrombus forms within the microvasculature. A vicious circle of endothelial injury, intravascular coagulation and microvascular occlusion develops, causing more tissue damage and further release of inflammatory mediators. In severe sepsis, intravascular coagulation can become widespread. This is referred to as disseminated intravascular coagulation (DIC) and usually heralds the onset of multi-organ failure. Specific aspects of the diagnosis and management of DIC are discussed on page 1013.

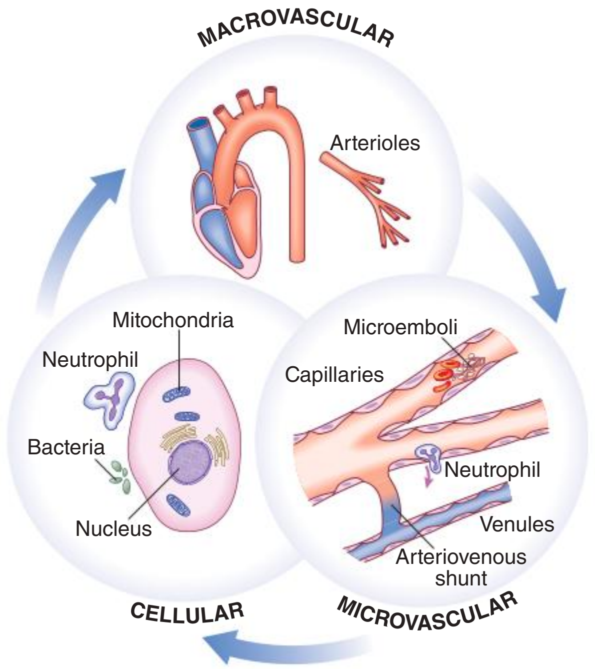

Fig. 10.15 Pathophysiology of organ damage in sepsis. *Macrovascular.* Severe hypovolaemia, vasodilatation or septic cardiomyopathy can reduce oxygen delivery, causing tissue hypoxia. Paradoxically, most patients with sepsis have an increased cardiac output and oxygen delivery. *Microvascular.* Tissue injury can occur from hypoxia secondary to microvascular injury and thrombosis. Damaged epithelium permits neutrophils, proteins and fluid to leak out. *Shunting.* Organs fail in sepsis despite supranormal blood flow. It is likely that arteriovenous shunt pathways exist within vascular beds; these shunts open up in septic shock. *Cellular.* Cells are damaged by a number of mechanisms in sepsis: (1) direct injury by microorganisms; (2) injury from toxins produced by immune cells, e.g. oxygen free radicals; (3) mitochondrial injury causing cytopathic hypoxia – cells are unable to metabolise oxygen; (4) apoptosis – if the cell injury is sufficient, caspase enzymes are activated within the nucleus and programmed cell death occurs; (5) hypoxia from micro- and macrovascular pathology.

Organ damage from sepsis

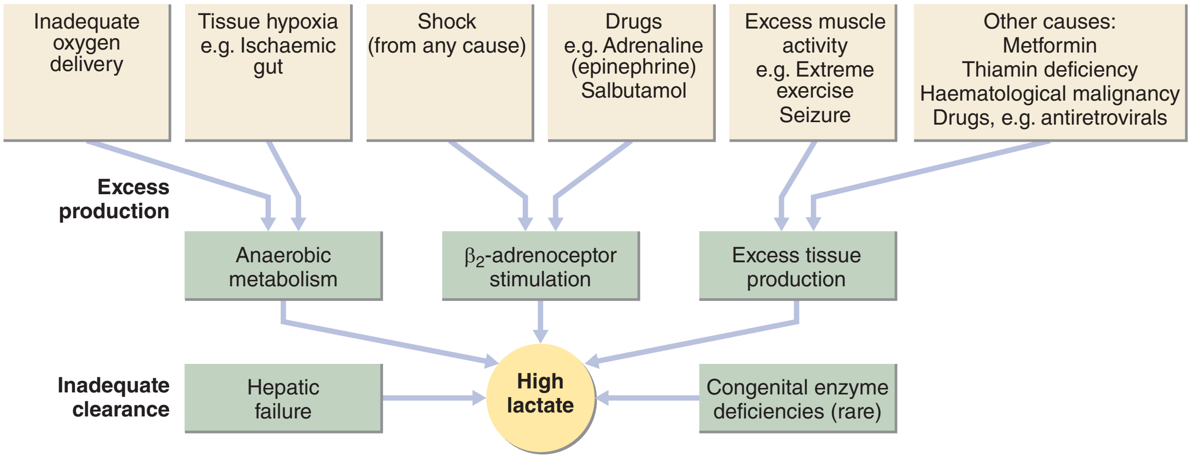
Any and all organs may be injured by severe sepsis. The pathological mechanisms are shown in Figure 10.15.

Lactate physiology

Lactate is an excellent biomarker for the severity of sepsis. Hyperlactataemia (serum lactate >2.4 mmol/L or 22 mg/dL) is used as a marker of severity. Figure 10.16 explains the physiology of hyperlactataemia; it is caused by all types of shock and therefore is not specific to sepsis. A lactate level of >8 mmol/L (72 mg/dL) is associated with an extremely high mortality and should trigger immediate escalation. Measures to optimise oxygen delivery should be sought and the adequacy of resuscitation measured by lactate clearance.

The anti-inflammatory cascade

As the inflammatory state develops, a compensatory anti-inflammatory system is activated involving the release of anti-inflammatory cytokines such as IL-4 and IL-10 from immune cells. While such mechanisms are necessary to keep the inflammatory response in check, they may lead to a period of immunosuppression after the initial septic episode. Patients



Inadequate oxygen delivery
Tissue hypoxia e.g. Ischaemic gut
Shock (from any cause)
Drugs e.g. Adrenaline (epinephrine) Salbutamol
Excess muscle activity e.g. Extreme exercise Seizure
Other causes: Metformin Thiamin deficiency Haematological malignancy Drugs, e.g. antiretrovirals
Excess production
Anaerobic metabolism
β2-adrenoceptor stimulation
Excess tissue production
Inadequate clearance
Hepatic failure
High lactate
Congenital enzyme deficiencies (rare)

Fig. 10.16 Physiology of hyperlactataemia.

recovering from severe sepsis are prone to developing secondary infections due to a combination of this immunosuppression and the presence of indwelling devices.

Management

The most important action is to consider sepsis as the cause of a patient's deterioration. Aligned to this is the requirement to consider other diagnoses that could be causing the presentation, such as haemorrhage, PE, anaphylaxis or a low cardiac output state.

Resuscitation in sepsis

General resuscitative measures are discussed on page 246. Early resuscitation can be aided by following the requirements of the 'Sepsis Six' (Box 10.33). Red cell transfusion should be used to target a haemoglobin concentration of 70–90 g/L. Albumin 4% can be used as colloid solution and has the theoretical benefit of remaining in the intravascular space for longer than crystalloid. Early intubation is recommended in severe cases to facilitate further management and reduce oxygen demand.

Appropriate antibiotics should be administered as early as possible (Box 10.34). Specific points in the history should be reviewed, such as underlying immune system status, risk factors for human immunodeficiency virus (HIV) and contacts with highly transmissible infections such as tuberculosis, pertussis or COVID-19. Immunocompromised patients will be susceptible to a far broader spectrum of infectious microorganisms (p. 315). The antibiotic choice will depend on local patterns of resistance, patient risk factors and the likely source of infection. Information on likely organisms and appropriate antibiotics can be found on pages 140 and 307). Microbiological samples (such as blood cultures, urine or CSF) should be taken, but this should not delay antibiotic administration if obtaining samples is difficult.

Early source control

Source control requires an accurate diagnosis; urgent investigations should be performed as soon as physiological stability has been established. A CT scan of the chest and abdomen with contrast is a high-yield test in this context. Specific actions may be required to control infection, such as drainage of an abscess or surgical debridement/resection of infected and/or necrotic tissue. Removal of potentially infected urine catheters or venous/arterial catheters should be promptly undertaken. Infected prosthetic devices, e.g. joint replacements, can be particularly challenging and require early specialist input.

Noradrenaline (norepinephrine) for refractory hypotension

Central venous access should be established early in the resuscitation process and a noradrenaline infusion commenced. If there is severe hypotension, it is not necessary to wait until 30 mL/kg of fluid has been administered before commencing noradrenaline; early vasopressor use may improve the outcome from acute kidney injury.

10.33 The 'Sepsis Six'*

- Deliver high-flow oxygen
- Take blood cultures
- Administer intravenous antibiotics
- Measure serum lactate and send full blood count
- Start intravenous fluid replacement
- Commence accurate measurement of urine output

*International recommendations for the immediate management of suspected sepsis from the Surviving Sepsis Campaign (all to be delivered within 1 hr of the initial diagnosis of sepsis).

10.34 Early administration of antibiotics in suspected sepsis

- Broad-spectrum antibiotics should be administered as soon as possible after sepsis is suspected.
- Every hour of delayed treatment is associated with a 5%–10% increase in mortality.

Other therapies for refractory hypotension

Refractory hypotension is due to either inadequate cardiac output or inadequate systemic vascular resistance (vasoplegia). When vasoplegia is suspected, it may be necessary to add vasopressin (antidiuretic hormone, ADH). This is a potent vasoconstrictor that may be used to augment noradrenaline (norepinephrine) in achieving an acceptable MAP. Intravenous glucocorticoids are also commonly used in refractory hypotension. There is little evidence that they improve the overall outcome, but they do lead to a more rapid reversal of the shocked state. There is a small increased risk of secondary infection following glucocorticoid use.

Septic cardiomyopathy

The myocardium can be affected by the septic process, presenting as either acute left or right ventricular dysfunction. A bedside echocardiogram is particularly useful to confirm the diagnosis, as ECG changes are usually non-specific. Dobutamine or adrenaline (epinephrine) can be used to augment cardiac output, and intravenous calcium should be replaced if ionised calcium is low.

Other interventions such as intravenous bicarbonate in profound metabolic acidosis, high-volume haemofiltration/haemodialysis and extracorporeal support are sometimes used, but currently lack evidence of benefit.

Review of the underlying pathology

While sepsis is the most common cause of acute systemic inflammation, up to 20% of patients initially treated for sepsis will have a non-infectious

10.35 Sepsis mimics

- Pancreatitis
- Drug reactions – e.g. reactions to immunotherapy
- Widespread vasculitis – catastrophic antiphospholipid syndrome, Goodpasture disease
- Autoimmune diseases – inflammatory bowel disease, rheumatoid arthritis, systemic lupus erythematosus
- Malignancy – carcinoid syndrome
- Haematological conditions – haemophagocytic syndrome, diffuse lymphoma, thrombotic thrombocytopenic purpura
- Toxicology – β-blocker or calcium channel blocker overdose

10.36 Berlin definition of ARDS

- Onset within 1 week of a known clinical insult, or new or worsening respiratory symptoms
- Bilateral opacities on chest X-ray, not fully explained by effusions, lobar/lung collapse or nodules
- Respiratory failure not fully explained by cardiac failure or fluid overload. Objective assessment (e.g. by echocardiography) must exclude hydrostatic oedema if no risk factor is present.
- Impaired oxygenation (see Box 10.37)

cause, i.e. a sepsis mimic (Box 10.35). These conditions should be considered where the clinical picture is not typical, no source of sepsis can be found, or the inflammatory response seems excessive in the context of local infection. Early reconsideration of the diagnosis of sepsis is crucial, as many of the 'sepsis mimics' offer a finite time window for specific intervention, after which irreversible organ damage will have occurred.

Acute respiratory distress syndrome

Aetiology and pathogenesis

Acute respiratory distress syndrome (ARDS) is a diffuse neutrophilic alveolitis caused by a range of conditions and characterised by bilateral radiographic infiltrates and hypoxaemia (Box 10.36). Activated neutrophils are sequestered into the lungs and capillary permeability is increased, with damage to cells within the alveoli. The pathophysiology is part of the inflammatory spectrum described in 'Sepsis' above, and the triggers are similar – infective and non-infective inflammatory processes. These processes result in exudation and accumulation of protein-rich cellular fluid within alveoli and the formation of characteristic 'hyaline membranes'. Local release of cytokines and chemokines by activated macrophages and neutrophils results in progressive recruitment of inflammatory cells. Secondary effects include loss of surfactant and impaired surfactant production. The net effect is alveolar collapse and reduced lung compliance, most marked in dependent regions of the lung (mainly dorsal in supine patients). The affected airspaces become fluid-filled and can no longer contribute to ventilation, resulting in hypoxaemia (due to increased pulmonary shunt) and hypercapnia (due to inadequate ventilation in some areas of the lung), i.e. ventilation–perfusion mismatch.

Diagnosis and management

ARDS can be difficult to distinguish from fluid overload or cardiac failure. Classic chest X-ray and CT appearances are shown in Figures 10.17 and 10.18, respectively. Occasionally, conditions may present in a similar way to ARDS but respond to alternative treatments; an example of this might be a glucocorticoid-responsive interstitial pneumonia (p. 573). There is debate within the intensive care community as to whether severe COVID-19 pneumonitis causes ARDS. Clinically and pathologically COVID-19 does appear to be a separate entity in which glucocorticoids and other immune mediators may be effective. Glucocorticoids remain of unproven benefit in ARDS from other causes, but are frequently used following some evidence of a mortality benefit. Safely reaching an accurate pathological diagnosis of respiratory failure is one of the key research areas within intensive care.

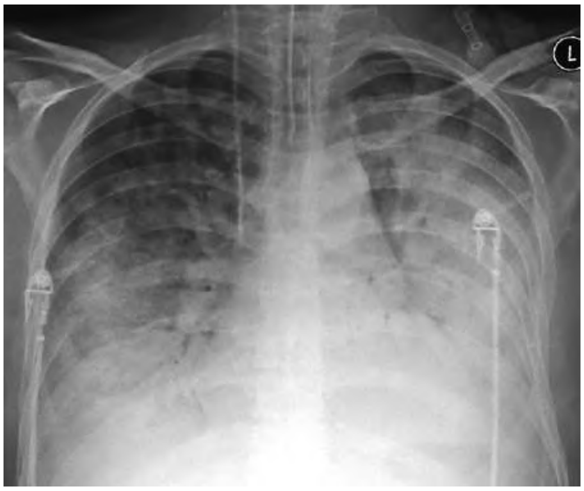


Fig. 10.17 Chest X-ray in acute respiratory distress syndrome (ARDS) showing extensive bilateral consolidation.

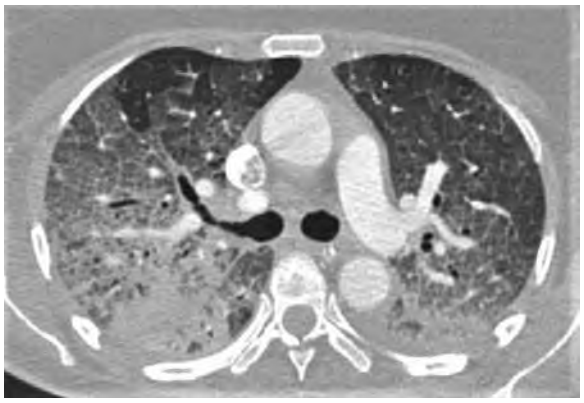

Fig. 10.18 CT scan of the thorax in a patient with severe ARDS demonstrating the typical features of increasingly dense consolidation towards the back of the lungs.

10.37 Determining the severity of ARDS

Severity of hypoxaemia is calculated using a Pa/FiO_2 ratio. This is a number calculated by using the PaO_2 from an arterial blood gas measurement divided by the fraction of inspired oxygen (FiO_2, expressed as a fraction).

For example, a patient with a PaO_2 of 10 kPa (75 mmHg) on 50% oxygen, i.e. FiO_2 of 0.5, would have a Pa/FiO_2 ratio of 20 kPa (150 mmHg). This would be defined as moderately severe ARDS, if the other Berlin criteria were met (see Box 10.36). All measurements should be taken on a minimum of 5 cmH_2O of PEEP or CPAP.

- Mild: 40–26.6 kPa (300–200 mmHg)
- Moderate: 26.6–13.3 kPa (200–100 mmHg)
- Severe: ≤ 13.3 kPa (≤ 100 mmHg)

(CPAP = continuous positive airway pressure; PEEP = positive end-expiratory pressure)

Management of ARDS is supportive, including use of lung-protective mechanical ventilation, inducing a negative fluid balance and treating the underlying cause. Establishing the severity of ARDS (Box 10.37) is useful, as severe disease will require more proactive management, such as prone positioning or extracorporeal membrane oxygenation (ECMO; see Fig. 10.26).

Acute circulatory failure (cardiogenic shock)

Definition and aetiology

Cardiogenic shock is defined as hypoperfusion due to inadequate cardiac output or, more technically, a cardiac index of $<2.2\,L/min/m^2$. While cardiogenic shock is the final common pathway of many disease processes (e.g. sepsis, anaphylaxis, haemorrhage), the important primary causes of acute heart failure or cardiogenic shock (Fig. 10.19) are described here.

Myocardial infarction

In the majority of cases, cardiogenic shock following acute MI is due to left ventricular dysfunction. However, it may also be due to infarction of the right ventricle, or a variety of mechanical complications, including tamponade (due to infarction and rupture of the free wall), an acquired ventricular septal defect (due to infarction and rupture of the septum) and acute mitral regurgitation (due to infarction or rupture of the papillary muscles).

Severe myocardial systolic dysfunction causes a fall in cardiac output, BP and coronary perfusion pressure. Diastolic dysfunction causes a rise in left ventricular end-diastolic pressure, pulmonary congestion and oedema, leading to hypoxaemia that worsens myocardial ischaemia. This is further exacerbated by peripheral vasoconstriction. These factors combine to create the 'downward spiral' of cardiogenic shock (Fig. 10.20). Hypotension, oliguria, delirium and cold, clammy peripheries are the manifestations of a low cardiac output, whereas breathlessness,

hypoxaemia, cyanosis and inspiratory crackles at the lung bases are typical features of pulmonary oedema. If necessary, a Swan–Ganz catheter can be used to measure the pulmonary artery pressures and cardiac output (see Fig. 10.27). These findings can be used to categorise patients with acute MI into four haemodynamic subsets (Box 10.38) and titrate therapy accordingly.

In cardiogenic shock associated with acute STEMI, immediate percutaneous coronary intervention should be performed (or, if not available, thrombolytic therapy should be administered). The viable myocardium surrounding a fresh infarct may contract poorly for a few days and then recover. This phenomenon is known as myocardial stunning and means that acute heart failure should be treated intensively because overall cardiac function may subsequently improve.

Acute massive pulmonary embolism

Massive PE may complicate leg or pelvic vein thrombosis and usually presents with sudden collapse. The clinical features and treatment are discussed on page 586. Bedside echocardiography may demonstrate a small, under-filled, vigorous left ventricle with a dilated right ventricle; it is sometimes possible to see thrombus in the right ventricular outflow tract or main pulmonary artery. In practice, it can be difficult to distinguish massive PE from a right ventricular infarct on transthoracic echocardiogram. CT pulmonary angiography usually provides a definitive diagnosis.

Acute valvular pathology, aortic dissection and cardiac tamponade

These conditions should be considered in an undifferentiated presentation of shock. The diagnosis and management of these conditions is discussed in Chapter 16.

Cardiac arrest

Cardiac arrest is the cessation of functional cardiac contraction and is the final common pathway in death from any pathology. In the clinical context, cardiac arrest refers to the sudden loss of cardiac output that prompts an emergency response. Pathogenesis, prognosis and management of in-hospital and out-of-hospital cardiac arrest are subtly different; however, the basic principles of cardiopulmonary resuscitation (CPR) are to maintain forward flow of oxygenated blood, correct the causative factor and restore spontaneous circulation.

Out-of-hospital cardiac arrest (OHCA)

This is the sudden and complete loss of cardiac output occurring in the community. The clinical diagnosis is based on the victim being unconscious and pulseless; breathing may take some time to stop completely after cardiac arrest. Death is virtually inevitable, unless effective treatment is given promptly.

Pathogenesis

Cardiac arrest may be caused by ventricular fibrillation (Fig. 10.21), pulseless ventricular tachycardia (see Ch. 16), asystole or pulseless electrical activity. Myocardial ischaemia is the most common trigger of OHCA. This can be due to an acute infarct, acute on chronic coronary insufficiency, post-infarct ventricular scarring or structural cardiac disease (cardiomyopathy, aortic stenosis). Ventricular fibrillation can occur in the absence of recognised structural abnormalities, e.g. congenital syndromes such as Brugada syndrome. Occasionally, sudden cardiac death can occur from an acute mechanical catastrophe such as cardiac rupture or aortic dissection. The causes are listed in Box 16.7.

Survivors of OHCA

The ‘Chain of Survival’ (Fig. 10.22) refers to the sequence of events that is necessary to maximise the chances of a cardiac arrest victim surviving. Survival is most likely if all links in the chain are strong: that is, if the arrest is witnessed, help is called immediately, basic life support is administered by a trained individual, the emergency medical services respond promptly, and defibrillation is achieved within a few minutes. CPR from bystanders, often assisted by ambulance service telephone dispatchers, is crucial. Good training in both basic and advanced life support is essential and should be maintained by regular refresher courses. Automated external defibrillators (AEDs) are increasingly available in public places, particularly where traffic congestion may impede the response of emergency services and should be used as soon as possible. Designated

individuals can respond to a cardiac arrest using basic life support and an automated external defibrillator.

For OHCA, survival rates of approximately 10% have been reported internationally. When STEMI (Box 16.47) is the suspected pathology, early coronary revascularisation should be considered. Those with reversible causes, such as exercise-induced ischaemia or aortic stenosis, should have the underlying cause treated if possible. Survivors of a ventricular tachycardia or ventricular fibrillation arrest, in whom no reversible cause can be identified, may be at risk of another episode and should be considered for an implantable cardiac defibrillator (p. 459) and anti-arrhythmic drug therapy.

In-hospital cardiac arrest (IHCA)

Historically, outcomes from IHCA were extremely poor. However, with appropriate anticipatory care planning and prompt intervention of hospital resuscitation teams, outcomes can be significantly better than for OHCA.

Pathogenesis

Although primary cardiac causes are the most common cause of IHCA, additional factors such as organ failure, sepsis or respiratory decompensation are often more pertinent. Correction of hypoxaemia with early tracheal intubation and ventilation is therefore of higher importance in this group than in OHCA, provided it can be achieved without interruption of chest compressions.

Clinical assessment and management

Basic life support

When a patient with suspected cardiac arrest is encountered, the ABCDE approach to management should be followed; this involves prompt assessment and restoration of the Airway, maintenance of ventilation using rescue Breathing ('mouth-to-mouth' breathing), and maintenance of the Circulation using chest compressions; Disability, in resuscitated patients, refers to assessment of neurological status, and Exposure entails removal of clothes to enable defibrillation, auscultation of the chest and assessment for a rash caused by anaphylaxis, for injuries and so on (Fig. 10.23). The term basic life support (BLS) encompasses manoeuvres that aim to maintain a low level of circulation until more definitive treatment with advanced life support can be given. Chest compression-only ('hands-only') CPR is easier for members of the public to learn and administer and is now advocated in public education campaigns.

Advanced life support

Advanced life support (ALS) (Fig. 10.24) aims to restore normal cardiac rhythm by defibrillation when the cause of cardiac arrest is a tachyarrhythmia, or to restore cardiac output by correcting other reversible causes of cardiac arrest. The initial priority is to assess the patient's cardiac rhythm by attaching a defibrillator or monitor. Once this has been done, treatment should be instituted based on the clinical findings. Only a minority of patients will have a shockable rhythm at the commencement of resuscitation.

Ventricular fibrillation or pulseless ventricular tachycardia should be treated with immediate defibrillation. Defibrillation is more likely to be effective if a biphasic shock defibrillator is used, where the polarity of the shock is reversed midway through its delivery. Defibrillation is usually administered using a 150 Joule biphasic shock, and CPR resumed immediately for 2 minutes without attempting to confirm restoration of a pulse, because restoration of mechanical cardiac output rarely occurs immediately after successful defibrillation. If, after 2 minutes, a pulse is not restored, a further biphasic shock of 150–200 J should be given. Thereafter, additional biphasic shocks of 150–200 J are given every 2 minutes after each cycle of CPR. During resuscitation, adrenaline (epinephrine, 1 mg IV) should be given every 3–5 minutes and consideration given to the use of intravenous amiodarone, especially if ventricular fibrillation or ventricular tachycardia re-initiates after successful defibrillation.

Ventricular fibrillation of low amplitude, or 'fine VF', may mimic asystole. If asystole cannot be confidently diagnosed, the patient should be treated for VF and defibrillated. Bedside echocardiography can be a useful clinical aid. The subcostal views can frequently be obtained without detriment to CPR quality, and can identify cardiac structural abnormalities such as an enlarged right heart in pulmonary embolism, aortic stenosis or ongoing fine VF. Refractory VF can be amenable to supplementary drugs (e.g. lidocaine, magnesium, procainamide) or alternative ways of using the defibrillator, e.g. anteroposterior pad placement.

If an electrical rhythm is observed that would be expected to produce a cardiac output, 'pulseless electrical activity' is present. Pulseless electrical activity should be treated by continuing CPR and adrenaline (epinephrine) administration while seeking causes. Asystole should be treated similarly, although prolonged asystole has an extremely poor prognosis.

There are many potentially reversible causes of cardiac arrest; the main ones can be remembered as a list of four Hs and four Ts (see Fig. 10.24). In specialist centres and in appropriate candidates, the use of extracorporeal life support has been used in cardiac arrest with good effect. However, this is not generally available outside of large urban centres. The use of automated chest compression devices is becoming more common, and their use should be considered in patients in whom a prolonged resuscitation is expected (e.g. when thrombolytic has been administered or in profound hypothermia). Injuries from CPR are common; their management is summarised in the section on 'Complications and outcomes of critical illness' later in this chapter.

Post cardiac arrest

The majority of cardiac arrest survivors will need a period of time in intensive care to achieve physiological stability, identify and manage the underlying cause of the arrest, and optimise neurological recovery.

Acute management

A MAP of >65 mmHg should be maintained to optimise cerebral perfusion. Shock is common following return of spontaneous circulation (ROSC) and is caused by a combination of the underlying condition leading to the arrest, myocardial stunning and a post-arrest vasodilated state. Support with inotropes, vasopressors and occasionally mechanical support from an intra-aortic balloon pump or venous–arterial ECMO (see Fig. 10.26) may be required. Specific cardiac interventions and their indications are described in Chapter 16. Other physiological targets are listed in Box 10.39.

Prognosis

Predicting which patients will not recover from the brain injury sustained at the time of cardiac arrest is very difficult. Certain features suggest that the outcome will be poor: for example, the absence of pupillary and corneal reflexes, absence of a motor response and persistent myoclonic jerking.

Tools to assist prognostication following cardiac arrest are shown in Box 10.40. The clinician should, where feasible, delay prognostication until a period of 72 hours of targeted temperature management has been completed. The bilateral absence of the 'N20' spike on the somatosensory evoked potential is the most specific test to predict irrecoverable brain injury. This test is performed by administering an electrical impulse over a peripheral nerve and recording the electrical impulses measured by the scalp electrodes overlying the part of the brain expected to receive the impulse. Where this is not available, prognostication based on all other available information, along with the perceived wishes relating to the level of disability the individual would be prepared to accept, should allow a decision regarding ongoing treatment to be made. Where there is doubt, more time should be given to allow assessment of neurological recovery.

Other causes of multi-organ failure

As previously discussed, sepsis is the most common cause of multi-organ failure. However, multi-organ failure secondary to single organ dysfunction, such as cardiac failure, liver failure, renal failure or respiratory failure, is also common. The multisystem insult in these disease

i 10.39 Physiological targets following a return of spontaneous circulation (ROSC)

- *Temperature management.* Facilitate maintenance of temperature at 36°C and avoidance of pyrexia using a cooling blanket. This should be continued for 72 hrs. Muscle relaxants may be required to prevent shivering.
- *Blood pressure management.* Aim for a MAP of at least 65 mmHg
- *Glucose control.* Control the glucose to 6–10 mmol/L (108–180 mg/dL).
- *Normal CO_2* (4.5–6 kPa, 33–45 mmHg) *and oxygen saturation* (94%–98%). Avoid both hypoxaemia and hyperoxia.

processes goes beyond the direct biochemical damage and tissue hypoxia caused by the primary organ dysfunction. It probably reflects cellular signalling pathways and the release of other systemic toxins by the failing organ, referred to as organ 'crosstalk'.

Multi-organ failure can also be caused by a physiological insult that damages a wide variety of cells in different organs, including toxins from extrinsic sources such as envenomation and intrinsic sources such as myoglobin in rhabdomyolysis (p. 235). Multi-organ failure can also be caused by profound physical injury to cells from processes such as nuclear radiation, heat exposure or blast trauma.

Critical care medicine

Decisions around intensive care admission

Being a patient in intensive care is seldom a pleasant experience. The interventions are usually painful and the loss of liberties that are normally taken for granted can be devastating. While much of the unpleasant sensory and emotional experience can be modified with high-quality care and analgesia, there is a strong case that it can only be morally 'right' to admit a patient to intensive care if 'the ends justify the means'. There must be a realistic hope that the patient will regain a quality of life that would be worth the pain and suffering that he or she will experience in intensive care. Few patients are able to comprehend fully what it means to be critically ill, so the physician should guide the process of determining who should be admitted to intensive care.

Selecting the appropriate level of intervention for an individual patient can be very difficult. The decision-making process should involve an assessment of the likelihood of reversibility of the disease, the magnitude of the interventions required, the underlying level of frailty, and the

personal beliefs and wishes of the patient (commonly expressed through their next of kin).

As technology and science have improved, conditions that were previously regarded as terminal can now be supported and life can be considerably prolonged (Box 10.41). There have been several prominent examples of individuals who have received intensive care, but where an onlooker might have considered treatment to be futile owing to frailty, comorbidity or profound neurological injury. Such cases will, in part, shape the views and expectations of society, and it is unlikely that making decisions in this area will become any easier. Some suggested techniques to aid decision-making are listed in Box 10.42.

Stabilisation and institution of organ support

In order to stabilise a critically unwell patient, the primary problem should be corrected as quickly as possible: for example, source control in sepsis and control of the bleeding point in haemorrhage. Immediate resuscitation and prioritisation of the safety of the patient are clearly important, but there is only a limited role for 'optimising' the patient if such measures may significantly delay a definitive treatment, such as laparotomy for a perforated viscus. In some cases, the definitive treatment is not readily apparent or treatments take time to have their full effect. In these cases, adequate organ support to stabilise the patient while the treatment is given becomes the main goal of care.

Respiratory support

Non-invasive respiratory support

Non-invasive respiratory support provides a bridge between simple oxygen delivery devices and invasive ventilation. It can be used in patients who are in respiratory distress but do not have an indication for invasive ventilation, or in those who are not suitable for intubation and ventilation for chronic health reasons. Patients must be cooperative, able to protect their airway, and have the strength to breathe spontaneously and cough effectively. Clinicians should avoid using non-invasive respiratory support to prolong the dying process in irreversible conditions such as end-stage lung disease. Likewise, a failure to respond to treatment or further deterioration should trigger a decision regarding intubation, as delayed invasive ventilation in this context is associated with worse outcome.

10.41 Critical illness in the context of congenital conditions

- **Longer survival**: there are many congenital conditions that would, in the past, have been fatal in childhood, but now patients survive into adulthood. Decision-making can be difficult when the adolescent has impaired decision-making capacity.
- **Parental views**: in such circumstances, the views of the parent or legal guardian become paramount.
- **Goals of care**: often a detailed explanation of what is, and is not, achievable in intensive care allows the direction of care to be switched to palliative when life expectancy is poor and quality of life is severely impaired.
- **Decision-making**: such conversations may require input from experts in the patient's congenital condition(s), and advanced decision-making regarding ICU admission should be encouraged whenever patients and families feel able to discuss such issues.

10.42 Techniques to improve admission decision-making

- *Always act in the best interests of the patient*: external influences are commonly present but these should be of only secondary importance.
- *Maximise patient capacity*: wherever possible, the patient should be involved in discussions of escalation and resuscitation status.
- *Communicate openly and honestly with the next of kin*: when communicating potential outcomes, it is best to use natural frequencies rather than percentages. For example, 'If we had 100 patients with the same illness as your mother, only 10 would survive' is easier for most people to understand than 'there is a 90% chance of death'.
- *Reach mutual agreement with the next of kin*: it is rare for there to be discord between clinicians and family, and in most cases the most appropriate course of action is clear.
- *Seek additional opinions*: other clinicians involved in the care of the patient will provide useful input. The premise should be to err on the side of escalation where the most appropriate course of action is unclear. Where there is an unresolvable difference in opinion, a mediation process or court ruling may be required to make the final decision. Thankfully, this is a very infrequent occurrence.
- *Plan ahead*: advance planning in chronic, progressive disease can make the decision easier. Some health facilities use an escalation form, which specifies the interventions that should be offered or are acceptable to the patient. This can be useful as the binary decision of for/not for resuscitation fails to account for the array of interventions that can be performed before cardiac arrest occurs.

High-flow nasal cannulae

High-flow nasal cannulae (HFNCs) are devices that provide very high gas flows of fully humidified oxygen and air. They offer distinct advantages over non-invasive ventilation (NIV) in selected patients, mainly those with type I respiratory failure (particularly pneumonia) who have not reached an indication for invasive ventilation. They allow patient comfort and increased expectoration while providing some degree of positive end-expiratory pressure (PEEP) and a high oxygen concentration that can be titrated to the SO_2.

Continuous positive pressure ventilation

Continuous positive pressure ventilation therapy involves the application of a continuous positive airway pressure (CPAP) throughout the patient's breathing cycle, typically 5–10 cmH_2O. It helps to recruit collapsed alveoli and can enhance clearance of alveolar fluid. It is particularly effective at treating pulmonary atelectasis (which may be post-operative) and pulmonary oedema. It can be delivered using a simpler device than NIV, may be better tolerated and avoids compounding the hypocapnia that sometimes occurs in type I respiratory failure. It can reduce the work of breathing and avoid intubation in selected patients with respiratory failure, for example in patients with severe viral pneumonitis.

Non-invasive ventilation or bi-level ventilation

NIV provides ventilatory support via a tight-fitting nasal or facial mask. It can be delivered by using a simple bi-level ventilation (BiPAP) turbine ventilator, or an intensive care ventilator. These machines can deliver pressure at a higher level (approximately 10–20 cmH$_2$O) for inspiration and a lower pressure (usually 4–10 cmH$_2$O) to allow expiration. Ventilation can be spontaneous (triggered by a patient's breaths) or timed (occurring at a set frequency). Systems that synchronise with a patient's efforts are better tolerated and tend to be more effective in respiratory failure. Timed breaths are used for patients with central apnoea. NIV is the first-line therapy in patients with type II respiratory failure secondary to an acute exacerbation of COPD because it reduces the work of breathing and offloads the diaphragm, allowing it to recover strength. It is also useful in pulmonary oedema, obesity hypoventilation syndromes and some neuromuscular disorders. It should be initiated early, especially when severe respiratory acidosis secondary to hypercapnia is present. NIV can also be used to support selected patients with hypercapnia secondary to pneumonia, or during weaning from invasive ventilation, but its effectiveness in these contexts is less certain; early intubation or re-intubation is probably more beneficial.

Intubation and intermittent positive pressure ventilation

Taking control of the respiratory system in a critically ill patient is one of the most significant and risky periods in a patient's journey. Critical incidents are common because the patient is often deteriorating rapidly and is exhausted. The potential for cardiovascular collapse is further exacerbated by the negatively inotropic and vasodilating drugs used to induce anaesthesia, and the period of apnoea invoked to facilitate intubation (Box 10.43).

The main aims of intermittent positive pressure ventilation (IPPV) are to avoid critical hypoxaemia and hypercapnia while minimising damage to the alveoli and encouraging the patient to breathe spontaneously once it is safe to do so. The determination of what constitutes *critical* will depend on the status of each patient. For example, a patient with raised ICP will have a strong indication for normocapnia (because hypercapnia increases ICP). Unfortunately, achieving the minute volumes required to maintain normocapnia can be harmful to the lungs.

Ventilator modes

Following intubation, most patients have a period of paralysis from the muscle relaxation. Mandatory ventilation is, therefore, required for a variable period, depending on the severity of the lung injury, the underlying disease process and the general condition of the patient. Mandatory ventilation means that the ventilator will deliver set parameters (either a set tidal volume or a set inspiratory pressure), regardless of patient effort. A physician can choose to support additional patient effort in between mandatory breaths with pressure support. This requires sufficient patient effort to 'trigger' the ventilator to deliver a synchronised breath, in time with the patient's own ventilation. Other parameters that should be considered when using mechanical ventilation are shown in Figure 10.25.

As a patient's illness resolves, or if the lung injury necessitating intubation is not severe, periods of spontaneous breathing with pressure support are commenced. While spontaneous breathing is preferable to mandatory ventilation modes, the shearing forces of patient effort can exacerbate lung injury in patients with severely damaged lungs. It is, therefore, important that a patient is permitted to breathe in a planned and controlled way.

Ventilator-induced lung injury

Every positive pressure breath causes cyclical inflation of alveoli followed by deflation. The resultant damage to alveoli occurs via several possible mechanisms:

- distending forces from the tidal volume, termed 'volutrauma'
- the pressure used to inflate the lung, referred to as 'barotrauma'
- alveoli collapsing at the end of expiration, called 'atelectotrauma'
- the release of inflammatory cytokines in response to cyclical distension, called 'biotrauma'.

10.43 Optimising safety during intubation

- Intervene early in the disease process (once it has become clear that the disease trajectory is downward).
- Use a stable anaesthetic technique: low doses of sedative agents and rapidly acting paralytic agents.
- Use techniques to optimise oxygenation and ventilation in the period around intubation, e.g. keeping high-flow nasal cannulae in position for the apnoeic period, manual ventilation via facemask while awaiting neuromuscular blockade, and using a video-laryngoscope in an anticipated difficult intubation.
- When the history and epidemiology suggests risk of an airborne communicable disease, intubation should be performed in an isolated room with adequate ventilation and with as few staff present as possible. Intubation is an aerosol-generating procedure and all staff should wear appropriate personal protective equipment.
- Use a checklist to ensure the whole team is briefed.
- If an anatomically or physiologically difficult airway is anticipated, awake techniques can be considered.

The threshold of injurious ventilation is unique to each patient. Moderate ventilator pressures and volumes used to ventilate healthy lungs may not cause ventilator-induced lung injury (VILI), but the same settings may cause significant VILI if delivered to a patient with lungs that are already damaged from another disease process.

Strategies that may reduce the incidence and severity of VILI include:

- *Permissive hypercapnia*. In the majority of patients who are ventilated for respiratory failure, it is preferable to tolerate moderate degrees of hypercapnia rather than strive for normal blood gases at the expense of VILI. For example, in a patient with isolated respiratory failure, a physician may choose to tolerate a $PaCO_2$ of up to 10 kPa (75 mmHg), provided the H^+ is < 63 nmol/L (pH > 7.2).
- *'Open lung' ventilation*. Maintaining a positive pressure within the airways at the end of expiration prevents atelectotrauma. This can be facilitated by the use of low tidal volumes and higher levels of PEEP (see Fig. 10.25). Recruitment manoeuvres (occasional short periods of sustained high airway pressures to open up alveoli that have collapsed) can improve oxygenation in ARDS, but has not been shown to improve outcome.
- *Paralysis*. When respiratory failure is severe, patient effort may worsen VILI. An infusion of muscle relaxant can be used to moderate dyssynchrony with the ventilator.

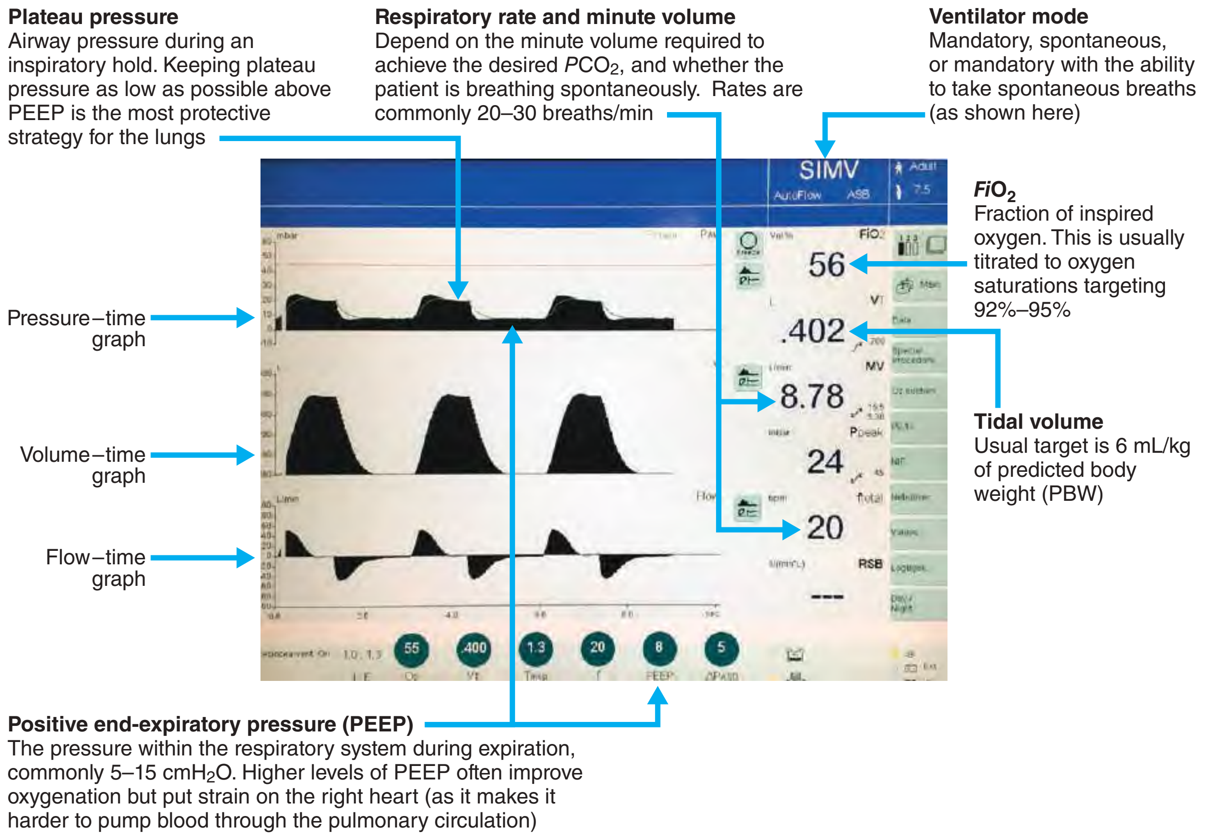
Advanced respiratory support

Airway pressure release ventilation

Airway pressure release ventilation (APRV) is a mode of ventilation that lengthens the inspiratory time to the extreme, with a very short period of time for expiration. It can be extremely effective in patients who have a tendency towards alveolar collapse (and who are requiring high levels of inspiratory pressure) such as obese patients and those with severe ARDS. Although survival benefit is lacking, if used carefully by an experienced team, it does appear to be a useful mode of ventilation in selected patients.

Prone positioning

In ARDS, the posterior parts of the lung lose airspaces due to atelectasis and inflammatory exudate. By placing patients on their front, the pattern of fluid distribution within the lung changes, and ventilation–perfusion matching is improved. This is used to enhance oxygenation in moderate to severe ARDS and may have some disease-modifying effects as the dependent areas of the lung are changed periodically. Although there are risks associated with nursing a patient in the prone position, it is a widely used therapy. Patients are usually placed in the prone position for 16–24 hours and then rotated back to the supine



Plateau pressure
Airway pressure during an inspiratory hold. Keeping plateau pressure as low as possible above PEEP is the most protective strategy for the lungs

Respiratory rate and minute volume
Depend on the minute volume required to achieve the desired PCO_2, and whether the patient is breathing spontaneously. Rates are commonly 20–30 breaths/min

Ventilator mode
Mandatory, spontaneous, or mandatory with the ability to take spontaneous breaths (as shown here)

FiO_2
Fraction of inspired oxygen. This is usually titrated to oxygen saturations targeting 92%–95%

Pressure–time graph

Volume–time graph

Flow–time graph

Tidal volume
Usual target is 6 mL/kg of predicted body weight (PBW)

Positive end-expiratory pressure (PEEP)
The pressure within the respiratory system during expiration, commonly 5–15 cmH_2O. Higher levels of PEEP often improve oxygenation but put strain on the right heart (as it makes it harder to pump blood through the pulmonary circulation)

Fig. 10.25 Settings to be considered when commencing mechanical ventilation.

position for a similar period. This cycle continues until there is evidence of resolving lung injury. Using prone positioning in the awake and cooperative patient on high-flow oxygen or CPAP may be a useful technique in some patients.

Extracorporeal respiratory support

Sometimes, despite optimal invasive ventilation, it is not possible to maintain adequate oxygenation or prevent a profound respiratory acidosis. When a patient has a reversible cause of respiratory failure (or is a potential lung transplant recipient) and facilities are available, extracorporeal respiratory support should be considered.

Venous–venous extracorporeal membrane oxygenation

In venous–venous extracorporeal membrane oxygenation (VV ECMO), large-bore central venous cannulae are inserted into the superior vena cava (SVC) and/or the inferior vena cava (IVC) via the jugular or femoral veins, and advanced under ultrasound or fluoroscopic guidance (Fig. 10.26). Venous blood is then pumped through a membrane oxygenator. This device has thousands of tiny silicone tubes with air/oxygen gas on the other side of the tubes (the membrane). This facilitates the passage of oxygen into the blood and diffusion of carbon dioxide across the membrane, where it is removed by a constant flow of gas (sweep gas). The oxygenated blood is then returned to the right atrium, from where it flows through the lungs as it would in the physiological state. This means that even if the lungs are contributing no oxygenation or carbon dioxide removal, a patient can remain well oxygenated and normocapnic.

Extracorporeal carbon dioxide removal

In some patients it is possible to maintain oxygenation but there is refractory hypercapnia. There are devices available that can remove carbon dioxide using a much lower blood flow rate than VV ECMO. Consequently, smaller venous cannulae, similar to those used in renal dialysis, can be sufficient to have a 'CO_2 dialysis' effect. This can be useful in patients in whom normocapnia is essential (such as those with a raised ICP), or those with refractory hypercapnia and adequate oxygenation. In addition, extracorporeal carbon dioxide removal can be used to reduce the required minute volume, which is a beneficial strategy for protecting the lungs against VILI or facilitating early extubation.

Cardiovascular support

Initial resuscitation

A brief assessment can usually yield enough information to determine whether a patient is at significant risk of an imminent cardiac arrest. If the patient is obtunded and there is no palpable radial or brachial pulse, then treatment should proceed as described on page 235.

In a peri-arrest situation, a single dose of intramuscular adrenaline (epinephrine) 0.5 mg (0.5 mL of 1 : 1000) can be life-saving. If expertise is available, a small dose of intravenous adrenaline (epinephrine) can delay cardiac arrest long enough to identify the cause of shock and institute other supportive measures; a suggested dose would be 50 µg (0.5 mL of 1 : 10 000). If haemorrhage is considered a possibility, a 'major haemorrhage' alert should be activated, facilitating rapid access to large volumes of blood and blood products. A classification of shock is shown in Box 10.44.

Venous access for the administration of drugs and fluids is vital but often difficult in critically unwell patients. Wide-bore cannulae are required for rapid fluid administration. In extremis, the external jugular vein can be cannulated; it is often prominent in low cardiac output states and readily visible on the lateral aspect of the neck. Occluding the vein distally with finger pressure makes it easier to cannulate, but care must be taken to remain high in the neck to avoid causing a pneumothorax. Intra-osseous or central venous access can be established if there are

Fluid and vasopressor use

Resuscitation of the shocked patient should usually include a 10 mL/kg fluid challenge. Using colloid or crystalloid is acceptable; starch solutions are associated with additional renal dysfunction and should be avoided. The fluid challenge can be repeated if shock persists, to a maximum total of 30 mL/kg of fluid. However, commencing vasopressor therapy early in resuscitation is better than delaying until a large volume of fluid has been given. Amongst other beneficial effects, vasopressors induce venoconstriction, reducing the capacitance of the circulation and effectively mobilising more fluid into the circulation.

If a patient remains shocked after 30 mL/kg of fluid has been administered, a re-evaluation of the likely cause is required, looking particularly for concealed haemorrhage or an obstructive pathology. A bedside echocardiogram is especially useful at this stage to evaluate cardiac output and exclude tamponade. Noradrenaline (norepinephrine) (Box 10.45) should be commenced as the first-line vasoactive agent in most cases, unless there is a strong indication to use a pure inotropic or chronotropic agent: for example, in cardiogenic shock or shock associated with bradycardia. If there is evidence of low cardiac output, adrenaline (epinephrine) or dobutamine should be commenced. Both agents are equally effective, but dobutamine causes more vasodilatation and additional noradrenaline may be required to maintain an adequate MAP. Vasopressin is added if hypotension persists despite high doses of noradrenaline and cardiac output is thought to be adequate.

In extreme situations it is acceptable to start infusions of inotropes through a well-sited, large-bore peripheral cannula, although central venous access and an arterial line (for monitoring) should be inserted as soon as possible. The actions of commonly used vasoactive drugs are summarised in Box 10.46.

Advanced haemodynamic monitoring

There are many different devices available to estimate cardiac output. Such devices employ a variety of mechanisms, including the Doppler effect of moving blood, changes in electrical impedance of the thorax, or the dilution of either an indicator substance or heat (thermodilution). The information is processed within the equipment, and often integrated with additional data, such as the arterial pressure waveform, to give an estimate of cardiac output and stroke volume.

Portable echocardiography has the advantage of giving qualitative information – for example, demonstrating aortic stenosis or a regional wall motion abnormality – as well as quantitative information on stroke volume, but it requires technical expertise.

Pulmonary artery (PA) catheters, sometimes referred to as Swan–Ganz catheters (Fig. 10.27), are invasive but provide useful information on pulmonary pressures, cardiac output, mixed venous oxygen saturations and, by extrapolation, whether the cause of the shock is vasodilatation or pump failure. They can be helpful in complex cases, such as shock after cardiac surgery, or in patients with suspected pulmonary hypertension. However, PA catheters are associated with some rare but serious complications, including lung infarction, PA rupture and thrombosis of the catheter itself. Such complications occur infrequently in centres that use PA catheters regularly; it should be stressed that a lack of familiarity within the wider clinical team is a relative contraindication to their use.

Although data from less invasive devices are less robust, they can guide the balance of inotropy, vasoconstriction and fluid resuscitation through estimation of stroke volume and heart–lung interactions that are more pronounced in hypovolaemia.

10.44 Categories of shock

Category	Description
Hypovolaemic	Can be haemorrhagic or non-haemorrhagic in conditions such as hyperglycaemic hyperosmolar state (p. 766) and burns
Cardiogenic	See page 239
Obstructive	Obstruction to blood flow around the circulation, e.g. major pulmonary embolism, cardiac tamponade, tension pneumothorax
Septic	See page 235
Anaphylactic	Inappropriate vasodilatation triggered by an allergen (e.g. bee sting), often associated with endothelial disruption and capillary leak (p. 219)
Neurogenic	Caused by major brain or spinal injury, which disrupts brainstem and neurogenic vasomotor control. High cervical cord trauma may result in disruption of the sympathetic outflow tracts, leading to inappropriate bradycardia and hypotension. Guillain–Barré syndrome (p. 1238) can involve the autonomic nervous system, resulting in periods of severe hypo- or hypertension
Others	e.g. Drug-related such as calcium channel blocker overdose; adrenal crisis

Mechanical cardiovascular support

When shock is so severe that it is not possible to maintain sufficient organ perfusion with fluids and inotropic support, it is sometimes necessary to use an internal device to augment or replace the inadequate native cardiac output.

Intra-aortic balloon pump

An intra-aortic balloon counter-pulsation device is a long tube that is usually inserted into the femoral artery and fed proximally into the thoracic aorta. The basic principle is that a helium-filled balloon is able to inflate and deflate rapidly in time with the cardiac cycle. It is inflated in diastole, thus augmenting forward flow of blood to the abdominal organs and improving diastolic pressure proximal to the balloon, thereby optimising coronary perfusion. While the principle is appealing, and an intra-aortic balloon pump (IABP) is often effective in achieving predetermined physiological goals, this does not translate into improved survival in cardiogenic shock. There are risks associated with thrombosis formation on the balloon, mesenteric ischaemia and femoral artery pseudo-aneurysm following removal of the device.

Venous–arterial extracorporeal membrane oxygenation

Venous–arterial extracorporeal membrane oxygenation (VA ECMO) can be life-saving in profound cardiogenic shock and has even been used

10.45 Noradrenaline (norepinephrine) dosing considerations*

Dose	Considerations
0.1–0.2 µg/kg/min	Low–moderate dose Could potentially be given peripherally Optimise fluid status
0.2–0.3 µg/kg/min	Moderate dose Consider adding in hydrocortisone in septic shock
Above 0.3 µg/kg/min	High dose Extreme caution on syringe changes (very short half-life) Consider adding in vasopressin if cardiac output is adequate

*Doses in micrograms per kilogram per minute (µg/kg/min)

10.46 Actions of commonly used vasoactive agents

	Action		
Drug	Vasoconstrictor	Inotrope	Chronotrope
Adrenaline (epinephrine)	++	+++	++
Noradrenaline (norepinephrine)	++++	+	+
Dobutamine	–	++++	+++
Vasopressin	+++++	No action	– (reflex bradycardia)

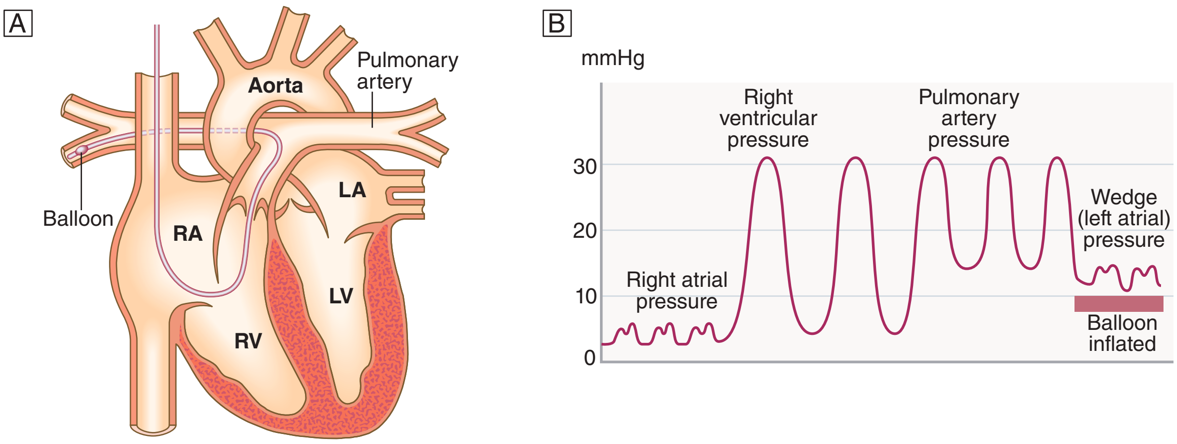

Fig. 10.27 A pulmonary artery (Swan–Ganz) catheter. A There is a small balloon at the tip of the catheter and pressure can be measured through the central lumen. The catheter is inserted via an internal jugular, subclavian or femoral vein and advanced through the right heart until the tip lies in the pulmonary artery. When the balloon is deflated, the pulmonary artery pressure can be recorded. B Advancing the catheter with the balloon inflated will 'wedge' the catheter in the pulmonary artery. Blood cannot then flow past the balloon, so the tip of the catheter will now record the pressure transmitted from the pulmonary veins and left atrium (known as the pulmonary artery capillary wedge pressure), which provides an indirect measure of the left atrial pressure. (LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle)

effectively in refractory cardiac arrest. The circuit and principles are very similar to those described in 'VV ECMO' above (see Fig. 10.26) with one important difference: oxygenated blood is returned to the arterial system (rather than into the right atrium). This means that the pump needs to generate sufficient pressure to allow blood to flow through the systemic circulation. The sites of venous and arterial access can be either central (via a thoracotomy or sternotomy) or peripheral via cannulae in the IVC/SVC and the femoral/subclavian artery. If the return cannula is peripherally sited (e.g. in the femoral artery), blood will flow back up the aorta from distal to proximal and perfuse the organs.

The outcome depends on the avoidance of complications (primarily, bleeding at the cannula site, intracranial haematoma, air embolism, infection and thrombosis) and improvement of the underlying condition. Most causes of profound cardiogenic shock are unlikely to resolve, and the potential availability of a longer-term solution, such as cardiac transplantation or insertion of a ventricular assist device, is a prerequisite for commencing VA ECMO in most centres.

Renal support

Renal replacement therapy (RRT) is explained in detail on page 634. The key points relating to RRT in an intensive care context are:

- Haemodynamic instability is common. Continuous therapies are widely believed to cause less haemodynamic instability than intermittent dialysis. However, many units use intermittent dialysis without significant problems.
- Haemodialysis and haemofiltration are equally good. Although there are theoretical benefits to removing inflammatory cytokines with haemofiltration, this does not translate into improved survival.
- Anticoagulation is usually achieved using citrate or heparin. Citrate has a better profile for anticoagulating the extracorporeal circuit without inducing an increased bleeding risk, but may accumulate in patients with profound multi-organ failure.
- Most patients who survive intensive care will regain adequate renal function to live without long-term renal support.
- A thorough investigation for reversible causes of renal dysfunction should always be undertaken in conjunction with instigation of renal support (see Fig. 18.19).
- RRT should commence if any hard indication is met (hyperkalaemia, acidosis, fluid overload or toxin). However, in the absence of this, early RRT is probably not beneficial, and a period of resuscitation with close observation in trends of urine output and renal biochemistry may obvert its requirement.

Neurological support

A diverse range of neurological conditions require management in intensive care. These include the various causes of coma, spinal cord injury, peripheral neuromuscular disease and prolonged seizures.

The goals of care in such cases are to:

- Protect the airway, if necessary by endotracheal intubation.
- Provide respiratory support to correct hypoxaemia and hypercapnia.
- Treat circulatory problems, e.g. neurogenic pulmonary oedema in subarachnoid haemorrhage, autonomic disturbances in Guillain–Barré syndrome, and spinal shock following high spinal cord injuries.
- Manage acute brain injury with control of ICP.
- Manage status epilepticus using antiepileptic agents such as levetiracetam, phenytoin and benzodiazepines. In refractory cases an infusion of sodium thiopental or ketamine may be required.

The aim of management in acute brain injury is to optimise cerebral oxygen delivery by maintaining normal arterial oxygen content and a cerebral perfusion pressure (CPP) of > 60 mmHg. Secondary insults to the brain, such as hypoxaemia, hyper/hypoglycaemia and prolonged seizures, must be avoided. ICP rises in acute brain injury as a result of haematoma, contusions, oedema or ischaemic swelling. Raised ICP causes damage to the brain in two ways: direct damage to the brainstem and motor tracts because of downward pressure and herniation through the tentorium cerebelli and foramen magnum, and indirect damage by reducing CPP. Cerebral blood flow is dependent on an adequate CPP. The CPP is determined by the formula:

$$\text{CPP} = \text{MAP} - \text{ICP}$$

ICP can be measured by pressure transducers that are inserted directly into the brain tissue. The normal upper limit for ICP is 15 mmHg and an upper acceptable limit of 20 mmHg is usually adopted in intensive care. Sustained pressures of > 30 mmHg are associated with a poor prognosis. Various strategies are used to control ICP: maintaining normocapnia, preventing any impedance to venous drainage from the head, giving osmotic agents such as mannitol and hypertonic saline, and using hypothermia and decompressive craniectomy. No single technique has been shown to improve outcome in severe intracranial hypertension.

CPP should be maintained above 60 mmHg by ensuring adequate fluid replacement and, if necessary, by treating hypotension with a vasopressor such as noradrenaline (norepinephrine). Complex neurological monitoring must be combined with frequent clinical assessment of GCS, pupillary response to light and focal neurological signs.

Daily clinical management in intensive care

Clinical review

In intensive care, detailed clinical examination should be performed daily to identify changes to a patient's condition and review the latest diagnostic information. Further focused clinical reviews are usually incorporated into twice-daily ward rounds. Each ward round offers an ideal opportunity to monitor and document adherence with relevant care bundles. A care bundle is a group of interventions that, when implemented concurrently, have provided evidence of clinical benefit. The mnemonic 'FAST HUG' provides a useful checklist of interventions that reduce intensive care complications: *f*eeding/fluids, *a*nalgesia, *s*edation, *t*hromboprophylaxis, *h*ead of bed elevation (to reduce the incidence of passive aspiration), *u*lcer prophylaxis and *g*lucose control.

Other key aspects of the daily review are outlined on page 212. The over-arching aim of the review is to identify the issues that are impeding recovery from critical illness and make alterations to address them. In addition, specific and realistic goals for each relevant organ system should be defined, facilitating the autonomous titration of therapy by the bedside critical care nurse. An example of daily goals may be: 'Titrate the noradrenaline (norepinephrine) to achieve a MAP of 65 mmHg, aim for a negative fluid balance, titrate FiO_2 to achieve oxygen saturations of 92%–95% and titrate sedation to a RASS score of 0 to –1' (see Box 10.48).

Infection surveillance

Infection surveillance is an important part of the daily review as nosocomial infection is common in critically ill patients. Trends in temperature, heart/respiratory rate and secretion load can all be early indicators of ventilator-associated pneumonia (VAP). Likewise, leucocytosis and a raised C-reactive protein are measured frequently, but are not specific enough to guide therapy alone. Procalcitonin (PCT) is increasingly used to give more specific information on bacterial infection. A rapidly reducing trend can allow for a shortening of antibiotic courses (reducing the likelihood of generating resistant organisms) and a persistently low PCT in a shocked patient can alert the clinician to the possibility of an aetiology other than sepsis. Severe viral and fungal infections, e.g. COVID-19, can cause an elevated PCT and occasionally sepsis can develop before the PCT has risen, so as with all investigations the result should be used as adjunct to clinical assessment.

Sedation and analgesia

Most patients require some degree of sedation and analgesia to ensure comfort, relieve anxiety and tolerate mechanical ventilation. Some conditions, such as critically high ICP or critical hypoxaemia, require deep sedation to reduce tissue oxygen requirements and protect the brain from the peaks in ICP associated with coughing or gagging. For the majority of patients, however, optimal sedation is an awake and lucid patient who is comfortable and able to tolerate an endotracheal tube (termed 'tube tolerance').

Over-sedation is associated with longer ICU stays, a higher prevalence of delirium, prolonged requirement for mechanical ventilation, and an increased incidence of ICU-acquired infection. Box 10.47 compares the various agents used for sedation in intensive care. The key principles are that the patient should primarily receive analgesia, rather than anaesthesia, and caution should be used with drugs that accumulate in hepatic and renal dysfunction. Often a combination of drugs is used to achieve the optimal balance of sedation and analgesia.

Sedation is monitored via clinical sedation scales that record responses to voice and physical stimulation. The Richmond Agitation–Sedation Scale (RASS) is the best-recognised tool (see Box 10.48 for details). Regular use of a scoring system to adjust sedation is associated with a shorter ICU stay. Many ICUs also have a daily 'sedation break', when all sedation is stopped in appropriate cases for a short period. This is commonly combined with a trial of spontaneous breathing aiming to shorten the duration of mechanical ventilation.

Delirium in intensive care

Delirium is discussed in Chapter 32. It is extremely common in critically ill patients and often becomes apparent as sedation is reduced. Hypoactive delirium is far more common than hyperactive delirium, but is easily missed unless routine screening is undertaken. A widely used bedside assessment is the Confusion Assessment Method (CAM)-ICU score. The patient is requested to squeeze the examiner's hand in response to instruction and questions, aiming to ascertain whether disordered thought or sensory inattention are present.

Delirium of any type is associated with poorer outcome. Management is focused on non-pharmacological interventions such as early mobilisation, reinstatement of day–night routine, noise reduction, cessation of drugs known to precipitate delirium, and treatment of potential underlying causes such as thiamin replacement in patients at risk of Wernicke encephalopathy. Patients with agitated delirium that is refractory to verbal de-escalation should initially be managed with small doses of parenteral antipsychotics, changed to the enteral route once control is established. Atypical antipsychotics such as olanzapine and quetiapine can be more efficacious than traditional drugs such as haloperidol. Pharmacological interventions are not useful as prophylaxis or in hypoactive delirium. Additional information on diagnosis and management of delirium can be found on page 1346.

i **10.47 Properties of sedative and analgesic agents used in ICU**

Drug	Mode of action	Advantages	Disadvantages
Propofol	Intravenous anaesthetic	Rapid onset and offset	Large cumulative doses can cause multi-organ failure, especially in children – the 'propofol infusion syndrome'
Alfentanil	Potent opiate analgesic	Rapid onset and offset	Can potentiate serotonin syndrome and muscle rigidity in high doses (in susceptible patients)
Morphine	Opioid	Analgesia	Active metabolites and accumulation cause slow offset
Midazolam	Benzodiazepine sedative	Can be used in children	Active metabolites and accumulation cause slow offset
Remifentanil	Very potent opiate	Analgesia and tube tolerance	Respiratory depression – extreme caution in non-intubated patients
Dexmedetomidine (or clonidine – unlicensed use in UK)	α_2-adrenergic agonist	Excellent tube tolerance Potentially less delirium Can be used in awake patients	Can cause bradycardia Dexmedetomidine associated with paralytic ileus Clonidine causes hypotension (can be desirable if hypertensive) Lack trial evidence of benefit – may be harmful in younger patients

i 10.48 Richmond Agitation–Sedation Scale (RASS)

Score	Term	Description
+4	Combative	Overtly combative, violent or immediate danger to staff
+3	Very agitated	Pulls on/removes tubes or catheters, or aggressive to staff
+2	Agitated	Frequent non-purposeful movement or patient–ventilator dyssynchrony
+1	Restless	Anxious or apprehensive but no aggressive or vigorous movements
0	Alert and calm	
−1	Drowsy	Not fully alert but sustained awakening (> 10 secs) with eye opening/contact to voice
−2	Light sedation	Brief awakening (< 10 secs) with eye contact to voice
−3	Moderate sedation	Movement but no eye contact to voice
−4	Deep sedation	Movement to physical stimulation but no response to voice
−5	Unrousable	No response to voice or physical stimulation

Weaning from respiratory support

As the condition that necessitated ventilation resolves, respiratory support is gradually reduced: the process of 'weaning' from ventilation. Some approaches to weaning are described below.

Spontaneous breathing trials

A spontaneous breathing trial involves the removal of all respiratory support followed by close observation of how long the patient is able to breathe unassisted. The technique is particularly effective when linked to a reduction in sedation. PEEP and pressure support are reduced to low levels, or patients are disconnected from the ventilator and breathe oxygen or humidified air through the endotracheal tube. Signs of failure include rapid shallow breathing, hypoxaemia, rising $PaCO_2$, sweating and agitation. Patients who pass a spontaneous breathing trial are assessed for suitability of extubation (endotracheal tube removal).

Progressive reduction in pressure support ventilation

Progressive reduction in pressure support ventilation (PSV) is applied to each breath over a period of hours or days, according to patient response. Some ICU ventilators have software that allows the facility to wean the support provided automatically.

A useful tool to guide the weaning process is the rapid shallow breathing index (RSBI). This composite score of a patient's spontaneous respiratory rate and tidal volume (respiratory rate divided by tidal volume in litres) gives a numerical indication of how difficult the patient is finding breathing at that particular level of support. An RSBI value of > 100 suggests that a patient is working at a level that would be unsustainable for longer periods.

Extubation

It is not possible to predict whether a patient is ready to be extubated accurately; the timing relies heavily on clinical judgement. There are, however, some principles that can aid decision-making. Patients must have stable ABGs with resolution of hypoxaemia and hypercapnia despite minimal ventilator pressure support and a low FiO_2. Conscious level must be adequate to protect the airway, comply with physiotherapy and cough. Furthermore, an assessment must be made as to whether the patient can sustain the required minute volume without ventilator support. This depends on the condition of patients' lungs, their strength and other factors affecting the $PaCO_2$, such as temperature and metabolic rate. Frequently it is not possible to meet all of these criteria and the decision to extubate relies on a balance of risks and benefits. The need for re-intubation following extubation is associated with poorer outcome, but patients who are not given the opportunity to breathe without a ventilator will also be at increased risk of ventilator-associated complications such as pneumonia and myopathy.

Tracheostomy

A tracheostomy is a percutaneous tube passed into the trachea (usually between the first and second, or second and third tracheal rings) to facilitate longer-term ventilation. The advantages and disadvantages of tracheostomy insertion are listed in Box 10.49. When ventilation weaning has been unsuccessful, a tracheostomy provides a bridge between intubation and extubation; the patient can have increasing periods free of ventilator support but easily have support reinstated. A tracheostomy can be inserted percutaneously, using a bronchoscope in the trachea for guidance, or surgically under direct vision. Occasionally, a patient will have a tracheostomy in situ following a laryngectomy. Such patients are important to identify, as emergency management in the event of a tracheostomy problem (blockage or displacement) must be through the tracheostomy site; access will not be possible via the upper airway.

Nutrition

It is crucial that critically ill patients receive adequate calories, protein and essential vitamins and minerals. Calculation of exact requirements is complex and requires the expertise of a dietitian. It is, however, useful to make a rough estimation of requirements (see Ch. 5). Under-feeding leads to muscle wasting and delayed recovery, while over-feeding can lead to biliary stasis, jaundice and steatosis. Enteral feeding is preferred where possible because it avoids the infective complications of total parenteral nutrition (TPN) and helps to maintain gut integrity. However, TPN is recommended for patients who are likely to have a sustained period without effective enteral feeding, or who are already malnourished. Caution must be taken to avoid the consequences of refeeding syndrome (p. 100).

Other essential components of intensive care

Survival after critical illness depends largely on the prevention of medical complications during recovery from the primary insult.

Thromboprophylaxis

DVT, venous catheter–related thrombosis and PE are common in critically ill patients. Low-molecular-weight heparin (LMWH) should be administered to all patients, unless there is a contraindication. Often patients

i 10.49 Advantages and disadvantages of tracheostomy

Advantages

- Patient comfort
- Improved oral hygiene
- Access for tracheal toilet
- Ability to speak with cuff deflated and a speaking valve attached
- Reduced equipment 'dead space' (the volume of tubing)
- Earlier weaning and ICU discharge
- Reduced sedation requirement
- Reduced vocal cord damage

Disadvantages

- Immediate complications: hypoxaemia, haemorrhage
- Tracheostomy site infection
- Tracheal damage; late stenosis

at highest risk of thrombosis, such as those with hepatic dysfunction or those who have suffered major trauma, have a relative contraindication to heparin. Such cases mandate daily evaluation of the risk–benefit ratio, and LMWH should be administered as soon as it is deemed safe to do so. Mechanical thromboprophylaxis, such as intermittent calf compression devices, are useful adjuvants in high-risk patients.

Glucose control

Hyperglycaemia is harmful in critical illness and may occur in people with pre-existing diabetes or undiagnosed diabetes, following administration of high-dose glucocorticoids, or as a consequence of 'stress hyperglycaemia'. Hyperglycaemia is commonly managed by a variable rate intravenous infusion of insulin. Intensive management of hyperglycaemia with insulin can result in hypoglycaemia, which may also be harmful in critical illness. Therefore, a compromise is to titrate insulin to a blood glucose level of 6–10 mmol/L (108–180 mg/dL).

Blood transfusion

Many critically ill patients become anaemic due to reduced red cell production and red cell loss through bleeding and blood sampling. However, red cell transfusion carries inherent risks of immunosuppression, fluid overload, organ dysfunction from microemboli and transfusion reactions. In stable patients, a haemoglobin level of 70 g/L is a safe compromise between optimisation of oxygen delivery and the risks of transfusion. This transfusion threshold should be adjusted upwards for situations where oxygen delivery is critical, such as in patients with active myocardial ischaemia.

Peptic ulcer prophylaxis

Stress ulceration during critical illness is a serious complication. Proton pump inhibitors or histamine-2 receptor antagonists are effective at reducing the incidence of ulceration. There is, however, a suggestion that the use of these agents, particularly in conjunction with antibiotics, may increase the incidence of nosocomial infection, especially with *Clostridioides* (formerly *Clostridium*) *difficile* (p. 365). It is therefore common practice to stop ulcer prophylaxis once consistent absorption of enteral feed is established.

Complications and outcomes of critical illness

The majority of patients will survive their episode of critical illness. While some will return to full, active lives, there are many who have ongoing physical, emotional and psychological problems.

Adverse neurological outcomes

Brain injury

Head injury, hypoxic–ischaemic injury and infective, inflammatory and vascular pathologies can all irreversibly injure the brain. If treatment is unsuccessful, patients will either die or be left with a degree of disability. In the latter situation, the provision of ongoing organ support will depend on the severity of the injury, the prognosis, and the wishes of the patient (usually expressed via relatives). Brain death is a state in which cortical and brainstem function is irreversibly lost. Diagnostic criteria for brain death vary between countries (Box 10.50); if satisfied, these criteria allow physicians to withdraw active treatment and discuss the potential for organ donation. Diagnosing brain death is complex and should be done only by physicians with appropriate expertise, as clinical differentiation from reduced consciousness can be challenging (Box 10.51). Where there is doubt – for example, in patients with coexisting spinal injury or localised brainstem pathology – additional investigations should be performed.

The 'locked-in' syndrome occurs when a patient is paralysed but has preserved hemispheric function. This is usually caused by a lesion in the pons and is frequently of vascular origin. Communication can usually be maintained via vertical eye movements or blinking if these functions are preserved. The term 'vegetative state' implies some retention of brainstem function and minimal cortical function, with loss of awareness of the environment. In contrast, 'minimally conscious state' implies that there is some degree of awareness and intact brainstem function. Confident distinction between these states is important and requires careful assessment, often over a period of time. Brain death is, by definition, irreversible but other states may offer hope for improvement.

ICU-acquired weakness

Weakness is common among survivors of critical illness. It is usually symmetrical, proximal and most marked in the lower limbs. Critical illness polyneuropathy and myopathy can occur simultaneously and, within the constraints of an altered sensorium, it can be impossible to distinguish the two conditions clinically. Risk factors for both processes include the severity of multi-organ failure, poor glycaemic control and the use of muscle relaxants and glucocorticoids.

Critical illness polyneuropathy

This is due to peripheral nerve axonal loss and characteristically presents as proximal muscle weakness with preserved sensation. It may also manifest as failure to wean from the ventilator secondary to respiratory muscle weakness. Electrophysiological studies of the affected nerves can be helpful, especially to rule out other potential causes such as Guillain–Barré syndrome. Conduction studies typically show reduced amplitude of transmitted voltage action potential with preserved velocity (compare with findings in Guillain–Barré syndrome; pp. 1161 and 1238). There are no specific treatments aside from resolution of the underlying cause and rehabilitation. Weakness may persist long into the convalescence stage of illness. In some cases, the clinical picture may be more in keeping with individual nerve involvement. This may be due to local pressure effects or part of a generalised picture. Great care must be taken to avoid pressure on high-risk areas such as the neck of the fibula where the common peroneal nerve navigates a superficial course. Nerve palsies such as foot drop can be permanent.

Critical illness myopathy

Although loss of muscle bulk is related to immobility and the catabolic state of critical illness, it is likely that microvascular and intracellular pathophysiological processes are also involved in critical illness myopathy. These processes result in loss of actin myofibrils and muscle weakness. Typically, the CK is normal or only mildly elevated. Like critical illness polyneuropathy, critical illness myopathy is usually a clinical diagnosis. Nerve conduction studies and electromyography may be suggestive of critical illness myopathy, and helpful in ruling out other pathology. A muscle biopsy is required to confirm the diagnosis (p. 1166), although it is seldom used in clinical practice as there are no specific treatment options. Biopsies typically show selective loss of the thick myofibrils and muscle necrosis. Management is conservative and the prognosis is good in ICU survivors.

Airway complications

Prolonged instrumentation of the airway is occasionally associated with injuries that may have long-term consequences. Vocal cord oedema is common after intubation, especially in female patients. This may require urgent re-intubation, a short course of systemic glucocorticoids or the insertion of a tracheostomy to allow oedema to settle. Long-term vocal cord problems occur in a small number of ICU survivors. This may include vocal cord palsies or chronically increased vocal cord tone causing either a weak voice or stridor.

10.50 Summary of criteria for the diagnosis of death by neurological criteria (brain death) in the United Kingdom

Brain death is the permanent loss of all brainstem reflexes, the capacity for awareness and the ability to breathe

The diagnosis of brain death should be made by two doctors of a specified status and experience. The tests are repeated after an interval (of unspecified length) to allow blood gases to normalise before brain death is confirmed. Time of death should be documented as the conclusion of the second set of tests. Once brain death is confirmed, death certification can be completed and there is the potential to donate organs.

Preconditions for considering a diagnosis of brain death

- The patient is deeply comatose for a defined period (more than 24 hours if post anoxic brain injury) with a known aetiology severe enough to cause permanent cessation of brainstem activity, and treating team satisfied that there are no further treatments that can reverse the situation
    a. Hypothermia has been excluded – temperature must exceed 36°C (active rewarming may be required)
    b. There is no profound abnormality of serum electrolytes, acid–base balance or blood glucose and exclusion of any metabolic or endocrine cause of coma
- The patient is maintained on a ventilator because spontaneous respiration has been inadequate or has ceased. Drugs, including depressant or neuromuscular blocking agents, must have been excluded as a cause of the respiratory failure

Tests for confirming brain death

- Absence of any conditions that would caution the diagnosis on clinical grounds alone, such as isolated posterior fossa lesions, high spinal cord lesions, the early period following hypoxic/ischaemic cardiac arrest, the early post-operative period following decompressive craniectomy or neuromuscular disorders
- All brainstem reflexes are absent
    a. The pupils are fixed and unreactive to light
    b. The corneal reflexes are absent on touching each cornea in turn
    c. The vestibulo-ocular reflexes are absent – there is no eye movement following the injection of 50 mL of ice-cold water into each external auditory meatus
    d. There are no motor responses to adequate stimulation within the cranial nerve distribution
    e. There is no gag reflex to touching the posterior pharynx and no cough reflex response to a suction catheter advanced into the trachea

Apnoea testing

- No respiratory movement occurs when the patient is disconnected from the ventilator for a minimum of 5 minutes to allow the carbon dioxide concentration to rise above the threshold for stimulating respiration ($Pa\text{CO}_2$ must reach 8 kPa; 60 mmHg, having risen at least 2.7 kPA; 20 mmHg (from > 5.3 kPa at the start of the test) and the final arterial blood pH must be below 7.3; hydrogen ion > 50 nmol/L)

Ancillary tests

- For example, a specific CT cerebral angiogram should be performed to confirm the absence of brain perfusion if any cautions exist to the confirmation on clinical grounds or if mandated by legislation

10.51 Classification of persistent brain injuries

Diagnosis	Features	Investigation	Prognosis
Vegetative state (VS) **'Persistent VS' > 1 month** **'Permanent VS' > 1 year**	No reaction to verbal stimuli Some reaction to noxious stimuli Sleep–wake cycles (periods of eye opening) Maintained respiratory drive Intact brainstem reflexes Occasional automatic movements (yawning, swallowing)	Cranial imaging for primary cause Maintained cortical blood flow	Poor May be better with traumatic aetiology
Minimally conscious state	Some reaction to verbal stimuli Some reaction to noxious stimuli Spontaneous movements Intact brainstem reflexes	EEG demonstrates reactivity	Variable. Recovery of function more likely than in VS
Locked-in syndrome	Cortex is intact but bilateral motor tracts are damaged Can be partial or complete, i.e. some response to verbal stimuli (e.g. vertical eye movements to communicate) Variable brainstem reflexes No limb movement to noxious stimuli	Imaging for primary cause – commonly MRI or CT will show brainstem or pontine infarction	Variable and depends on cause – progress can continue over months to years

Both tracheal intubation and tracheostomy can cause damage to the trachea (either at the insertion point or from ischaemia at the level of the cuff). This may be associated with tracheal stenosis or a tracheoesophageal fistula. If any of these complications is suspected, referral to a throat specialist is recommended.

Micro- and macrovascular complications

Areas of tissue ischaemia can occur during an episode of critical illness. Causative mechanisms may include: micro-emboli; reduced tissue perfusion from vasoconstriction or poor cardiac output; pressure from positioning or medical devices such as those securing a tracheostomy; invasive arterial lines causing arterial thrombosis. Vascular surgical opinion may be helpful in recommending specific treatments or management of necrotic tissue. Wherever possible, steps should be taken to reduce the incidence of these complications, e.g. active pressure management. However, in critically unwell patients, peripheral ischaemia can occur despite optimal management.

Other complications

Cardiopulmonary resuscitation can frequently lead to damage to the integrity of the chest wall. This appears to be more common with the use of automated compression devices although it is possible this reflects increased survivorship in this cohort. Anterior rib fractures and sternocostal dislocation are seen most commonly and this pattern of injury can lead to a flail segment of the chest wall, or a flail sternum. The segment moves independently from the rest of the chest; this is a problem when ventilation is spontaneous as the negative pressure draws the flail segment inwards. Simple rib fractures can usually be managed with analgesia, but flail segments frequently benefit from surgical fixation (Fig. 10.28).

The experience of critical illness and the necessary invasive management can leave patients with profound psychological sequelae akin to the post-traumatic stress syndrome seen in many survivors of conflict. Specialist psychological help is required in managing these issues. Sometimes recovering patients benefit from returning to the ICU to see the environment in a different way and gain a better understanding of the processes and procedures that haunt them.

Long-term physical consequences are also common. Many diseases are not completely cured and instead follow a relapsing–remitting course; patients who have been critically ill with sepsis are far more likely than others in the general population to suffer from it again. Intensive care follow-up clinics provide an excellent forum for addressing such issues, and for coordinating care involving a variety of medical specialties.

The older patient

Critically ill older patients present additional challenges following intensive care discharge (Box 10.52). As the ability to make a full recovery depends on frailty rather than chronological age, it can be helpful to use a validated frailty scoring system (p. 1342) to inform admission decision-making.

Rehabilitation medicine has much to offer survivors of critical illness, and an early referral is beneficial when a patient is likely to survive with significant morbidity.

Withdrawal of active treatment and death in intensive care

Futility

The idea of futility is not new: Hippocrates stated that physicians should 'refuse to treat those who are overmastered by their disease, realising that in such cases medicine is powerless'. In intensive care, where the concept of futility is often used as a criterion to limit or withdraw life-sustaining treatment, it is helpful to have a working definition on which families and physicians can agree. It is, therefore, reasonable to define futility in such circumstances as the point at which recovery to a quality of life that the patient would find acceptable has passed. The primary insult may be neurological (irreversible brain injury not meeting criteria for brain death), or multi-organ failure that is refractory to treatment.

Death

While most patients prefer to die at home, many spend their final days in hospital. Chapter 9 details the medical and ethical priorities that should guide patient management once the decision to withdraw active treatment has been made. The decision to shift the focus of care to palliation should not change its intensity; it is the over-arching objective that changes. Only interventions that will improve the quality of a patient's remaining life should be offered. In the ICU, it is often appropriate to continue infusions of sedatives and analgesics, as reducing or stopping them may cause unnecessary pain and agitation. Measures that were instituted to prolong life should be withdrawn (usually including cessation of inotropes and extubation) to allow the patient to die peacefully with their family and friends present.

Organ donation

Donation after brain death

The diagnosis of brain death is discussed in Box 10.50. Once brain death has been confirmed, consideration should be given to organ donation, termed 'donation after brain death' (DBD). Time of death is recorded as the time when the second series of brain death tests are completed, although the deceased patient continues to be ventilated. The practice of organ donation varies throughout the world, but the principles remain the same.

10.52 The critically ill older patient

- **ICU demography**: increasing numbers of critically ill older patients are admitted to the ICU; more than 50% of patients in many general ICUs are over 65 years old.
- **Outcome**: affected to some extent by age, as reflected in APACHE II (see Box 10.54), but age should not be used as the sole criterion for withholding or withdrawing ICU support.
- **Cardiopulmonary resuscitation (CPR)**: successful hospital discharge following in-hospital CPR is rare in patients over 70 years old in the presence of significant chronic disease.
- **Functional independence**: tends to be lost during an ICU stay and prolonged rehabilitation may subsequently be necessary.
- **Specific problems**:
  - Skin fragility and ulceration
  - Poor muscle strength: difficulty weaning from ventilator and mobilising
  - Delirium: compounded by sedatives and analgesics
  - High prevalence of underlying nutritional deficiency

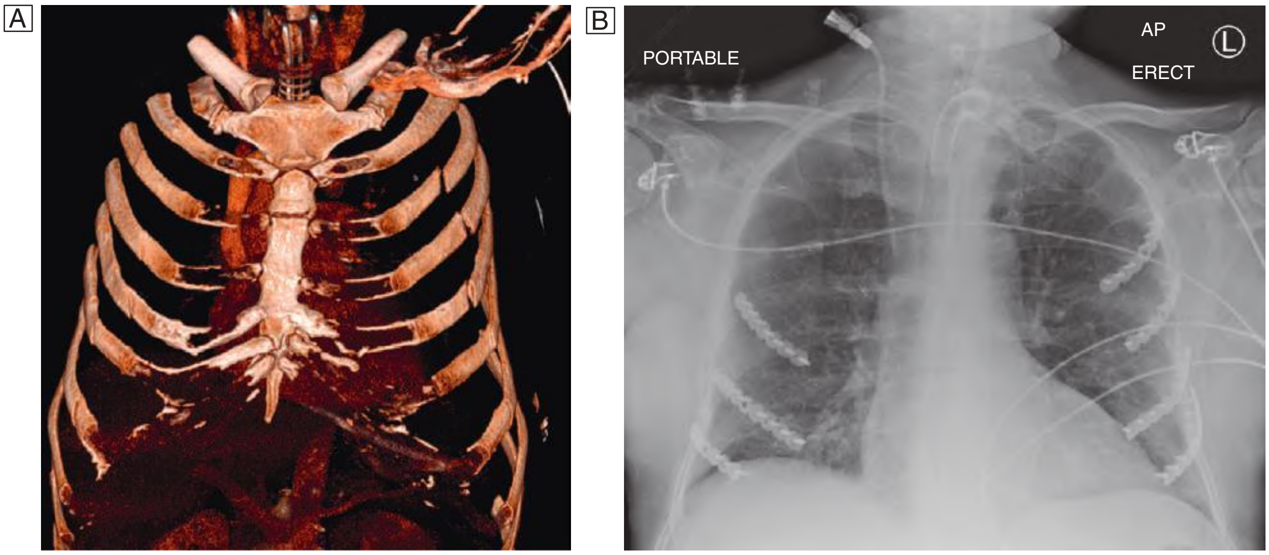

Fig. 10.28 Anterior chest wall injuries are common after CPR. **A** Flail sternum with multiple bilateral chest wall fractures. The patient underwent rib fixation following unsuccessful attempts at weaning. **B** Post-fixation chest radiograph. Weaning was successful shortly afterwards. *Images courtesy of Dr Jonathan Serhan.*

10.53 How to write an ICU discharge summary: information to be included

- Summary of diagnosis and progress in intensive care
- Current medications and changes to regular medications with justifications
- Antibiotic regimen and suggested review dates
- Results of positive microbiological tests
- Positions of invasive devices and insertion dates
- Escalation plan in the event of deterioration
- Pending investigations and specialty consultations
- If the physiology remains abnormal due to chronic disease, rapid response triggers should be adjusted accordingly

10.54 Comparison of APACHE II and SOFA scores

APACHE II score

- An assessment of admission characteristics (e.g. age and pre-existing organ dysfunction) and the maximum/minimum values of 12 routine physiological measurements during the first 24 hours of admission (e.g. temperature, blood pressure, GCS) that reflect the physiological impact of the illness
- Composite score out of 71
- Higher scores are given to patients with more serious underlying diagnoses, medical history or physiological instability; higher mortality correlates with higher scores

SOFA score

- A score of 1–4 is allocated to six organ systems (respiratory, cardiovascular, liver, renal, coagulation and neurological) to represent the degree of organ dysfunction, e.g. platelet count $> 150 \times 10^9$/L scores 1 point, $< 25 \times 10^9$/L scores 4 points
- Composite score out of 24
- Higher scores are associated with increased mortality

Organ donation specialists are contacted, and they begin the process of establishing the suitability of any organs for transplantation and matching potential recipients. Many patients will have expressed their wishes through an organ donor registration scheme but agreement of family and next of kin is a moral (and sometimes legal) prerequisite. Once the organ retrieval theatre team has been assembled and all preliminary tests have been completed, the deceased patient is transferred to the operating theatre and the organs are sequentially removed.

Donation after cardiac death

If a patient does not meet brain death criteria, but withdrawal of treatment has been agreed, donation of organs with residual function may be appropriate. This is termed 'donation after cardiac death' (DCD). If the patient dies within a short period following the commencement of 'warm ischaemic time' (the time to asystole following the onset of physiological derangement after the withdrawal of active treatment), then DCD can proceed. The deceased patient is transferred to an operating theatre and the agreed organs (lungs, liver, kidney and pancreas and occasionally heart) are retrieved. As heart valves and corneas can be retrieved later (within a longer time frame), tissue retrieval may occur in the mortuary.

Postmortem examination or autopsy

There are several indications to request a postmortem examination. A coroner (or legal equivalent) may initiate the process if a death is unexpected, violent, or has occurred under suspicious circumstances. The treating physician(s) may request one if they are unable to establish a cause of death or there is agreement that it may yield information of interest to the family or clinical team. The postmortem diagnosis is occasionally at odds with the antemortem diagnosis, and it is a very useful learning exercise to review the results with all those involved in the patient's care.

Discharge from intensive care

Discharge is appropriate when the original indication for admission has resolved, and the patient has sufficient physiological reserve to continue to recover without the facilities of intensive care. Many ICUs and HDUs function as combined units, allowing 'step-down' of patients to HDU care without changing the clinical team involved. Discharge from ICU is stressful for patients and families, and clear communication with the clinical team accepting responsibility is vital. Nursing ratios change from 1 : 1 (one nurse per patient) or 1 : 2 to much lower staffing levels. Discharges from ICU or HDU to standard wards should take place within normal working hours to ensure adequate medical and nursing support and detailed handover. Discharge outside normal working hours is associated with higher ICU re-admission rates and increased mortality. The receiving team should be provided with a written summary, including the information listed in Box 10.53. The ICU team should remain available for advice; many ICU teams provide an outreach service to supply advice and facilitate continuity of care.

Critical care scoring systems

Admission and discharge criteria vary between ICUs, so it is important to define the characteristics of the patients admitted in order to assess the effects of the care provided on the outcomes achieved. Two systems are widely used to measure severity of illness (see Box 10.54 for further details):

- *APACHE II*: Acute Physiology Assessment and Chronic Health Evaluation
- *SOFA score*: Sequential Organ Failure Assessment tool.

When combined with the admission diagnosis, scoring systems have been shown to correlate well with the risk of death in hospital. Such outcome predictions are useful at a population level, but lack the specificity to be of use in decision-making for individual patients.

Multiple Choice Questions

10.1. Regarding monitoring in the critical care area, which one of the following statements is true?

A. The three-lead ECG does not accurately reflect the ventricular rate
B. Oxygen saturation readings are inaccurate in severe jaundice
C. End-tidal carbon dioxide ($ETCO_2$) is a reliable reflection of arterial CO_2 in critically ill patients
D. The central venous pressure gives an estimate of left atrial pressure
E. The pulse oximetry trace can suggest if peripheral perfusion is poor

Answer: E.

When perfusion is poor, the saturation plethysmograph can become flat as the pulsatile element of the blood plethysmography is lost. Modern SpO_2 monitors can compensate for a degree of reduction in perfusion, but the loss of the plethysmograph can be a useful clinical aid to recognise acute deterioration. They are not affected by jaundice. The ECG trace reflects ventricular rate. $ETCO_2$ becomes less reflective of arterial CO_2 – as the efficiency of the lungs decreases, the larger the discrepancy. Central venous pressure gives an estimation of right atrial pressure.

10.2. TThere are several proposed physiological mechanisms that cause hypoxaemia. Which of these disease–mechanism pairings is correct?

A. Pulmonary embolism – shunt
B. Opiate overdose – shunt
C. Pulmonary oedema – $\bar{V}/\dot{Q}$ mismatch
D. Chronic obstructive pulmonary disease – $\bar{V}/\dot{Q}$ mismatch
E. Lobar pneumonia – central hypoventilation

Answer: D.

COPD causes areas of hypoventilated lung; however, these areas may still have reasonable perfusion, i.e. $\bar{V}/\dot{Q}$ mismatch. Pulmonary embolism likewise causes $\bar{V}/\dot{Q}$ mismatch as unaffected lung units get relatively over-perfused. Opiate overdose causes central hypoventilation and lobar pneumonia typically causes shunt.

10.3. A 50-year-old man sustains a cardiac arrest while out jogging. He is resuscitated by paramedics at the scene but has sustained a severe brain injury. Four months after the event, he is examined and found to have normal brainstem reflexes. He coughs spontaneously and swallows secretions; however, he makes no sound other than occasional grunts. He has jerky eye movements and appears to follow people within the room but makes no movement to command and is unable to communicate. He will open his eyes to a loud noise and withdraws from a painful stimulus. Which of the following statements most accurately describes his condition?

A. Locked-in syndrome
B. Coma
C. Permanent vegetative state
D. Brain death has occurred
E. Minimally conscious state

Answer: E.

This patient has sustained a severe brain injury and is in a minimally conscious state. Prognosis is uncertain but after one year it becomes less likely that meaningful recovery will occur. Traumatic brain injury appears to recover to a certain extent more frequently than other aetiologies. The difference between a vegetative state and minimally conscious state is subtle and requires an expert in neuro-rehabilitation to differentiate accurately. The diagnosis of permanent vegetative state requires it to be ongoing for greater than one year (see Box 10.51).

10.4. A 65-year-old woman is recovering from bacterial pneumonia in intensive care. She has failed extubation twice and a percutaneous tracheostomy is planned. When explaining the process of a tracheostomy to the next of kin, which of the following statements is true?

A. A percutaneous tracheostomy is considerably safer than a surgical tracheostomy
B. Infection at the tracheostomy site is extremely rare
C. The patient will require moderate levels of sedation to tolerate the tracheostomy after the procedure
D. Long-term complications such as tracheal stenosis are comparable to complication rates from prolonged oral–tracheal intubation
E. The patient will not be able to talk or eat until the tracheostomy is removed

Answer: D.

Tracheostomy is frequently performed when a patient is unable to be successfully extubated and is a useful bridge to extubation allowing incremental reduction in support, cessation of sedation and, as weaning continues, the facility to talk (using a one-way valve on the breathing circuit and a deflated tracheostomy cuff). Swallowing can be assessed and diet commenced if appropriate. Surgical and percutaneous tracheostomy both have similar complication rates (comparative studies are skewed by the population, i.e. surgical tracheostomy is often performed on more difficult anatomy). There are insufficient data to demonstrate that a tracheostomy is safer in the long term than a prolonged intubation and probably has a comparable complication rate, albeit with less laryngeal damage but more distal airway pathology.

10.5. Severe lactic acidosis (> 10 mmol/L; 90 mg/dL) is characteristic of the following scenarios except which?

A. Sulphonylurea overdose
B. Ingestion of anti-freeze (ethylene glycol)
C. Metformin use with acute kidney injury
D. Diarrhoea and vomiting in a patient with pyruvate decarboxylase deficiency
E. Adrenaline (epinephrine) infusion for anaphylaxis

Answer: A.

Severe lactic acidosis, regardless of cause, is associated with a high mortality. Classic causes include metformin (overdose or accumulation), adrenaline infusion and certain enzyme deficiencies. Ethylene glycol typically causes an erroneously elevated lactate on the blood gas analysis (less elevated on venous lactate – termed the 'lactate gap'), however there is still frequently a coexisting genuine lactate acidosis. Profound hypoglycaemia is the usual presenting feature of sulphonylurea overdose.

10.6. A 72-year-old woman with mild COPD is recovering after coronary artery bypass grafts. She has sustained a stroke during the operation and has a dense left hemiparesis. Today she has developed a high temperature and rigors. Which of the following statements is most accurate?

A. Administration of broad-spectrum antibiotics and 50 mL/kg of fluid in the first 2 hours would be appropriate
B. High-flow oxygen should be commenced to obtain a SpO_2 of 98%–100%
C. Three sets of peripheral cultures should be taken before commencing antibiotics as endocarditis is a possibility
D. A saturation target of 94%–98% is appropriate
E. The lactate should be measured and, if greater than 5 mmol/L, an infusion of sodium bicarbonate should be given

Answer: D.

The ‘Sepsis Six’ interventions are well recognised as the first response to suspected sepsis (see Box 10.33). Up to 30 mL/kg of fluid may be appropriate; a set of blood cultures should be drawn but three sets will likely delay the administration of antibiotics. Sodium bicarbonate is not usually given for a raised anion gap acidosis (such as lactic acidosis). Oxygen should be titrated to saturations of 92%–98%. Less than this reduces oxygen delivery and more than this exposes the patient to risks of hyperoxia (especially important following a stroke).

10.7. A 65-year-old man with peripheral vascular disease is admitted to hospital with severe abdominal pain. He has lost 10 kg of weight in the past 2 months. The abdomen is soft but diffusely tender. He is febrile, tachycardic and hypotensive. The venous lactate is 1.2 mmol/L (10 mg/dL) and the haemoglobin is 15 g/L, a creatinine of 212 µmol/L (2.4 mg/dL) from a baseline of 106 µmol/L (1.4 mg/dL). Which of the following statements is most correct?

A. The normal lactate virtually excludes ischaemic gut as a diagnosis
B. Broad-spectrum antibiotics should be given to treat for potential gut translocation of bacteria
C. A non-contrast CT should be performed as there is an acute kidney injury
D. The normal haemoglobin makes bleeding very unlikely to be the cause
E. CT scan can wait until the following day to allow for resuscitation and conservative management to improve his condition

Answer: B.

Ischaemic gut is certainly possible in this scenario (as is undiagnosed abdominal malignancy). Lactate may remain normal in gut ischaemia until the later stages when hepatic clearance becomes saturated. Risks of a delayed diagnosis are greater than those of renal injury from contrast. Contrast is essential in making diagnostic decisions from the CT abdomen; this patient warrants urgent investigation. Haemoglobin does not usually reduce significantly in acute bleeding until the patient receives IV volume replacement, so this could still be haemorrhage. Bacterial translocation and sepsis are common in the acute abdomen and broad-spectrum antibiotics should be administered early.

10.8. A woman is undergoing brainstem death (BSD) testing following a massive intracranial haemorrhage. The CT head scan shows a large haemorrhage in the basal ganglia with extension into the lateral ventricles bilaterally, the 3rd and 4th ventricles, with marked hydrocephalus and early tentorial herniation. Which of the following statements is true?

A. The absence of a doll’s head reflex is part of the UK BSD criteria
B. A temperature of 36.2°C precludes BSD testing at this time
C. Grimacing during supra-orbital pressure is just a reflex movement and BSD can still be diagnosed
D. The presence of seizures at presentation does not preclude the performance of BSD testing
E. Towards the end of the apnoea test, following the absence of all other brainstem reflexes, some very shallow breaths are noted. The patient can still be certified as brain dead

Answer: D.

Brain death testing must leave no room for uncertainty; where uncertainty exists, the tests should be delayed, abandoned or auxiliary investigations should be undertaken, such as a cerebral CT angiogram or levels of some longer-acting sedative drugs. In this case, the only correct answer is that seizures on presentation do not preclude the diagnosis – ongoing status epilepticus at the time of testing would create some uncertainty among clinicians as to the potential reversibility of the situation, but if there was strong evidence of brainstem ischaemia, the tests could still proceed. Absence of doll’s head reflex, although suggestive of a major brain injury, does not form part of the UK test. Any movement in the distribution of a cranial nerve in response to supra-orbital pressure or respiratory effort during the apnoea test is incompatible with a diagnosis of BSD. The UK criteria have changed in January 2025 (see Box 10.50), so the temperature must be over 36 degrees to allow testing.

10.9. A 36-year-old woman presents one month post-partum. She has been referred into the medical unit with a severe headache and concerns that it could be a subarachnoid haemorrhage. The pain is mainly frontal and described as a band across the front and top of her head. The pain came on acutely this morning, but maximal intensity developed over the course of an hour. It did not have a postural element and has eased slightly with simple analgesia. On questioning she says it has been present on and off for the past three weeks. The CT brain has been reported as normal. She is apyrexial, does not look unwell, has no abnormal neurology and has normal inflammatory markers although is still in quite some discomfort. Her blood pressure is 105/70 mmHg and heart rate is 60. What is the most appropriate next investigation?

A. Lumbar puncture and oligo-clonal bands
B. Lumbar puncture and xanthochromia
C. MRI brain
D. Erythrocyte sedimentation rate (ESR)
E. EEG

Answer: C.

This scenario could just be a tension-type headache as there are no adverse features. However, there is some increased risk of venous sinus thrombosis in the peri-partum period and the severity of the headache warrants further investigation. A subarachnoid haemorrhage is unlikely given the history and normal CT, and temporal arteritis is also unlikely. A CT angiogram/venogram to look for cerebral aneurysm or sinus thrombosis would be a reasonable next step but would expose the patient to additional radiation, so if an MRI is available that is the investigation of choice.

10.10. A 63-year-old woman is admitted to a general medical ward with lower limb cellulitis. She is receiving an infusion of co-amoxiclav (amoxicillin and clavulanic acid) when, having previously had reasonably normal physiology, she acutely becomes shocked. Her non-invasive blood pressure will not record and she has no palpable radial pulses with a weak carotid pulse at approximately 120 beats per minute. She remains conscious but confused. Her oxygen saturations are not reading as she is cool peripherally, tachypnoeic and wheezy on chest auscultation. Regarding the management of this situation, the following treatments are all appropriate except:

A. 1 mg of adrenaline (epinephrine) should be given intravenously (10 mL of 1:10 000)
B. Fluid challenge of 10 mL per kg of a balanced salt solution
C. Oxygen via a non-rebreathe mask and 15 L/min
D. Salbutamol nebuliser
E. Intravenous steroid and antihistamine

Answer: A.

This patient is likely to be having anaphylaxis and going into anaphylactic shock. The most important intervention is the administration of adrenaline (epinephrine). The preferred route for adrenaline administration in a medical ward would be deep intramuscular injection. A typical dose in an adult would be 0.5 mg, which is 0.5 mL of 1:1000. This dose is reduced in paediatric cases according to age. Intravenous adrenaline can be used perioperatively or where suitable expertise is present and patients frequently require an adrenaline infusion to be commenced – however, the above dose is a cardiac arrest dose; a typical intravenous dose in an adult as described would be 0.5 mL of 1:10 000, i.e. 50 mg. The other interventions are all appropriate but are less important than the adrenaline, which will restore the circulation and alter the disease course.

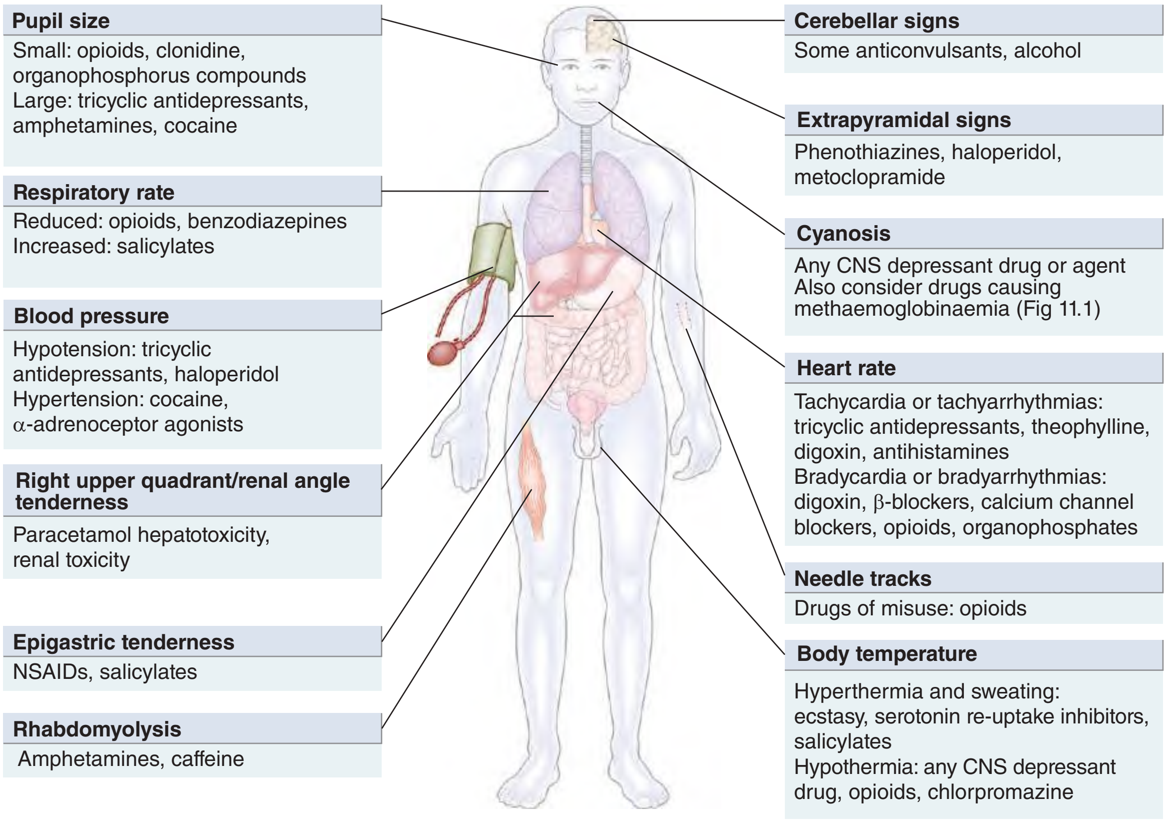
i Taking a history in poisoning

- What toxin(s) have been taken and how much?
- What time were they taken and by what route?
- Have alcohol or other substances (including drugs of misuse) also been taken?
- Obtain details from witnesses (family, friends, ambulance personnel) of the circumstances of the overdose.
- Assess immediate suicide risk in those with apparent self-harm (full psychiatric evaluation when patient has recovered physically).
- Assess capacity to make decisions about accepting or refusing treatment.
- Establish past medical history, drug history and allergies, social and family history.
- Record all information carefully.



Pupil size
Small: opioids, clonidine, organophosphorus compounds
Large: tricyclic antidepressants, amphetamines, cocaine

Respiratory rate
Reduced: opioids, benzodiazepines
Increased: salicylates

Blood pressure
Hypotension: tricyclic antidepressants, haloperidol
Hypertension: cocaine, α-adrenoceptor agonists

Right upper quadrant/renal angle tenderness
Paracetamol hepatotoxicity, renal toxicity

Epigastric tenderness
NSAIDs, salicylates

Rhabdomyolysis
Amphetamines, caffeine

Cerebellar signs
Some anticonvulsants, alcohol

Extrapyramidal signs
Phenothiazines, haloperidol, metoclopramide

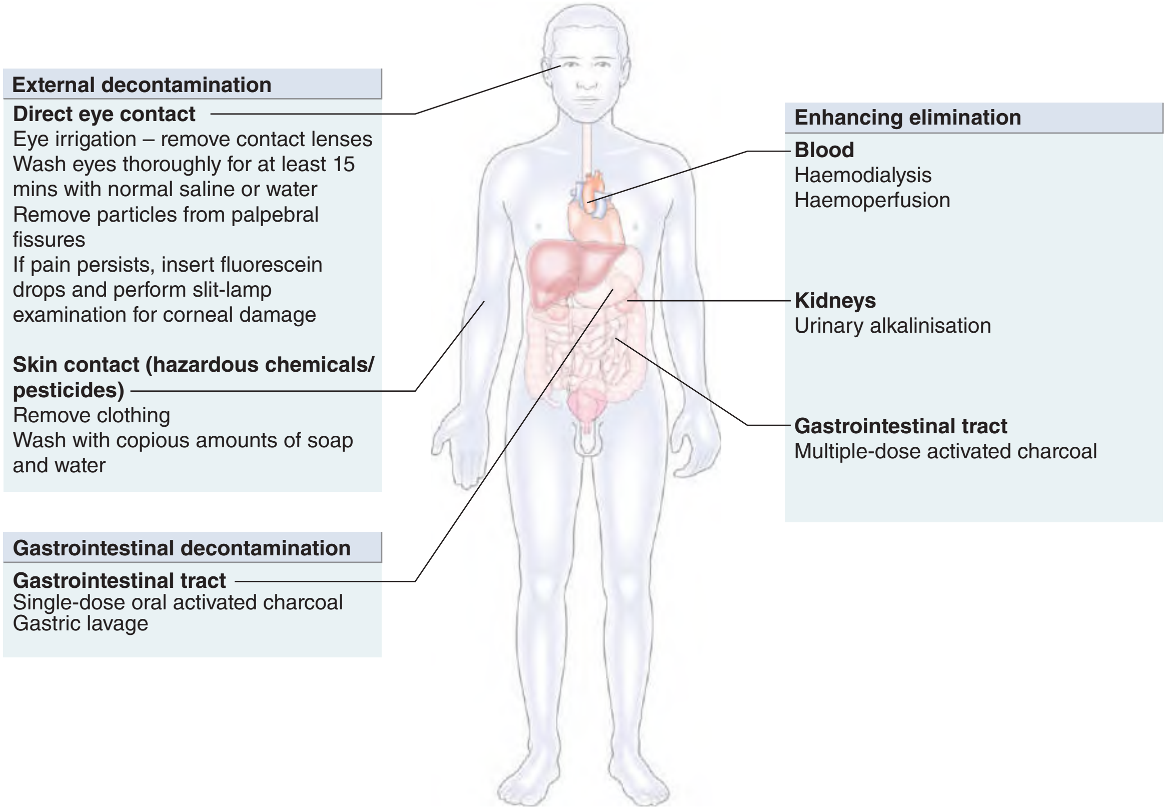
Cyanosis
Any CNS depressant drug or agent
Also consider drugs causing methaemoglobinaemia (Fig 11.1)

Heart rate
Tachycardia or tachyarrhythmias: tricyclic antidepressants, theophylline, digoxin, antihistamines
Bradycardia or bradyarrhythmias: digoxin, β-blockers, calcium channel blockers, opioids, organophosphates

Needle tracks
Drugs of misuse: opioids

Body temperature
Hyperthermia and sweating: ecstasy, serotonin re-uptake inhibitors, salicylates
Hypothermia: any CNS depressant drug, opioids, chlorpromazine

Clinical signs of poisoning by pharmaceutical agents and drugs of misuse. (CNS = central nervous system; NSAIDs = non-steroidal anti-inflammatory drugs)



External decontamination

Direct eye contact
Eye irrigation – remove contact lenses
Wash eyes thoroughly for at least 15 mins with normal saline or water
Remove particles from palpebral fissures
If pain persists, insert fluorescein drops and perform slit-lamp examination for corneal damage

Skin contact (hazardous chemicals/pesticides)
Remove clothing
Wash with copious amounts of soap and water

Gastrointestinal decontamination

Gastrointestinal tract
Single-dose oral activated charcoal
Gastric lavage

Enhancing elimination

Blood
Haemodialysis
Haemoperfusion

Kidneys
Urinary alkalinisation

Gastrointestinal tract
Multiple-dose activated charcoal

Decontamination and enhanced elimination. One of the key aspects in the evaluation of a poisoned patient is deciding if decontamination and/or enhanced elimination is required.

Acute poisoning is common, accounting for about 1% of hospital admissions in the UK. Common or otherwise important substances involved are shown in Box 11.1. In high-income countries, the most frequent cause is intentional drug overdose in the context of self-harm, often involving prescribed or over-the-counter medicines. Accidental poisoning is also common, especially in children and older people (Box 11.2). Toxicity also results from alcohol or recreational substance use and following occupational or environmental exposure. Criminal poisoning may also occur, including drug-facilitated robbery or sexual assault. Poisoning is a major cause of death in young adults; most deaths occur before patients reach medical attention, while overall mortality is low (< 1%) in those admitted to hospital.

In low- and middle-income countries, the frequency of self-harm is more difficult to estimate. Because of their widespread availability and use, household and agricultural products, such as pesticides and herbicides, are common sources of poisoning and have a much higher case fatality. In China and South-east Asia, pesticides account for about 300 000 suicides each year. Snake bite and other forms of envenomation are also important causes of morbidity and mortality internationally and are discussed in Chapter 12.

General approach to the poisoned patient

A general approach is shown on pages 258–259. In many countries, poisons centres are available to provide advice on management of suspected poisoning with specific substances and the use of antidotes. Information is also available online (see ‘Further information’).

11.1 Substances commonly involved in poisoning

In the UK

- Analgesics: paracetamol and non-steroidal anti-inflammatory drugs (NSAIDs)
- Antidepressants: selective serotonin re-uptake inhibitors (SSRIs), serotonin–norepinephrine re-uptake inhibitors, tricyclic antidepressants (TCA) and lithium
- Cardiovascular agents: β-blockers, calcium channel blockers and cardiac glycosides
- Drugs of misuse: depressants (opiates, benzodiazepines), stimulants and entactogens (amphetamines, MDMA, mephedrone, cocaine), hallucinogens (cannabis, synthetic cannabinoid receptor agonists)
- Carbon monoxide
- Alcohol

In South and South-east Asia

- Organophosphorus and carbamate insecticides
- Aluminium and zinc phosphide
- Paraquat
- Oleander
- Corrosives
- Snake and insect venoms (Ch. 12)

(MDMA = 3,4-methylene-dioxymethamphetamine, ecstasy)

11.2 Poisoning in old age

- **Aetiology**: may result from accidental poisoning due to delirium or dementia or drug toxicity because of impaired renal or hepatic function or drug interaction. Toxic prescription medicines are more likely to be available.
- **Psychiatric illness**: self-harm is less common than in younger adults, but more frequently associated with depression and other psychiatric illness, as well as chronic illness and pain. There is a higher risk of subsequent suicide.
- **Severity of poisoning**: increased morbidity and mortality result from reduced renal and hepatic function, lower functional reserve, increased sensitivity to sedative agents and frequent comorbidity.

Triage and resuscitation

Patients who are seriously poisoned must be identified early so that appropriate management is not delayed. Triage involves:

- immediately assessing vital signs
- identifying the poison(s) involved and obtaining adequate information about them
- identifying patients at risk of further attempts at self-harm and removing any remaining hazards.

Those with possible external contamination with chemical or environmental toxins should undergo appropriate decontamination (p. 258). Critically ill patients must be resuscitated.

The Glasgow Coma Scale (GCS) is commonly employed to assess conscious level but has not been specifically validated in poisoning. The AVPU (alert/verbal/painful/unresponsive) scale is also a simple and quick method to record conscious level. An electrocardiogram (ECG) should be performed, and cardiac monitoring instituted in all patients with abnormal findings or where exposure to potentially cardiotoxic substances is suspected. Patients who may need antidotes should be weighed if possible, so that appropriate weight-related doses can be prescribed.

Hospital admission and medical interventions are not usually required when substances are ingested that are unlikely to be toxic in humans (Box 11.3).

Clinical assessment and investigations

History and examination are described on page 258. Patients may be unaware of or confused about what they have taken, or may exaggerate (or, less commonly, underestimate) the size of the overdose, but rarely mislead medical staff deliberately. Multiple drug exposure (including alcohol) is common in episodes of self-harm. It is important to obtain information on all substances involved and consider the potential toxicity of combinations of different agents. In regions of the world where self-poisoning is illegal, patients may be reluctant to give an accurate history.

Toxic causes of abnormal physical signs are shown on page 259. The patient may have a cluster of clinical features (‘toxidrome’) suggestive of poisoning with a particular drug type, such as the anticholinergic, serotoninergic (see Box 11.10), stimulant, sedative, opioid (see Box 11.12) and cholinergic (see Box 11.14) feature clusters. Poisoning is a common cause of coma, especially in younger people, but it is important to exclude other potential causes (see Box 10.31).

Urea, electrolytes and creatinine should be measured in all patients with suspected systemic poisoning. Arterial blood gases should be checked in those with significant respiratory or circulatory compromise, or after poisoning with substances likely to affect acid–base status (Box 11.4). Calculation of anion and osmolar gaps may help to inform diagnosis and management (Box 11.5). Potent oxidising agents may cause methaemoglobinaemia, with consequent blue discoloration of skin and blood, and reduced tissue oxygen delivery (Fig. 11.1).

For some substances, measurement of the amount of toxin in the blood can help guide management. Qualitative urine screens for potential toxins, including near-patient testing kits, have a limited clinical role.

11.3 Substances of very low toxicity

- Writing materials, such as pencil graphite, crayons, and chalk
- Decorating products, such as emulsion paint, wallpaper paste
- Cleaning products (except dishwasher tablets and liquid laundry detergent capsules, which can be corrosive)
- Oral contraceptives, most antibiotics (but not tetracyclines or anti-tuberculous drugs), vitamins B, C and E, prednisolone, emollients and other skin creams, baby lotion
- Plasticine, silica gel, most household plants, plant food, pet food, soil

Psychiatric assessment

Patients presenting with drug overdose in the context of self-harm should undergo psychiatric evaluation prior to discharge by a health professional with appropriate training (Ch. 29). This should occur after they have recovered from poisoning, unless there is an urgent issue, such as uncertainty about their capacity to decline medical treatment.

11.4 Causes of acidosis in the poisoned patient

Cause	Normal lactate[1]	High lactate
Ingested toxin[2]	Salicylates Methanol Ethylene glycol Paraldehyde	Metformin Iron Cyanide Sodium valproate Carbon monoxide
Other[3]	Renal failure Ketoacidosis Severe diarrhoea	Shock

[1] Unless shock is present.
[2] Acidosis is caused directly by the ingested toxin, its metabolites or by their metabolic effects.
[3] Acidosis is secondary to the physiological effects of poisoning.

11.5 Anion and osmolar gaps in poisoning

	Anion gap	Osmolar gap
Calculation	$[Na^+ + K^+] - [Cl^- + HCO_3^-]$	[Measured osmolality] − [(2 × Na) + Urea + Glucose][1]
Reference range	12–16 mmol/L	< 10
Common toxic causes of elevation[2]	Ethanol Ethylene glycol Methanol Salicylates Iron Cyanide	Ethanol Ethylene glycol Methanol

[1] All units are in mmol/L, except osmolality, which is mOsmol/kg. For non-SI units, the corresponding formula is [Measured osmolality (mOsmol/kg)] − [(2 × Na (mEq/L)) + Urea/2.8 (mg/dL) + Glucose/18 (mg/dL)].
[2] Box 19.19 gives non-toxic causes.

General management

Patients presenting with eye/skin contamination should undergo local decontamination measures as described on page 259.

Gastrointestinal decontamination

Patients who have ingested toxins in potentially harmful amounts may be considered for gastrointestinal decontamination if poisoning has been recent.

Activated charcoal

Given orally as a slurry, activated charcoal absorbs toxins in the bowel because of its large surface area. It can prevent absorption of a significant proportion of the ingested dose of toxin, but efficacy decreases with time. Activated charcoal is most effective if given within 1 hour of overdose, but may have useful efficacy later than this, for perhaps up to 6 hours after ingestion of a sustained-release preparation or when gastric emptying is delayed. In some cases, where there has been a substantial ingestion, an additional dose of activated charcoal may be administered after an interval. Use is ineffective for some toxins that do not bind to activated charcoal (Box 11.6) or for substances like ethanol that are taken in large amounts. In patients with impaired swallowing or a reduced level of consciousness, activated charcoal given via a nasogastric tube carries a risk of aspiration pneumonitis, but this can be reduced (though not eliminated) by protecting the airway using a cuffed endotracheal tube.

Multiple doses of oral activated charcoal (50 g 6 times daily in an adult) may enhance the elimination of some substances at any time after poisoning (Box 11.7). This interrupts enterohepatic circulation or reduces the concentration of the toxic substance in the gut lumen, to the extent that the substance diffuses from the blood back into the bowel to be absorbed on to the charcoal (gastrointestinal dialysis). A laxative is generally given with the charcoal to reduce the risk of constipation or intestinal obstruction by charcoal 'briquette' formation in the gut lumen.

Evidence suggests that single or multiple doses of activated charcoal do not improve clinical outcomes after poisoning with pesticides or oleander.

Gastric aspiration and lavage

Gastric aspiration and/or lavage is seldom indicated in acute poisoning, as it is no more effective than activated charcoal for most substances and complications are common, especially pulmonary aspiration. It is contraindicated if strong acids, alkalis or petroleum distillates have been

Causes

Non-toxic

- Congenital methaemoglobinaemias

Toxic (oxidising agents)

- Organic nitrites
- Nitrates
- Benzocaine
- Dapsone
- Chloroquine
- Aniline dyes
- Chlorobenzene
- Naphthalene
- Copper sulphate

Consequences

- Haemoglobin–oxygen dissociation curve is shifted to the left (see Box 24.5)
- Oxygen delivery to tissues is reduced
- There is apparent 'cyanosis'
- Breathlessness, fatigue, headache and chest pain occur
- Delirium, impaired consciousness and seizures may occur in severe cases

Treatment

- Methylthioninium chloride ('methylene blue') 1–2 mg/kg (intravenous) is given
- Reduces methaemoglobin (see below)
- Used for symptomatic patients with severe methaemoglobinaemia (e.g. > 30%)
- Patients with anaemia or other comorbidities may need treatment at lower concentrations

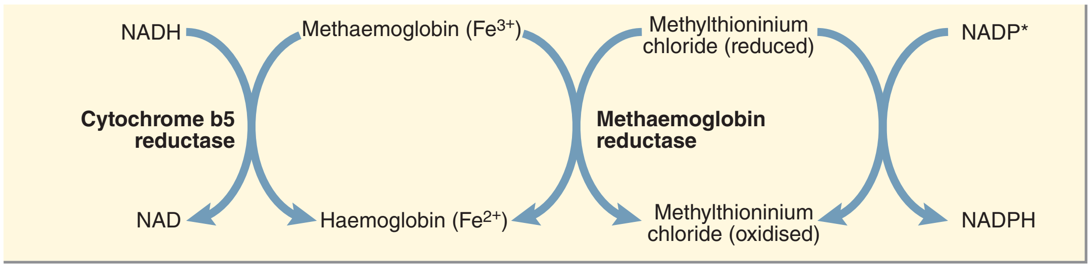


Fig. 11.1 **Causes, consequences and management of methaemoglobinaemia.** (H = hydrogen; NAD = nicotinamide adenine dinucleotide; P = phosphate)

11.6 Substances for which activated charcoal administration is ineffective

Medicines	
Iron	Lithium
Chemicals	
Acids*	Mercury
Alkalis*	Methanol
Ethanol	Petroleum distillates*
Ethylene glycol	

*Gastric lavage contraindicated.

11.7 Examples of poisons effectively eliminated by multiple doses of activated charcoal, haemodialysis or haemoperfusion

Multiple doses of activated charcoal	
Carbamazepine	Quinine
Dapsone	Theophylline
Phenobarbital	Cardiac glycosides
Haemodialysis	
Ethylene glycol	Salicylates
Isopropanol	Sodium valproate
Methanol	Lithium
Haemoperfusion	
Theophylline	Phenobarbital
Phenytoin	Amobarbital
Carbamazepine	

ingested. Use may be justified for life-threatening overdoses of those substances that are not absorbed by activated charcoal (see Box 11.6).

Whole bowel irrigation

This involves the administration of large quantities of osmotically balanced polyethylene glycol and electrolyte solution (1–2 L/hr for an adult), usually by a nasogastric tube, until the rectal effluent is clear. It is occasionally indicated to enhance the elimination of ingested packets of illicit drugs or slow-release tablets such as iron and lithium that are not absorbed by activated charcoal. Contraindications include inadequate airway protection, haemodynamic instability, gastrointestinal haemorrhage, obstruction or ileus. Whole bowel irrigation may precipitate nausea and vomiting, abdominal pain and electrolyte disturbances.

Urinary alkalinisation

Urinary excretion of weak acids and bases is affected by urinary pH, which changes the extent to which they are ionised. Highly ionised molecules are excreted by the kidney as they cannot easily pass through lipid membranes and be reabsorbed by the renal tubules. If the urine is alkalinised (pH > 7.5) by the administration of sodium bicarbonate (1.5 L of 1.26% sodium bicarbonate over 2 hrs), weak acids like salicylates and methotrexate become highly ionised, resulting in enhanced urinary excretion.

Urinary alkalinisation is currently recommended for patients with clinically significant salicylate poisoning when the criteria for haemodialysis are not met (see below). It is also sometimes used for poisoning with methotrexate. Complications include alkalaemia, hypokalaemia and occasionally alkalotic tetany (Ch. 19). Hypocalcaemia may also occur but is rare.

Haemodialysis and haemoperfusion

These techniques can enhance the elimination of poisons that have a small volume of distribution and a long half-life after overdose. Their use is appropriate when poisoning is severe. The toxin must be small enough to cross the dialysis membrane (haemodialysis) or must bind to activated charcoal (haemoperfusion) (see Box 11.7). Haemodialysis can also correct acid–base and metabolic disturbances associated with poisoning.

Lipid emulsion therapy

Lipid emulsion therapy is increasingly used for poisoning with lipid-soluble agents. Evidence for efficacy is most compelling for local anaesthetics, especially bupivacaine. The treatment has also been used with anecdotal reports of success for poisoning with tricyclic antidepressants, calcium channel blockers and lipid-soluble β-adrenoceptor antagonists (β-blockers) such as propranolol. It involves intravenous administration of 20% lipid emulsion such as Intralipid, at an initial dose of 1.5 mL/kg, followed by a continued infusion of 0.25 mL/kg/min until there is clinical improvement. It is thought that lipid-soluble toxins partition into the intravenous lipid, reducing target tissue concentrations. The elevated myocardial free fatty acid concentrations may also have beneficial effects on myocardial metabolism and performance by counteracting the inhibition of myocardial fatty acid oxidation produced by some cardiotoxins, enabling increased adenosine triphosphate (ATP) synthesis and energy production. Some animal studies have suggested efficacy and case reports of use in human poisoning have also been encouraging, with recovery of circulatory collapse reported in cases where other treatment modalities have been unsuccessful. No controlled trials of this technique have been performed, however, and efficacy remains uncertain, especially for substances other than local anaesthetics.

Supportive care

For most poisons, antidotes and methods to accelerate elimination are inappropriate, unavailable or incompletely effective. Outcome is dependent on appropriate nursing and supportive care, and treatment of complications (Box 11.8).

Antidotes

Antidotes are available for some poisons and work by a variety of mechanisms (Box 11.9). The use of some of these in the management of specific poisons is described below.

Poisoning by specific pharmaceutical agents

Analgesics

Paracetamol

Paracetamol (acetaminophen) is the most commonly used drug to be overdosed in the UK. Toxicity is caused by an intermediate reactive metabolite that binds covalently to cellular proteins, causing cell death. This results in hepatic and occasionally renal failure. In therapeutic doses, the toxic metabolite is detoxified in reactions requiring glutathione, but in overdose, glutathione reserves become exhausted.

Management

Activated charcoal may be used in patients presenting sufficiently early. Antidotes for paracetamol act by replenishing hepatic glutathione, and acetylcysteine is the treatment of choice. It should be administered to all patients with acute poisoning and paracetamol concentrations above a ‘treatment line’ provided on paracetamol poisoning nomograms (Fig. 11.2). The threshold used for these nomograms varies between countries, however, and local guidance should be followed. Liver and renal function, International Normalised Ratio (INR) and a venous bicarbonate should also be measured. Arterial blood gases and lactate should be assessed in patients with reduced bicarbonate or severe liver function abnormalities; metabolic acidosis indicates severe poisoning. If multiple ingestions of paracetamol have taken place over several hours (staggered overdose) or days (chronic therapeutic excess), acetylcysteine may be indicated, but paracetamol treatment nomograms are not useful

11.8 Complications of poisoning and their management

Complication	Causative agents	Management
Coma	Sedative agents	Appropriate airway protection and ventilatory support Oxygen saturation and blood gas monitoring Pressure area and bladder care Identification and treatment of aspiration pneumonia
Seizures	NSAIDs Anticonvulsants TCA Theophylline	Appropriate airway and ventilatory support IV benzodiazepine (diazepam 10–20 mg or lorazepam 2–4 mg) Correction of hypoxia, acid–base and metabolic abnormalities
Acute dystonias	Typical antipsychotics Metoclopramide	Procyclidine, benzatropine or diazepam
Hypotension		
Due to vasodilatation	Vasodilator antihypertensives Anticholinergic agents TCA	IV fluids Vasopressors (rarely indicated; p. 247)
Due to myocardial suppression	β-blockers Calcium channel blockers TCA	IV fluids if evidence of hypovolaemia with close monitoring to avoid volume overload and pulmonary oedema Inotropic agents (p. 247)
Ventricular tachycardia		
Monomorphic, associated with QRS prolongation	Sodium channel blockers	Correction of electrolyte and acid–base abnormalities and hypoxia Sodium bicarbonate (50 mL 8.4% solution, IV repeated if necessary)
Torsades de pointes, associated with QT_c prolongation	Anti-arrhythmic drugs (quinidine, amiodarone, sotalol) Antimalarials Organophosphate insecticides Antipsychotic agents Antidepressants Antibiotics (erythromycin)	Correction of electrolyte and acid–base abnormalities and hypoxia Magnesium sulphate, 2 g IV (adults) over 1–2 mins, repeated if necessary

(IV = intravenous; NSAID = non-steroidal anti-inflammatory drug; TCA = tricyclic antidepressant)

for assessing this; specific treatment recommendations are based on the reported dose ingested and vary between countries.

When indicated, acetylcysteine given intravenously (or orally in some countries) is highly efficacious if administered within 8 hours of overdose. However, efficacy declines thereafter, so administration should not be delayed while waiting for a measurement of paracetamol in blood for patients presenting after 8 hours. The antidote can be stopped if the paracetamol concentration is subsequently shown to be below the nomogram treatment line. High-dose acetylcysteine regimens are increasingly used in patients with very large paracetamol overdoses.

Anaphylactoid reactions are the most important adverse effects of acetylcysteine and are caused by histamine release, which is dose related. Common features are itching and urticaria, and in severe cases, bronchospasm and hypotension. Most cases can be managed by temporary discontinuation of acetylcysteine and administration of an antihistamine.

An alternative antidote is methionine 2.5 g orally (adult dose) every 4 hours to a total of four doses, but this may be less effective, especially after delayed presentation. Liver transplantation should be considered for paracetamol poisoning with life-threatening liver failure (p. 980).

11.9 Antidotes to treat poisoning

Mechanism of action	Examples of antidote	Poisoning treated
Agents that bind to receptor for toxin	Naloxone	Opioids
	Flumazenil	Benzodiazepines
	Atropine	Organophosphorus compounds Carbamates
Agents that interfere with mechanism of toxicity		
Glutathione (binds toxic metabolites of paracetamol)	Acetylcysteine Methionine	Paracetamol
Bypasses inhibition of pyridoxine phosphokinase (inhibited by isoniazid)	Pyridoxine	Isoniazid
Antagonises inhibitory effect of warfarin on vitamin K epoxide reductase complex subunit 1	Vitamin K	Warfarin
Alcohol dehydrogenase inhibitors (prevent formation of toxic metabolites)	Fomepizole Ethanol	Ethylene glycol Methanol
Cholinesterase reactivators (restore cholinesterase function)	Pralidoxime Obidoxime	Organophosphorus compounds
Agents that enhance metabolism of toxin		
Hydrolysing enzymes (metabolise toxin)	Glucarpidase	Methotrexate
Rhodanase enhancers (enhance enzyme-related detoxification by donating sulphur)	Sodium thiosulphate	Cyanide
Agents that bind to toxin		
Chelating agents	Desferrioxamine	Iron
	Hydroxocobalamin Dicobalt edetate	Cyanide
	DMSA Sodium calcium edetate	Lead
	Protamine	Heparins
Decoy receptors	Andexanet alfa	Apixaban, rivaroxaban
Antibody fragments	Digoxin Fab fragments	Digoxin
	Idarucizumab	Dabigatran etexilate
Reducing agents (convert methaemoglobin to haemoglobin)	Methylthioninium chloride	Aniline dyes, organic nitrites, phenacetin, sulphonamides
Oxidising agents (convert haemoglobin to methaemoglobin, which has high affinity for binding cyanide)	Sodium nitrite	Cyanide

(DMSA = dimercaptosuccinic acid; Fab = antigen binding fragments)

Salicylates

Clinical features

Salicylate (aspirin) overdose commonly causes nausea, vomiting, sweating, tinnitus and deafness. Direct stimulation of the respiratory centre produces hyperventilation and respiratory alkalosis. Peripheral vasodilatation with bounding pulses and profuse sweating occurs in moderately severe cases. Serious poisoning is associated with

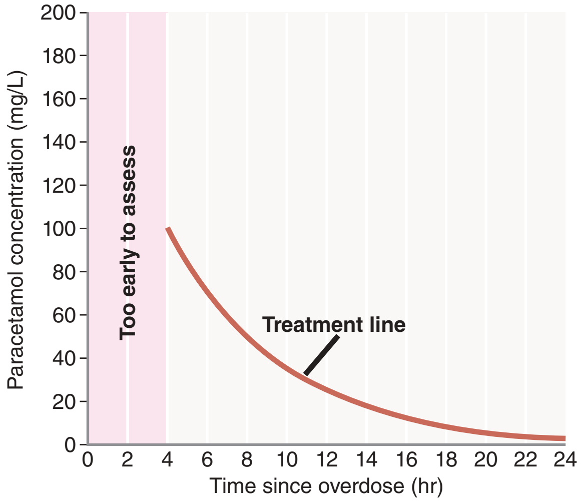

Fig. 11.2 **Paracetamol treatment nomogram (UK)**. Above the treatment line, benefits of treatment outweigh risk. Below it, risks of treatment outweigh benefits.

metabolic acidosis, hypoprothrombinaemia, hyperglycaemia, hyperpyrexia, renal failure, pulmonary oedema, shock and cerebral oedema. Agitation, delirium, coma and fits may occur, especially in children. Toxicity is enhanced by acidosis, which increases salicylate transfer across the blood–brain barrier.

Management

Activated charcoal should be administered if the patient presents sufficiently early, and an additional dose can be used if the overdose is very large. Multiple doses may enhance salicylate elimination but are not routinely recommended.

The plasma salicylate concentration should be measured at least 2 hours (symptomatic patients) or 4 hours (asymptomatic patients) after overdose and repeated in suspected serious poisoning, as concentrations may continue to rise for several hours. Clinical status, however, is more important than the salicylate concentration when assessing severity.

Dehydration should be corrected carefully because of the risk of pulmonary oedema. Metabolic acidosis should be treated with intravenous sodium bicarbonate (8.4%), after plasma potassium has been corrected. Urinary alkalinisation is indicated for adults with salicylate concentrations above 500 mg/L.

Haemodialysis is very effective for removing salicylate and correcting associated acid–base and fluid balance abnormalities. It should be considered when serum concentrations are above 700 mg/L in adults with severe toxic features, or in renal failure, pulmonary oedema, coma, convulsions or refractory acidosis.

Non-steroidal anti-inflammatory drugs

Clinical features

Overdose of most non-steroidal anti-inflammatory drugs (NSAIDs) usually causes only minor abdominal discomfort, vomiting and/or diarrhoea, but convulsions can occur occasionally, especially with mefenamic acid. Coma, prolonged seizures, apnoea, liver dysfunction and renal failure may follow substantial overdose but are rare. Features of toxicity are unlikely to develop in patients who are asymptomatic more than 6 hours after overdose.

Management

Electrolytes, liver function tests and a full blood count should be checked in all but the most trivial cases. Activated charcoal may be given if the patient presents sufficiently early. Symptomatic treatment for nausea and gastrointestinal irritation may be needed.

Antidepressants

Tricyclic antidepressants

Overdose with tricyclic antidepressants (TCA) carries a high morbidity and mortality because of their sodium channel-blocking, anticholinergic and α-adrenoceptor-blocking effects.

Clinical features

Anticholinergic effects are common (Box 11.10). Severe complications include convulsions, coma and arrhythmias (ventricular tachycardia, ventricular fibrillation and, less commonly, heart block). Hypotension results from inappropriate vasodilatation or impaired myocardial contractility. Serious complications appear more common with dosulepin and amitriptyline.

Management

Activated charcoal should be administered if the patient presents sufficiently early. As gastric emptying may be impaired, use for up to 2 hours after ingestion is justified. A 12-lead ECG should be taken, and continuous cardiac monitoring maintained for at least 6 hours. Prolongation of the QRS interval (especially if >0.16 secs) indicates severe sodium channel blockade and a high risk of arrhythmia (Fig. 11.3). QT interval prolongation may also occur. Arterial blood gases should be measured in suspected severe poisoning.

In patients with arrhythmias, significant QRS or QT prolongation or acidosis, intravenous sodium bicarbonate (50 mL of 8.4% solution) should be administered and repeated to correct pH. The correction of the acidosis and the increased extracellular sodium loading improve sodium channel function and may bring about rapid improvement in ECG features and arrhythmias. Hypoxia and electrolyte abnormalities should also be corrected. Anti-arrhythmic drugs should be given only on specialist

i **11.10 Anticholinergic and serotonergic feature clusters**

	Anticholinergic	Serotonin syndrome
Common causes	Benzodiazepines Antipsychotics TCA Antihistamines Scopolamine Benzatropine Belladonna Some plants and mushrooms (see Box 11.18)	SSRIs MAOIs TCA Amphetamines Tryptamines Buspirone Bupropion (especially in combination)
Clinical features		
Cardiovascular	Tachycardia, hypertension	Tachycardia, hyper- or hypotension
Central nervous system	Delirium, hallucinations, sedation	Delirium, hallucinations, sedation, coma
Muscle	Myoclonus	Shivering, tremor, myoclonus, raised creatine kinase
Temperature	Fever	Fever
Eyes	Diplopia, mydriasis	Normal pupil size
Abdomen	Ileus, palpable bladder	Diarrhoea, vomiting
Mouth	Dry	
Skin	Flushing, hot, dry	Flushing, sweating
Complications	Seizures	Seizures Rhabdomyolysis Renal failure Metabolic acidosis Coagulopathies

(MAOI = monoamine oxidase inhibitor; SSRI = selective serotonin re-uptake inhibitor; TCA = tricyclic antidepressant)

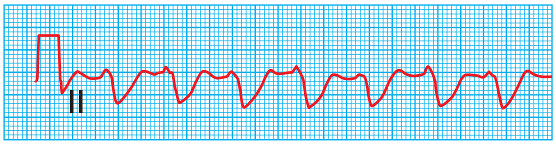

Fig. 11.3 **ECG in severe tricyclic antidepressant poisoning.** This rhythm strip shows a broad QRS complex due to impaired conduction.

advice. Prolonged seizures should be treated initially with intravenous benzodiazepines (see Box 11.8).

Selective serotonin and noradrenaline re-uptake inhibitors

Selective serotonin re-uptake inhibitor (SSRI) antidepressants such as fluoxetine, paroxetine, fluvoxamine, sertraline, citalopram and escitalopram are commonly used to treat depression and are less toxic in overdose than TCA. Serotonin–noradrenaline re-uptake inhibitors (SNRIs), such as venlafaxine and duloxetine, are also commonly used to treat depression and are more toxic than SSRIs in overdose. The pre-synaptic alpha-2 antagonist mirtazapine, which increases central noradrenergic and serotonergic neurotransmission, is also increasingly encountered in overdose.

Clinical features and management

Overdose of SSRIs may produce nausea and vomiting, tremor, insomnia and sinus tachycardia. Agitation, drowsiness and convulsions occur infrequently and may be delayed for several hours. Serotonin syndrome may occur (see Box 11.10), especially if SSRIs are taken in combination or with other serotonergic agents. Cardiac arrhythmias are infrequent and most patients require supportive care only. The toxic effects of SNRIs are similar but tachycardia, hypertension or hypotension and ECG changes (QRS and QT prolongation) are more prominent and hypoglycaemia can also arise. Mirtazapine has lower toxicity, but high doses may cause sedation, tachycardia and serotonin syndrome.

Lithium

Severe lithium toxicity is uncommon after intentional acute overdose but may be encountered in patients taking therapeutic doses as a result of interactions with drugs such as diuretics or NSAIDs or because of worsening renal function. Severe toxicity is more common after acute overdose in patients already taking chronic therapy (acute on chronic poisoning).

Clinical features

Nausea, diarrhoea, polyuria, dizziness and tremor may progress to muscular weakness, drowsiness, delirium, myoclonus, fasciculations, choreoathetosis and renal failure. Coma, seizures, ataxia, cardiac dysrhythmias such as heart block, blood pressure disturbances and renal failure may occur in severe poisoning.

Management

Activated charcoal is ineffective. Early gastric lavage is of theoretical benefit, but lithium tablets are likely to remain intact in the stomach and may be too large for aspiration via a lavage tube. Whole bowel irrigation is often used after substantial overdose, but efficacy is unproven.

Lithium concentrations should be measured immediately (symptomatic patients) or after at least 6 hours (asymptomatic patients) following acute overdose. The usual therapeutic range is 0.4–1.0 mmol/L. Adequate hydration should be maintained with intravenous fluids. Seizures should be treated as in Box 11.8.

Haemodialysis should be considered for severe toxicity associated with high lithium concentrations (>4.0 mmol/L after chronic or acute on chronic poisoning, or >7.5 mmol/L after acute poisoning). Lithium concentrations are reduced substantially during dialysis, but rebound increases occur after discontinuation and multiple sessions are usually required.

Cardiovascular medications

While uncommon, cardiovascular drug overdose is important because features of toxicity are often severe.

Beta-blockers

Major features of toxicity are bradycardia and hypotension; heart block, pulmonary oedema and cardiogenic shock occur in severe poisoning. Those with additional sodium channel-blocking effects such as propranolol, acebutolol, and carvedilol may cause seizures, delirium and coma, while sotalol, which also blocks potassium channels, may cause QT_c prolongation and torsades de pointes (see Box 11.8 and p. 454).

Management

Intravenous fluids may reverse hypotension, but care is required to avoid pulmonary oedema. Bradycardia and hypotension may respond to high doses of atropine (up to 3 mg in an adult) or an intravenous bolus dose of 20–60 μg isoproterenol followed by 2–20 μg/min infusion titrated to patient response. Glucagon (5–10 mg IV over 10 mins, then 50–150 μg/kg/hr by infusion) counteracts β-blockade by stimulating intracellular cyclic adenosine monophosphate (cAMP) production and is now more commonly used. In severe cases, hyperinsulinaemia euglycaemic therapy has been used, as described under calcium channel blockers below. The efficacy of lipid emulsion therapy in severe poisoning with lipid-soluble β-blockers, such as propranolol, carvedilol and oxprenolol, is uncertain.

Calcium channel blockers

In therapeutic doses, dihydropyridine calcium channel blockers such as nifedipine and amlodipine cause vasodilatation, whereas diltiazem and verapamil have predominantly cardiac effects, including bradycardia and reduced myocardial contractility. All L-type calcium channel blockers, however, are highly toxic in overdose.

Clinical features

Hypotension due to vasodilatation or myocardial depression is common and bradycardias and heart block may also occur, especially with verapamil and diltiazem. Gastrointestinal disturbances, delirium, metabolic acidosis, hyperglycaemia and hyperkalaemia may also be present.

Management

Hypotension should be corrected with intravenous fluids, taking care to avoid pulmonary oedema. Persistent hypotension may respond to intravenous calcium gluconate (10 mg IV over 5 mins, repeated as required). Isoproterenol and glucagon may also be useful, whilst vasopressors may also be indicated if there is profound vasodilatation. Hyperinsulinaemia euglycemic therapy has been successfully used for the treatment of poisoning with calcium channel blockers in patients unresponsive to other strategies. This consists of high-dose intravenous insulin initially at 0.5–2.0 U/kg/hr, increasing to 5–10 U/kg/hr according to clinical response with intravenous 10%–20% dextrose to maintain blood glucose concentrations within the reference range. The mechanism of action remains to be fully elucidated, but in states of shock, myocardial metabolism switches from use of free fatty acids to glucose. Calcium channel blocker poisoning is also associated with hypoinsulinaemia and insulin resistance, impeding glucose uptake by myocytes. High doses of insulin inhibit lipolysis and increase glucose uptake and the efficiency of glucose utilisation. Cardiac pacing may be needed for severe unresponsive bradycardias or heart block. Lipid emulsion therapy and methylthioninium chloride have also been used in severe poisoning with apparent benefit, although evidence is largely anecdotal.

Digoxin and oleander

Poisoning with digoxin is usually accidental, arising from prescription of an excessive dose, impairment of renal function or drug interactions.

In South Asia, deliberate self-poisoning with the plant yellow oleander *(Cascabela thevetia)*, which contains cardiac glycosides, is common.

Clinical features

Cardiac effects include tachyarrhythmias (either atrial or ventricular) and bradycardias, with or without atrioventricular block. Ventricular bigeminy is common and atrial tachycardia with evidence of atrioventricular block is highly suggestive of the diagnosis. Severe poisoning is often associated with hyperkalaemia. Non-cardiac features include delirium, headache, nausea, vomiting, diarrhoea and rarely altered colour vision. Digoxin poisoning can be confirmed by elevated plasma concentration (usual therapeutic range 1.3–2.5 mmol/L). After chronic exposure, concentrations > 5 mmol/L suggest serious poisoning, although this may sometimes also occur with lower concentrations.

Management

Activated charcoal adsorbs cardiac glycosides and is commonly administered to patients presenting soon after acute ingestion, although evidence of benefit is lacking. Urea, electrolytes and creatinine should be measured, a 12-lead ECG performed and cardiac monitoring instituted. Hypoxia, hypokalaemia (sometimes caused by concurrent diuretic use), hypomagnesaemia and acidosis increase the risk of arrhythmias and should be corrected. Significant bradycardias may respond to atropine, although temporary pacing is sometimes needed. Ventricular arrhythmias may respond to intravenous magnesium (see Box 11.8). If available, digoxin-specific antibody fragments should be administered when there are severe refractory ventricular arrhythmias or bradycardias. These are effective for both digoxin and yellow oleander poisoning. Multiple doses of activated charcoal can enhance cardiac glycoside elimination and may be used, especially if digoxin-specific antibodies are not available.

Iron

Overdose with iron can cause severe and sometimes fatal poisoning, with toxicity of individual iron preparations related to their elemental iron content.

Clinical features

Early features include gastrointestinal disturbance with the passage of grey or black stools, progressing to hyperglycaemia, leucocytosis, haematemesis, rectal bleeding, drowsiness, convulsions, coma, metabolic acidosis and cardiovascular collapse in severe cases. Early symptoms may improve or resolve within 6–12 hours, but hepatocellular necrosis can develop 12–24 hours after overdose and occasionally progresses to hepatic failure. Gastrointestinal strictures are late complications.

Management

Activated charcoal is ineffective, but gastric lavage or whole bowel elimination may be considered in patients presenting soon after substantial overdose, although the efficacy of these approaches is uncertain. Serum iron concentration should be measured at least 4 hours after overdose or earlier if there are features of toxicity. Desferrioxamine chelates iron and should be administered immediately in patients with severe features such as coma, shock, metabolic acidosis, and haemolysis, without waiting for serum iron concentrations, as well as symptomatic patients with high serum iron concentrations (> 5 mg/L). Desferrioxamine may cause hypotension, allergic reactions and occasionally pulmonary oedema. Otherwise, treatment is supportive and directed at complications.

Antipsychotic drugs

Antipsychotic drugs (see Box 29.22) are often prescribed for patients at high risk of self-harm or suicide and are often taken in overdose.

Clinical features

Anticholinergic features (see Box 11.10) including drowsiness, tachycardia and hypotension are common and convulsions may occur. Acute dystonias, including oculogyric crisis, torticollis and trismus, may occur after overdose with typical antipsychotics like haloperidol or chlorpromazine (see Box 11.8). QT interval prolongation and torsades de pointes can occur with both typical (haloperidol) and atypical (quetiapine, amisulpride, ziprasidone) agents.

Management

Activated charcoal may be of benefit if given early. Cardiac monitoring should be undertaken for at least 6 hours. Management is largely supportive, with treatment directed at complications (see Box 11.8).

Antidiabetic agents

Overdose is uncommon, but toxic effects can be severe.

Clinical features

Sulphonylureas, meglitinides such as nateglinide, and repaglinide and parenteral insulin cause hypoglycaemia when taken in overdose, although insulin is non-toxic if ingested by mouth. The duration of hypoglycaemia depends on the half-life or release characteristics of the preparation and may be prolonged over several days with long-acting agents such as glibenclamide, insulin degludec or insulin glargine.

Features of hypoglycaemia include nausea, agitation, sweating, aggression, delirium, tachycardia, hypothermia, drowsiness, convulsions and coma. Permanent neurological damage can occur if hypoglycaemia is prolonged. Hypoglycaemia can be diagnosed using bedside glucose strips, but venous blood should also be sent for laboratory confirmation.

Metformin is uncommonly associated with hypoglycaemia. Its major toxic effect is lactic acidosis, which can have a high mortality, and this is particularly common in older patients and those with renal or hepatic impairment, or when ethanol has been co-ingested. Other features of metformin overdose are nausea, vomiting, diarrhoea, abdominal pain, drowsiness, coma, hypotension and cardiovascular collapse.

There is limited experience of overdose involving thiazolidinediones like pioglitazone and dipeptidyl peptidase 4 (DPP-4) inhibitors like sitagliptin, but significant hypoglycaemia is unlikely, unless taken in combination with other hypoglycaemic agents.

Management

Activated charcoal should be considered for recent substantial overdose. Venous blood glucose and urea and electrolytes should be measured and measurement repeated regularly. Hypoglycaemia should be corrected using oral or intravenous glucose (50 mL of 50% dextrose); an infusion of 10%–20% dextrose may be required to prevent recurrence. Intramuscular glucagon can be used as an alternative, especially if intravenous access is unavailable. If the patient remains hypoglycaemic despite these measures, subcutaneous or intravenous octreotide may be used. Failure to regain consciousness within a few minutes of normalisation of the blood glucose can indicate that a central nervous system (CNS) depressant has also been ingested, the hypoglycaemia has been prolonged, or there is another cause of coma such as a stroke or cerebral oedema.

Arterial blood gases and plasma lactate should be taken after metformin overdose; acidosis should be corrected with intravenous sodium bicarbonate (250 mL 1.26% solution or 50 mL 8.4% solution, repeated as necessary). In severe cases, haemodialysis or haemodiafiltration may be required.

Pharmaceutical agents less commonly taken in poisoning

An overview of the clinical features and management for drugs less commonly involved in poisoning is provided in Box 11.11.

Drugs of misuse

Drugs of misuse are common causes of toxicity causing presentation to hospitals. Management has recently become more complex because of the emergence of new psychoactive substances (NPS). These are often chemically related to traditional drugs of misuse, but with structural modifications made to evade legal control. The constituents of branded NPS products are often unknown and knowledge about the clinical features and management of NPS toxicity is limited.

Depressants

These produce CNS depression, including drowsiness, ataxia, delirium and coma, sometimes with respiratory depression, airway compromise, aspiration pneumonia and respiratory arrest (Box 11.12). Other complications of coma include pressure blisters or sores and rhabdomyolysis. Effects are potentiated by other CNS depressants, including alcohol. Treatment is with supportive care as detailed in Box 11.8. Antidotes are available for some depressants.

Benzodiazepines

Benzodiazepines like diazepam and related substances like zopiclone are of low toxicity when taken alone in overdose, but can enhance CNS and respiratory depression when taken with other sedative agents, including alcohol or heroin. They are more hazardous in older people and those with chronic lung or neuromuscular disease (see Box 11.12). Dependency develops after chronic use over a few weeks and features of withdrawal commonly occur after rapid discontinuation of use. Highly potent novel benzodiazepines, such as etizolam, flualprazolam and flubromazolam, have recently been encountered as causes of poisoning, especially in counterfeit tablets purchased from dealers or via the internet. These agents are sometimes called street benzodiazepines and can cause toxic effects even at low doses.

The specific benzodiazepine antagonist flumazenil (0.5 mg IV, repeated if needed) increases conscious level in patients with benzodiazepine overdose, but carries a risk of seizures and is contraindicated in patients co-ingesting agents with pro-convulsant properties like TCA and cocaine and in those with a history of epilepsy.

Opioids

Toxicity may result from misuse of illicit drugs such as heroin or from intentional or accidental overdose of medicinal opiates. In recent years, novel synthetic opioids such as fentanyl and its analogues and nitazenes such as isotonitazene have increasingly been used to fortify heroin preparations in North America. These synthetic compounds are highly potent, their presence increases the risk of overdose and consequently

11.11 Clinical features and management of poisoning with less commonly implicated drugs

Substance	Clinical features	Management
Anticonvulsants		
Carbamazepine, phenytoin	Cerebellar signs Convulsions Cardiac arrhythmias Coma	Multiple dose activated charcoal (carbamazepine)
Sodium valproate	Coma Metabolic acidosis Hepatotoxicity	Haemodialysis for severe poisoning L-carnitine may be useful for severe cases with hyperammonaemia or hepatotoxicity
Isoniazid	Peripheral neuropathy Convulsions	Activated charcoal IV pyridoxine
Theophylline	Cardiac arrhythmias Convulsions Coma	Multiple dose activated charcoal
Antimalarial drugs		
Chloroquine	Acidosis and hypokalaemia Visual loss Convulsions, coma ECG changes and arrhythmias	Correction of pH (but not potassium) Monitoring and treatment of cardiac rhythm High-dose diazepam with mechanical ventilation
Quinine	Tremor, tinnitus, deafness, ataxia, convulsions, coma Haemolysis ECG changes and arrhythmias Retinal toxicity	Correction of pH (but not potassium) Monitoring and treatment of cardiac rhythm Multiple dose activated charcoal No effective treatment for visual loss

11.12 Stimulant, sedative and opioid feature clusters

	Stimulant	Sedative hypnotic	Opioid
Common causes	Amphetamines MDMA (ecstasy) Ephedrine Pseudoephedrine Cocaine Cannabis Phencyclidine Mephedrone Benzylpiperazine	Benzodiazepines Barbiturates Ethanol GHB	Heroin Morphine Methadone Fentanyl and derivatives Isotonitazene and derivatives Oxycodone Dihydrocodeine Codeine Pethidine Buprenorphine Dextropropoxyphene Tramadol
Clinical features			
Respiratory	Tachypnoea	Reduced respiratory rate and ventilation[1]	Reduced respiratory rate and ventilation
Cardiovascular	Tachycardia, hypertension	Hypotension[1]	Hypotension, relative bradycardia
Central nervous system	Restlessness, anxiety, anorexia, insomnia	Delirium, hallucinations, slurred speech	Delirium, hallucinations, slurred speech
	Hallucinations	Sedation, coma[1]	Sedation, coma[2]
Muscle	Tremor	Ataxia, reduced muscle tone	Ataxia, reduced muscle tone
Temperature	Fever	Hypothermia	Hypothermia

Skin	Piloerection	Blisters, pressure sores	Needle tracks[2]
Complications	Seizures Myocardial infarction Dysrhythmias Rhabdomyolysis Renal failure Intracerebral haemorrhage or infarction	Respiratory failure[1] Aspiration	Respiratory failure[2] Non-cardiogenic pulmonary oedema Aspiration

[1] Especially barbiturates.
[2] With intravenous use.
(GBH = gamma hydroxybutyrate, MDMA = 3,4,methylene-dioxymetamphetamine)

there has been a sharp increase in deaths related to opioid overdose in the United States and Canada in particular.

Intravenous or smoked heroin gives a rapid, intensely pleasurable experience, often accompanied by heightened sexual arousal. Physical dependence occurs within a few weeks of regular high-dose use. Withdrawal can start within 12 hours, causing intense craving, rhinorrhoea, lacrimation, yawning, perspiration, shivering, piloerection, vomiting, diarrhoea and abdominal cramps. Examination reveals tachycardia, hypertension, mydriasis and facial flushing.

Commonly encountered opioids and clinical features of poisoning are shown in Box 11.12. Needle tracks may be visible in intravenous users and there may be drug-related paraphernalia. Methadone may also cause QT_c prolongation and torsades de pointes. Features of opioid poisoning can be prolonged for up to 48 hours after use of long-acting agents such as methadone or oxycodone.

Use of the specific opioid antagonist naloxone (0.4–2 mg IV or 1.8 mg intranasally in an adult, repeated if necessary) may obviate the need for intubation, although excessive doses may precipitate acute withdrawal in chronic opiate users and breakthrough pain in those receiving opioids for pain management. Repeated doses or an infusion are often required because the half-life of the antidote is short compared to that of most opiates, especially those with prolonged elimination. Patients should be monitored for at least 6 hours after the last naloxone dose. Rare complications of naloxone therapy include seizures, ventricular arrhythmias and pulmonary oedema.

Gamma hydroxybutyrate

Gamma hydroxybutyrate (GHB), and the related compounds gamma butyrolactone (GBL), 1,4 butanediol, gamma-hydroxyvaleric acid (GHV) and gamma-valerolactone (GVL), are sedative substances with psychedelic and body-building effects. They are usually supplied as clear fluids and have been administered surreptitiously to enable drug-facilitated sexual assaults or other crimes.

As well as sedative hypnotic features (see Box 11.12), toxicity may cause nausea, diarrhoea, vertigo, tremor, myoclonus, extrapyramidal signs, euphoria, bradycardia, convulsions, metabolic acidosis, hypokalaemia and hyperglycaemia. Coma usually resolves abruptly within a few hours, but occasionally persists for several days. Dependence may develop in regular users, who experience severe, prolonged withdrawal effects if use is discontinued suddenly.

Management is largely supportive. All patients should be observed for a minimum of 2 hours and until symptoms resolve, with monitoring of blood pressure, heart rate, respiratory rate and oxygenation. Withdrawal symptoms may require treatment with very high doses of benzodiazepine.

Stimulants and entactogens

These are sympathomimetic and serotonergic amines that have overlapping clinical features, depending on the balance of their stimulant (see Box 11.12) and serotonergic (see Box 11.10) effects. As well as traditional drugs such as cocaine, amphetamines and ecstasy, the group includes many more recently emerging new psychoactive substances, including cathinones such as mephedrone, piperazines such as benzylpiperazine, piperadines such as ethylphenidate, benzofurans such as 5-aminopropylbenzofuran and NBOMe compounds such as 25I-NBOMe.

Cocaine

Cocaine is available as a water-soluble hydrochloride salt powder suitable for nasal inhalation (snorting), or as insoluble free-base (crack cocaine) that, unlike the hydrochloride salt, vaporise at high temperature and can be smoked, giving a more rapid and intense effect.

Effects appear rapidly after inhalation and especially after smoking. Sympathomimetic stimulant effects predominate (see Box 11.12). Serious complications usually occur within 3 hours of use and include coronary artery spasm, leading to myocardial ischaemia or infarction, hypotension and ventricular arrhythmias. Cocaine toxicity should be considered in younger adults presenting with ischaemic chest pain. Hyperpyrexia, rhabdomyolysis, acute renal failure and disseminated intravascular coagulation may occur.

A 12-lead ECG and ECG monitoring should be undertaken. ST segment elevation may occur in the absence of myocardial infarction and troponin T estimations are the most sensitive and specific markers of myocardial damage. Benzodiazepines and intravenous nitrates are useful for managing patients with chest pain or hypertension. Sodium bicarbonate should be used for those with acidosis, wide complex tachycardia or cardiac arrest. Aggressive physical cooling measures should be used for hyperpyrexia. Beta-blockers may be contraindicated because of the risk of unopposed α-adrenoceptor stimulation, but this is debated. Coronary angiography should be considered in patients with myocardial infarction or acute coronary syndromes. Vasodilators like glyceryl trinitrate given sublingually or intravenously may be effective for the treatment of cocaine-induced coronary vasospasm.

Amphetamines and cathinones

Amphetamine-related compounds include amphetamine sulphate (speed), methylamphetamine (crystal meth) and 3,4-methylene-dioxymethamphetamine (MDMA, or ecstasy). Synthetic cathinones have a closely related chemical structure and include mephedrone, methylenedioxypyrovalerone (MDPV) and n-ethylpentylone. Tolerance is common, leading regular users to seek ever-higher doses.

Toxic features usually appear within a few minutes of use and last 4–6 hours, or substantially longer after a large overdose. Sympathomimetic stimulant and serotonergic effects are common (see Boxes 11.10 and 11.12). Some users develop hyponatraemia as a result of excessive water-drinking or inappropriate vasopressin secretion. Muscle rigidity, pain and bruxism (clenching of the jaw), hyperpyrexia, rhabdomyolysis, metabolic acidosis, acute renal failure, disseminated intravascular coagulation, hepatocellular necrosis, acute respiratory distress syndrome (ARDS) and cardiovascular collapse have all been described following MDMA use. Cerebral infarction and haemorrhage have been reported, especially after intravenous amphetamine use. Management is supportive and directed at complications (see Box 11.8).

Hallucinogens

Cannabis

Derived from the dried leaves and flowers of *Cannabis sativa*, cannabis produces euphoria, perceptual alterations and conjunctival injection, followed by enhanced appetite, relaxation and occasionally hypertension, tachycardia, slurred speech and ataxia. Effects occur 10–30 minutes after smoking or 1–3 hours after ingestion, and last 4–8 hours. Solutions are also available for vaping using electronic cigarettes. High doses of cannabis may produce anxiety, delirium, hallucinations and psychosis, but serious acute toxicity is uncommon, and supportive treatment is all that is required. Psychological dependence is common, but tolerance and withdrawal symptoms are unusual. Long-term use is thought to increase the lifetime risk of psychosis, and a cannabis hyperemesis syndrome is also recognised, involving episodes of vomiting that respond poorly to antiemetics but improve on discontinuation of cannabis use.

Synthetic cannabinoid receptor agonists

Synthetic cannabinoid receptor agonists (SCRAs), sometimes referred to collectively as ‘spice’, have recently been in common use as legal alternatives to cannabis. More than 150 different SCRAs have been encountered, with recently prevalent examples including MDMB-4en-PINACA, 4F-MDMB-BINACA and ADB-BUTINACA. They are usually sprayed on a herbal smoking mix and packaged as smoking products with appealing brand names. These may contain more than one SCRA and content may change with time. Vaping of SCRA solutions has also been reported.

The toxic effects of SCRAs differ from those of cannabis, being generally more marked and including agitation, panic, delirium, hallucinations, tachycardia, ECG changes, hypertonia, dyspnoea and vomiting. Coma, respiratory acidosis, seizures, hypokalaemia and renal dysfunction may also occur. There is increasing evidence of pharmacological tolerance and dependence with SCRA use, and features of withdrawal may occur after discontinuation. Treatment of intoxication is supportive.

Tryptamines

These are predominantly 5-hydroxytryptamine (5-HT, serotonin; especially 5-HT2A) agonists with associated stimulant effects. Typical clinical features include hallucinations, agitation, delirium, hypertension, tachycardia, sweating, anxiety and headache. Serotonin syndrome may occur (see Box 11.10), especially if tryptamines are used in combination with other serotonergic agents. Naturally occurring examples are psilocin and psilocybin, found in 'magic mushrooms', and dimethyltryptamine (DMT) in traditional ayahuasca brews. Synthetic tryptamines, such as alpha-methyltryptamine (AMT), have also been encountered.

D-Lysergic acid diethylamide

D-Lysergic acid diethylamide (LSD) is a synthetic ergoline usually ingested as small squares of impregnated absorbent paper (often printed with a distinctive design) or as microdots. The drug causes perceptual effects, such as heightened visual awareness of colours or distortion of images. Hallucinations may be pleasurable or terrifying (bad trip). Other features are delirium, agitation, aggression, dilated pupils, hypertension, pyrexia and metabolic acidosis. Psychosis may sometimes last several days.

Patients with psychotic reactions or CNS depression should be observed in hospital, preferably in a quiet, dimly lit room to minimise external stimulation. A benzodiazepine can be used for sedation if required; avoid antipsychotics if possible because these may precipitate cardiovascular collapse or convulsions.

Dissociative drugs

Ketamine, its *N*-ethyl derivative methoxetamine and phencyclidine (now rarely encountered) produce a sense of dissociation from reality, often associated with visual and auditory distortions. Memory loss, impaired consciousness, agitation, hallucinations, tremors and numbness may also occur. Long-term ketamine or methoxetamine use can cause severe chronic cystitis with dysuria, frequency, urgency, haematuria and incontinence. These features are often severe, debilitating and difficult to treat. Management of acute intoxication is supportive.

Volatile substances

Inhalation of volatile nitrites such as amyl nitrite and isobutyl nitrite, often sold in bottles or vials known as 'poppers', is reported to produce a feeling of pleasure and warmth, relax the anal sphincter and prolong orgasm. These potent vasodilators commonly provoke headache, dizziness, hypotension and tachycardia. They also oxidise haemoglobin to produce methaemoglobinaemia, with resulting breathlessness and delirium. Severe methaemoglobinaemia is treated with methylthioninium chloride (methylene blue, see Fig. 11.1). Regular use may also precipitate maculopathy with visual loss.

Several volatile solvents found in household products, such as propane, butane, toluene and trichloroethylene, have a mild euphoriant effect if inhaled. Serious toxic effects can occur, including reduced level of consciousness, seizures and cardiac arrhythmias; there is also a risk of asphyxia from some methods of inhalation.

Nitrous oxide is an anaesthetic gas, but canisters of it are sold for the domestic production of whipped cream and the contents of these can be transferred to balloons for inhalation. The gas has euphoriant effects (laughing gas), but hazards include asphyxia from inhalation without oxygen, or vitamin B_{12} inactivation from chronic use leading to megaloblastic anaemia, psychosis and other neurological sequelae.

Body packers and body stuffers

Body packers (mules) attempt to smuggle illicit drugs (usually cocaine, heroin or amphetamines) by ingesting multiple small packages wrapped in several layers of clingfilm or in condoms. Body stuffers are those who have ingested unpackaged or poorly wrapped substances, often to avoid arrest. Both groups are at risk of severe toxicity if the packages rupture. This is more likely for body stuffers, who may develop symptoms of poisoning within 8 hours of ingestion. The risk of poisoning depends on the quality of the wrapping, and the amount and type of drug ingested. Cocaine, for example, presents a much higher risk than heroin because of its high toxicity and lack of a specific antidote.

Patients suspected of body packing or stuffing should be admitted for observation. A careful history taken in private is important, but for obvious reasons patients may withhold details of the drugs involved. Examination of the mouth, rectum and vagina as possible sites for concealed drugs should be arranged with patient consent, consistent with local laws. A urine toxicology screen performed at intervals may provide evidence of leakage, although positive results may reflect earlier drug use. Packages may be visible on plain abdominal films (Fig. 11.4), but ultrasound and computed tomography (CT) are more sensitive. One of these (preferably CT) should be performed in all suspected body packers.

Antimotility agents are often used by body packers to prevent premature passage of packages; it can take several days for packages to pass spontaneously, during which the carrier is at risk from package rupture. Whole bowel irrigation is commonly used to accelerate passage and is continued until all packages have passed. Surgery may be required when there is mechanical bowel obstruction or when evolving clinical features suggest package rupture, especially with cocaine.

Chemicals and pesticides

Carbon monoxide

Carbon monoxide (CO) is a colourless, odourless gas produced by faulty appliances burning organic fuels. It is also present in vehicle exhaust fumes and sometimes in smoke from house fires or barbecues. It binds with haemoglobin (to form carboxyhaemoglobin) and cytochrome

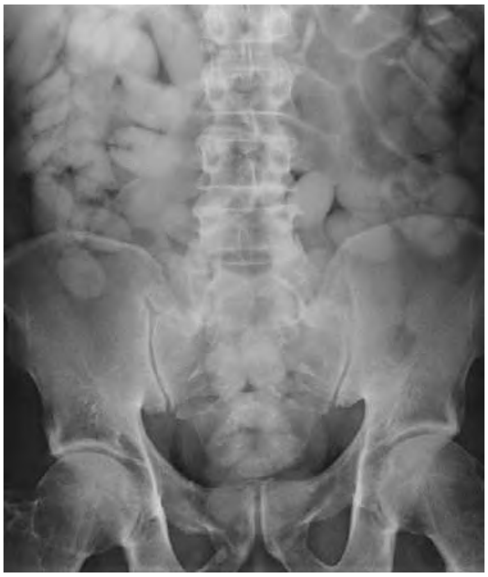

Fig. 11.4 Abdominal X-ray of a body packer showing multiple drug-filled condoms.

oxidase, reducing tissue oxygen delivery and inhibiting cellular respiration. Poisoning with CO is a common cause of death and most patients die before reaching hospital.

Clinical features

Early features include headache, nausea, irritability, weakness and tachypnoea. The cause of these non-specific features may not be obvious if the exposure is occult, such as from a faulty domestic appliance. Subsequently, ataxia, nystagmus, drowsiness and hyper-reflexia may develop, progressing to coma, convulsions, hypotension, respiratory depression, cardiovascular collapse and death. Myocardial ischaemia may result in arrhythmias or myocardial infarction. Cerebral oedema is common, and rhabdomyolysis may cause myoglobinuria and renal failure. In those who recover from acute toxicity, longer-term neuropsychiatric effects are common, such as personality change, memory loss and concentration impairment. Extrapyramidal effects, urinary or faecal incontinence, and gait disturbance may also occur. Poisoning during pregnancy may cause fetal hypoxia and intrauterine death.

Management

Patients should be removed from exposure as soon as possible and resuscitated as necessary. A high concentration of oxygen should be administered via a tightly fitting facemask; this reduces the half-life of carboxyhaemoglobin from 4–6 hours to about 40 minutes. Measurement of carboxyhaemoglobin is useful for confirming exposure; levels > 20% suggest significant exposure, but do not correlate well with the severity of poisoning, partly because concentrations fall rapidly after removal of the patient from exposure, especially if supplemental oxygen has been given.

An ECG should be performed in all patients with acute CO poisoning, especially those with pre-existing heart disease. Arterial blood gas analysis should be checked in those with serious poisoning. Pulse oximetry may provide misleading oxygen saturation levels because the devices do not distinguish between carboxyhaemoglobin and oxyhaemoglobin. Excessive intravenous fluid administration should be avoided, particularly in the older patients, because of the risk of pulmonary and cerebral oedema. Convulsions should be controlled with diazepam.

Hyperbaric oxygen therapy is used to treat CO poisoning but its efficacy is not proven. At 2.5 atmospheres, the half-life of carboxyhaemoglobin is reduced to about 20 minutes and the amount of oxygen dissolved in plasma is increased 10-fold, but systematic reviews have not consistently shown improved clinical outcomes. The logistical difficulties of transporting sick patients to hyperbaric chambers and managing them therein are substantial.

Organophosphorus insecticides and nerve agents

Organophosphorus (OP) compounds (Box 11.13) are widely used as pesticides, especially in low- and middle-income countries. Case fatality following deliberate ingestion is high (5%–20%). Legal controls banning the most toxic examples have substantially reduced the rates of suicide with these agents, for example, in Sri Lanka.

Nerve agents, developed for chemical warfare, are derived from OP insecticides and are much more toxic. They are commonly classified as G (originally synthesised in Germany) or V (venomous) agents. The G agents, such as tabun, sarin and soman, are volatile, absorbed by inhalation or via the skin, and dissipate rapidly after use. The V agents, such as VX, are contact poisons unless aerosolised and contaminate the ground for weeks or months. Novichok agents, originally developed in the former Soviet Union, have also recently been encountered. The toxicology and management of nerve agent and pesticide poisoning are similar.

Mechanism of toxicity

Organophosphorus compounds inactivate acetylcholinesterase (AChE), resulting in the accumulation of acetylcholine (ACh) in cholinergic synapses (Fig. 11.5). Initially, spontaneous hydrolysis of the OP–enzyme complex allows reactivation of the enzyme but, subsequently, loss of a chemical group from the OP–enzyme complex prevents further enzyme reactivation. After this process (termed ageing) has taken place, new enzyme needs to be synthesised before function can be restored. The rate of ageing is an important determinant of toxicity and is more rapid with dimethyl (3.7 hours) than diethyl (31 hours) compounds (see Box 11.13) and especially rapid after exposure to nerve agents (soman in particular), which cause 'ageing' within minutes.

Clinical features and management

Organophosphate poisoning causes an acute cholinergic phase, which may occasionally be followed by the 'intermediate syndrome' and organophosphate-induced delayed polyneuropathy (OPIDN). The

11.14 Cholinergic features in poisoning*

	Muscarinic	Nicotinic
Respiratory	Bronchorrhoea, bronchoconstriction	Reduced ventilation
Circulation	Bradycardia, hypotension	Tachycardia, hypertension
Higher mental function	Anxiety, delirium, psychosis	
Muscle	–	Fasciculation, paralysis
Temperature	Fever	–
Eyes	Diplopia, miosis, lacrimation	Mydriasis
Abdomen	Vomiting, profuse diarrhoea	–
Mouth	Salivation	–
Skin	Sweating	–
Complications	Coma, seizures, respiratory depression	

*Both muscarinic and nicotinic features occur in organophosphorus poisoning. Nicotinic features occur in nicotine poisoning and black widow spider bites. Cholinergic features may be seen as the result of poisoning with some mushrooms.

onset, severity and duration depend on the route of exposure and agent involved.

Acute cholinergic syndrome

This usually starts within a few minutes of exposure and nicotinic or muscarinic features may be present (Box 11.14). Vomiting and profuse diarrhoea are typical following ingestion. Bronchoconstriction, bronchorrhoea and salivation may cause severe respiratory compromise. Excess sweating and miosis are characteristic and the presence of muscular fasciculations strongly suggests the diagnosis, although this feature is often absent, even in serious poisoning. Subsequently, generalised flaccid paralysis may develop and affect respiratory and ocular muscles, resulting in respiratory failure. Ataxia, coma, convulsions, cardiac repolarisation abnormalities and torsades de pointes may occur.

Management

The airway should be cleared of excessive secretions, breathing and circulation assessed, high-flow oxygen administered, and intravenous access obtained. Appropriate external decontamination is needed (p. 159). Gastric lavage or activated charcoal may be considered if the patient presents sufficiently early. Seizures should be treated as described in Box 11.8. The ECG, oxygen saturation, blood gases, temperature, urea and electrolytes, amylase and glucose should be monitored closely.

Early use of atropine is potentially life-saving in patients with severe toxicity. Atropine reverses ACh-induced bronchospasm, bronchorrhoea, bradycardia and hypotension. When the diagnosis is uncertain, a marked increase in heart rate associated with skin flushing after a 1 mg intravenous dose makes OP poisoning unlikely. In OP poisoning, atropine (2 mg IV) should be administered, and this dose should be doubled every 5–10 minutes until clinical improvement occurs. Further bolus doses should be given until secretions are controlled, the skin is dry, blood pressure is adequate, and heart rate is > 80 bpm. Large doses may be needed, but excessive doses may cause anticholinergic effects (see Box 11.10).

In severe poisoning requiring atropine, an oxime (such as pralidoxime chloride or obidoxime) is generally recommended if available, although efficacy is debated. This may reverse or prevent muscle weakness, convulsions or coma, especially if given rapidly after exposure. Oximes reactivate AChE that has not undergone ageing and are therefore less effective with dimethyl compounds and nerve agents, especially soman. Oximes may provoke hypotension, especially if administered rapidly.

Intravenous magnesium sulphate has been reported to increase survival in animals and in small human studies of OP poisoning; however, further clinical trial evidence is needed before this can be recommended routinely.

Ventilatory support should be instituted before the patient develops respiratory failure. Benzodiazepines may be used to treat agitation, fasciculations and seizures and for sedation during mechanical ventilation.

Exposure is confirmed by measurement of plasma or red blood cell cholinesterase activity, but antidote use should not be delayed pending results. Plasma cholinesterase is reduced more rapidly but is less specific than red cell cholinesterase. Values correlate poorly with the severity of clinical features, but are usually < 10% in severe poisoning, 20%–50% in moderate poisoning and > 50% in subclinical poisoning.

The acute cholinergic phase usually lasts 48–72 hours, with most patients requiring intensive cardiorespiratory support and monitoring. Cholinergic features may be prolonged over several weeks with some lipid-soluble agents.

Intermediate syndrome

About 20% of patients with OP poisoning develop weakness that spreads rapidly from the ocular muscles to those of the head and neck, proximal limbs and the muscles of respiration, resulting in ventilatory failure. This 'intermediate syndrome' generally develops 1–4 days after exposure, often after resolution of the acute cholinergic syndrome and may last 2–3 weeks. There is no specific treatment and supportive care is needed, including maintenance of airway and ventilation.

Organophosphate-induced delayed polyneuropathy

Organophosphate-induced delayed polyneuropathy (OPIDN) is a rare complication that usually occurs 2–3 weeks after acute exposure. It is a mixed sensory/motor polyneuropathy, affecting long myelinated neurons especially, and appears to result from inhibition of enzymes other than AChE. It is a feature of poisoning with some OPs such as triorthocresyl phosphate but is less common with nerve agents. Early clinical features are muscle cramps followed by numbness and paraesthesia, proceeding to flaccid paralysis of the lower and subsequently the upper limbs, with foot and wrist drop and a high-stepping gait, progressing to paraplegia. Sensory loss may also be present but is variable. Initially, tendon reflexes are reduced or lost but mild spasticity may develop later.

There is no specific therapy for OPIDN. Regular physiotherapy may limit deformity caused by muscle wasting. Recovery is often incomplete and may be limited to the hands and feet, although substantial functional recovery after 1–2 years may occur, especially in younger patients.

Carbamate insecticides

Carbamate insecticides such as bendiocarb, carbofuran, carbaryl and methomyl inhibit a number of tissue esterases, including AChE. The mechanism, clinical features and management of toxicity are similar to those of OP compounds. However, clinical features are usually less severe and of shorter duration, because the carbamate–AChE complex dissociates quickly, with a half-life of 30–40 minutes, and does not undergo ageing. Also, carbamates penetrate the CNS poorly. Intermediate syndrome and OPIDN are not common features of carbamate poisoning. Despite this, case fatality can be high for some carbamates, depending on their formulation. Atropine may be given intravenously for carbamate poisoning if there are cholinergic features using the same dosage regime as described for organophosphorus poisoning as described above.

Paraquat

Paraquat is a herbicide that has been widely used across the world, although it has been banned in the European Union and some other countries for many years. It is highly toxic if ingested, with clinical features including oral burns, vomiting and diarrhoea, progressing to pneumonitis, pulmonary fibrosis and multi-organ failure.

Exposure can be confirmed by a urinary dithionite test, while the plasma paraquat concentration gives an indication of prognosis. There is no specific antidote, but activated charcoal is commonly administered. Immunosuppression with glucocorticoids and cyclophosphamide is sometimes used, but evidence for benefit is weak. Irrespective of treatment, death is common and may occur within 24 hours with substantial poisoning or after 1–2 weeks with lower doses.

Alcohols and glycols

Ethanol (alcohol, ethyl alcohol) is commonly consumed in alcoholic beverages but is also found in some cosmetics, perfumes and antiseptic hand gels. It may also be used as an industrial solvent or produced illicitly. It can also be used as an antidote in ethylene glycol or methanol poisoning (see below). The health effects of chronic alcohol use are described in Chapter 29.

Acute alcohol consumption causes concentration-related toxicity, although it is unusual for ethanol toxicity alone to precipitate hospital admission. Severe and fatal toxicity, however, is more likely in children or when alcohol has been used with other sedative substances such as opioids or benzodiazepines. High concentrations of alcohol produce incoordination and slurred speech, and this may progress to unconsciousness with respiratory depression, loss of airway reflexes, hypotension, metabolic acidosis and occasionally hypothermia, hypoglycaemia and convulsions. Investigations should include measurement of blood alcohol concentration, arterial blood gases as well as full blood count, glucose, renal and hepatic function. Management involves protection of the airway, maintenance of ventilation and oxygenation, fluid resuscitation, correction of hypoglycaemia with glucose and treatment of convulsions. Thiamine should be administered if chronic excess alcohol use is suspected. Haemodialysis is effective for increasing alcohol clearance and should be considered in severe cases associated with very high ethanol concentrations.

Ethylene glycol (1,2-ethanediol) is found in antifreeze, brake fluids and, in lower concentrations, windscreen washes. Methanol is present in some antifreeze products and commercially available industrial solvents, and in low concentrations in some screen washes and methylated spirits. It may also be an adulterant of illicitly produced alcohol. Both are rapidly absorbed after ingestion. Methanol and ethylene glycol are not intrinsically toxic but are converted by alcohol dehydrogenase to toxic metabolites that are largely responsible for their clinical effects (Fig. 11.6).

Early features of poisoning with either methanol or ethylene glycol include vomiting, ataxia, drowsiness, dysarthria and nystagmus. As toxic metabolites are formed, metabolic acidosis, tachypnoea, coma and seizures may develop.

Toxic effects of ethylene glycol include ophthalmoplegia, cranial nerve palsies, hyporeflexia and myoclonus. Renal pain and acute tubular necrosis occur because of renal calcium oxalate precipitation. Hypocalcaemia, hypomagnesaemia and hyperkalaemia are common.

Methanol poisoning causes headache, delirium and vertigo. Visual impairment and photophobia develop, associated with optic disc and retinal oedema and impaired pupil reflexes. Blindness may be permanent, although some recovery may occur over several months. Pancreatitis and abnormal liver function have also been reported.

Urea and electrolytes, chloride, bicarbonate, glucose, calcium, magnesium, albumin, plasma osmolarity and arterial blood gases should be measured in all patients with suspected methanol or ethylene glycol toxicity. The osmolar and anion gaps should be calculated (see Box 11.5). Initially, poisoning is associated with an increased osmolar gap, but as toxic metabolites are produced an increased anion gap develops associated with metabolic acidosis. The diagnosis can be confirmed by measurement of ethylene glycol or methanol concentrations, but assays are not widely available.

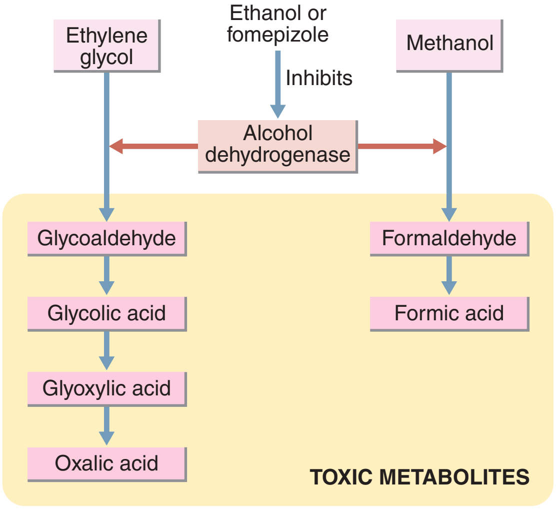

Fig. 11.6 Metabolism of ethanol methanol and ethylene glycol. Alcohol dehydrogenase metabolises methanol and ethylene glycol to the toxic metabolites indicated. Alcohol is metabolised by the same enzyme to acetaldehyde, which is toxic, but is short lived and broken down to form acetate, which is harmless. Fomepizole inhibits alcohol dehydrogenase and prevents the formation of toxic metabolite formation.

An antidote, ideally fomepizole or otherwise ethanol, should be administered to all patients with suspected significant exposure while awaiting the results of laboratory investigations. These block alcohol dehydrogenase and delay the formation of toxic metabolites until the parent drug is eliminated in the urine or by dialysis. The antidote should be continued until ethylene glycol or methanol concentrations are undetectable. Metabolic acidosis should be corrected with 250 mL of 1.26% intravenous sodium bicarbonate and repeated as necessary. Convulsions should be treated with an intravenous benzodiazepine. In ethylene glycol poisoning, hypocalcaemia should be corrected only if there are severe ECG features or if seizures occur, as this may increase calcium oxalate crystal formation. In methanol poisoning, folinic acid should be administered to enhance the metabolism of the toxic metabolite, formic acid.

Haemodialysis or haemodiafiltration should be used in severe poisoning, especially if renal failure is present or there is visual loss in the context of methanol poisoning. It should be continued until acute toxic features are no longer present and ethylene glycol/methanol concentrations are undetectable.

Corrosive substances

Products containing acids such as hydrochloric or sulphuric acid or alkalis such as sodium hydroxide or sodium hypochlorite (bleach) may be ingested accidentally or intentionally, causing gastrointestinal pain, ulceration and necrosis, with risk of perforation. Severity depends on the volume and pH of the substance ingested.

External decontamination (p. 159) should be performed after initial resuscitation if needed. Gastric lavage should not be attempted, and neutralising chemicals should not be administered after large ingestions because of the risk of tissue damage from heat release. Cardiorespiratory monitoring is necessary and full blood count, renal function, coagulation and acid–base status should be assessed. An erect chest X-ray should be performed if perforation is suspected and may show features of mediastinitis or gas under the diaphragm. Strong analgesics should be administered for pain.

Severe abdominal or chest pain, abdominal distension, shock or acidosis may indicate perforation and should prompt an urgent CT scan of chest and abdomen and surgical review. In the absence of perforation, drooling, dysphagia, stridor or oropharyngeal burns suggest possible severe oesophageal damage and early endoscopy by an experienced operator should be considered. Delayed endoscopy may carry a higher risk of perforation than early endoscopy.

Aluminium and zinc phosphide

These rodenticides and fumigants are a common means of self-poisoning in northern India. The mortality rate for aluminium phosphide ingestion has been estimated at 60%, but zinc phosphide ingestion appears less toxic (mortality about 2%). When ingested, both compounds react with gastric acid to form phosphine, a potent pulmonary and gastrointestinal toxicant. Clinical features include severe gastrointestinal disturbances, chest tightness, cough and breathlessness progressing to ARDS and respiratory failure, tremor, paraesthesia, convulsions, coma, tachycardia, metabolic acidosis, electrolyte disturbances, hypoglycaemia, myocarditis, liver and renal failure, and leucopenia. Ingestion of a few tablets can be fatal.

Treatment is supportive and directed at correcting electrolyte abnormalities and treating complications; there is no specific antidote. Early gastric lavage is sometimes used, often with vegetable oil to reduce the release of toxic phosphine, but the benefit is uncertain.

Elemental phosphorus

Elemental phosphorus has industrial uses in the production of matches, fireworks, munitions and pesticides and as a rodenticide. Red phosphorus has limited human toxicity, but white phosphorus (sometimes also called yellow phosphorus because of discoloration due to contamination with red phosphorus) is unstable, highly flammable and very toxic.

Skin contact with white/yellow phosphorus causes thermal burns aggravated by the generation of phosphoric acid and significant dermal absorption of phosphorus may occur. Absorption via the gastrointestinal tract causes vomiting with a musty or garlic smell and occasionally luminescence of the vomitus. Mucosal burns, haematemesis and abdominal pain occur due to corrosive effects; circulatory shock, arrhythmias and death may occur within 24 hours in severe cases. Combustion releases phosphorus pentoxide, which is an irritant to mucous membranes and may cause acute lung injury. Irrespective of the route of exposure, hepatotoxicity and nephrotoxicity may develop in those who survive the first few days, sometimes after a period of improvement. Headache, reduced consciousness, and occasionally seizures may occur and blood tests may show electrolyte disturbances, especially hypocalcaemia, hyperphosphataemia and hyperkalaemia.

Management is supportive and directed at the clinical features observed. Those treating exposed patients should avoid contaminating themselves. Burns should be immersed in water to extinguish combustion of residual phosphorus. Fragments and necrotic tissue should be removed meticulously and dressings soaked in water or saline employed to prevent exposure to oxygen. The ECG, renal and liver function, electrolytes, clotting, glucose and acid–base status should be monitored and electrolytes and calcium corrected as necessary. Management of gastrointestinal effects is as for other corrosive substances. Most deaths occur within a few days of ingestion.

Copper sulphate

This is used as a fungicide. If ingested, clinical features of toxicity include nausea, vomiting, abdominal pain, diarrhoea, discoloured (blue/green) secretions, corrosive effects on the gastrointestinal tract, renal or liver failure, methaemoglobinaemia, haemolysis, rhabdomyolysis, convulsions and coma. Treatment is as for other corrosive substances (see above) and should address complications, including use of methylthioninium chloride for methaemoglobinaemia (see Fig. 11.1). Chelation therapy is unlikely to be beneficial after acute exposure.

Chemicals less commonly taken in poisoning

An overview of the clinical features and management for chemicals less commonly involved in poisoning is provided in Box 11.15. Lead poisoning is seldom deliberate but occurs as the result of chronic occupational exposure, leaded paint, water contaminated by lead pipes, or the use of kohl cosmetics. The most common agents responsible for poisoning with petroleum distillates are white spirit and kerosene. Organochlorine poisoning can occur as the result of ingestion of dichlorodiphenyltrichloroethane (DDT), lindane, dieldrin or endosulfan. Examples of pyrethroid insecticides include cypermethrin, permethrin and imiprothrin. Anticoagulant rodenticides responsible for poisoning include brodifacoum, bromadiolone and warfarin.

Chemical warfare agents

Some toxins have been developed for use as chemical warfare agents. These are summarised in Box 11.16.

Environmental poisoning

Arsenism

Chronic arsenic exposure from drinking water has been reported in many countries, especially India, Bangladesh, Nepal, Thailand, Taiwan, China, Mexico and South America, where a large proportion of the drinking water (ground water) has a high arsenic content, placing local populations at risk. The World Health Organization (WHO) guideline value for arsenic content in well water is $< 10\,\mu g/L$.

Health effects associated with chronic exposure to arsenic in drinking water are shown in Box 11.17. In exposed individuals, high concentrations of arsenic are present in bone, hair and nails. Specific treatments are of no benefit in chronic arsenic toxicity and recovery from the peripheral neuropathy may never be complete, so the emphasis should be on prevention.

Fluorosis

Fluoride poisoning can result from exposure to excessive quantities of fluoride (> 10 ppm) in drinking water, industrial exposure to fluoride dust or consumption of brick teas. Clinical features include yellow staining and pitting of permanent teeth, osteosclerosis, soft tissue calcification, kyphosis and joint ankylosis. Changes in the bones of the thoracic cage may lead to rigidity that causes dyspnoea on exertion. Very high doses of fluoride may cause abdominal pain, nausea, vomiting, seizures and muscle spasm. In calcium-deficient children, the toxic effects of fluoride manifest even at marginally high exposures to fluoride.

In endemic areas, such as Jordan, Turkey, Chile, India, Bangladesh, China and Tibet, fluorosis is a major public health problem, especially in communities engaged in physically strenuous agricultural or industrial activities. Dental fluorosis is endemic in East Africa and some West African countries.

Food-related poisoning

Paralytic shellfish poisoning

Paralytic shellfish poisoning is caused by consumption of bivalve molluscs like mussels, clams, oysters, cockles and scallops, which are contaminated with saxitoxins. These are concentrated in the shellfish because of constant filtration of toxic algae during algal blooms (red tide). Symptoms develop within 10–120 minutes of eating the contaminated shellfish and include gastrointestinal disturbances, paraesthesia around the mouth or in the extremities, ataxia, mental state changes and

11.15 Clinical features and management of poisoning due to less commonly implicated agents

Substance	Clinical features	Management
Lead	Abdominal pain Microcytic anaemia with basophilic stippling Headache and encephalopathy Motor neuropathy Nephrotoxicity Hypertension Hypocalcaemia	Prevention of further exposure Measurement of blood lead concentration, full blood count and blood film, urea and electrolytes, liver function tests and calcium Abdominal X-ray in children to detect pica Bone X-ray for 'lead lines' Chelation therapy with DMSA or sodium calcium edetate
Barium salts	Gastrointestinal disturbances, haematemesis, hypersalivation, perioral paraesthesia Cyanosis, bradycardia, chest pain, breathlessness Profound hypokalaemia	Abdominal X-ray to confirm ingestion of radio-opaque material Aggressive correction of hypokalaemia Haemodialysis in severe cases (removes barium and may correct hypokalaemia)
Strychnine	Rapid onset of gastrointestinal symptoms Agitation, sweating, tachycardia, chest pain Muscular stiffness and twitching, convulsions and respiratory arrest	Supportive care including treatment of agitation and convulsions
Thallium	Gastrointestinal disturbances including bleeding Subsequently pancreatitis, parotid swelling, confusion, peripheral neuropathy, alopecia, renal, liver, cardiac or bone marrow failure Coma and death developing over 7–21 days	Oral Prussian blue or repeated doses of activated charcoal (adsorb thallium in the gut) Supportive care including treatment of convulsions and cardiac complications
Petroleum distillates	Vomiting Aspiration pneumonitis	Gastric lavage contraindicated Activated charcoal ineffective Oxygen and nebulised bronchodilators Chest X-ray to assess pulmonary effects
Organochlorines	Nausea, vomiting Agitation Fasciculation Paraesthesia (face, extremities) Convulsions Coma Respiratory depression Cardiac arrhythmias Hyperthermia Rhabdomyolysis Pulmonary oedema Disseminated intravascular coagulation	Activated charcoal (with nasogastric aspiration for liquid preparations) if presenting soon enough after ingestion Cardiac monitoring
Pyrethroid insecticides	Skin contact: dermatitis, skin paraesthesia Systemic features may occur after substantial exposure Eye contact: lacrimation, photophobia and oedema of the eyelids Inhalation: dyspnoea, nausea, headaches Ingestion: epigastric pain, nausea, vomiting, hypersalivation, headache, coma, convulsions, pulmonary oedema	Symptomatic and supportive care Washing contaminated skin makes irritation worse Hyoscine (20 mg subcutaneously every 4 hrs) may be useful for severe hypersalivation
Anticoagulant rodenticides	Abnormal bleeding (prolonged)	Monitor INR/prothrombin time Vitamin K_1 by slow IV injection if there is coagulopathy Fresh frozen plasma or specific clotting factors for bleeding
Anticoagulant rodenticides	Abnormal bleeding (prolonged)	Monitor INR/prothrombin time Vitamin K_1 by slow IV injection if there is coagulopathy Fresh frozen plasma or specific clotting factors for bleeding

(DMSA = dimercaptosuccinic acid; INR = International Normalised Ratio; IV = intravenous)

dysphagia. In severe cases, paralysis and respiratory failure can develop. There is no specific antidote and treatment is supportive. Most cases resolve over a few days.

Ciguatera poisoning

Ciguatera toxin and related toxins are produced by dinoflagellate plankton that adhere to algae and seaweed. These accumulate in the tropical herbivorous fish that feed on these and in their larger predators like snapper and barracuda, especially in the Pacific and Caribbean. Human exposure occurs through eating contaminated fish, even if well cooked. Nausea, vomiting, diarrhoea and abdominal pain develop within a few hours, followed by paraesthesia, ataxia, blurred vision, ataxia and tremor. Convulsions and coma can occur, although death is uncommon. Fatigue and peripheral neuropathy can be long-term effects. There is no specific treatment. In the South Pacific and Caribbean, there are approximately 50 000 cases per year, with a case fatality of 0.1%.

Scombrotoxic fish poisoning

Under poor storage conditions, histidine in scombroid fish like tuna, mackerel, bonito, skipjack and the dark meat of canned sardines may be converted by bacteria to histamine and other chemicals. Within minutes of consumption, flushing, burning, sweating, urticaria, pruritus, headache, colic, nausea and vomiting, diarrhoea, bronchospasm and hypotension may occur. Management is with nebulised salbutamol, intravenous antihistamines and, occasionally, intravenous fluid replacement.

i 11.16 Agents used in chemical warfare

Examples	Clinical effects	Antidotes
Nerve agents		
Tabun Sarin Soman VX Novichok agents	Eyes: miosis (sometimes painful) Gastrointestinal disturbance: diarrhoea, vomiting, salivation Respiratory: bronchoconstriction, respiratory paralysis/failure Neurological: fasciculations, tremor, ataxia, convulsions, flaccid muscular paralysis See also p. 270 and Box 11.13	Atropine Oximes such as pralidoxime, obidoxime) (see Fig. 11.5)
Blistering agents		
Nitrogen/sulphur Mustard Lewisite	Eyes: watering, blepharospasm, corneal ulceration Skin: erythema, blistering Respiratory: cough, hoarseness, dyspnoea, pneumonitis	None
Choking agents		
Chlorine Phosgene	Eyes: watering, blepharospasm, corneal ulceration Respiratory: cough, hoarseness, dyspnoea, pneumonitis	None
Blood agents		
Cyanide	Cardiovascular: dizziness, shock Respiratory: dyspnoea, cyanosis CNS: anxiety, headache, delirium, convulsions, coma, fixed dilated pupils Other: vomiting, lactic acidosis	Dicobalt edetate Hydroxocobalamin Sodium nitrite Sodium thiosulphate

(CNS = central nervous system)

i 11.17 Clinical features of chronic arsenic poisoning

Gastrointestinal tract

- Anorexia, vomiting, weight loss, diarrhoea, increased salivation, metallic taste

Neurological

- Peripheral neuropathy (sensory and motor) with muscle wasting and fasciculation, ataxia

Skin

- Hyperpigmentation, palmar and plantar keratosis, alopecia, multiple epitheliomas, Mees lines (transverse white lines on fingernails)

Eyes

- Conjunctivitis, corneal necrosis and ulceration

Bone marrow

- Aplastic anaemia

Other

- Low-grade fever, vasospasm and gangrene, jaundice, hepatomegaly, splenomegaly

Increased risk of malignancy

- Lung, liver, bladder, kidney, larynx and lymphoid system

Tetrodotoxin poisoning

The highly toxic tetrodotoxin is found in the skin and viscera of puffer fish. Tetrodotoxin blocks voltage-gated sodium channels, inhibiting action potential generation and propagation. Clinical features include paraesthesia, salivation, gastrointestinal disturbances, sweating, headache, tachycardia, hypokalaemia, twitching or tremor, vertigo, dysphonia and dysphagia. In severe cases ataxia, paralysis and fixed dilated pupils occur, mimicking brain death. Without appropriate ventilator support, respiratory paralysis can be fatal. Otherwise there is no specific treatment and management is supportive.

Plant poisoning

A substantial number of plants and mushrooms (fungi) are potentially toxic if consumed, with patterns of poisoning depending on their geographical distribution. Some toxic examples and the clinical features of toxicity are shown in Box 11.18.

Mushroom poisoning

Mushroom poisoning is an important source of human toxicity, affecting especially those who harvest wild mushrooms for food. Recreational use of hallucinogenic mushrooms is also common. It is estimated that 50–100 deaths occur each year in Europe, many caused by *Amanita phalloides* (death cap), but there are numerous other toxic mushroom species worldwide, with their prevalence varying according to geographic region.

Gastrointestinal symptoms are common after ingestion, and many species cause these in isolation. Other specific organ systems can be affected by different species as follows, with the pattern and timing of clinical effects useful for diagnosis. These are summarised in Box 11.18, with the most important described in more detail below.

Primary hepatotoxicity is caused by amatoxin-containing mushrooms, especially *Amanita phalloides* (death cap) but also other species (see Box 11.18). Amatoxins are a major cause of hepatotoxicity requiring liver transplantation in some countries. Symptoms of ingestion start with general gastrointestinal disturbance after 6–12 hours, which often resolve within 36 hours, but hepatotoxicity develops around day 3, sometimes with renal failure, and can progress to death around day 7 in severe cases.

Nephrotoxicity is caused by aminohexadienoic acid (AHDA) and by orellanines and species containing these toxins are detailed in Box 11.18. Features of AHDA ingestion include prodromal general malaise lasting up to 12 hours followed by acute renal failure starting at 2–5 days and lasting for several months, but which usually resolves. Orellanine toxicity presents with renal injury 4–15 days after ingestion, which may be preceded by various prodromal symptoms. Chronic renal failure may ensue in severe cases.

Neurological syndromes caused by mushroom poisoning include hallucinations with *Psilocybe* species, which may be taken recreationally, muscarinic effects such as sweating, salivation and lacrimation from ingesting *Clitocybe* or *Inocybe* species containing muscarine and direct CNS toxicity from mushrooms containing ibotenic acid or muscimol such as *Amanita muscaria*. Initial drowsiness is followed by hallucinations, bizarre behaviour, agitation, and confusion progressing to coma and even death.

Some other syndromes associated with mushroom poisoning are summarised in Box 11.18. Mushrooms may also cause other adverse reactions not shown in Box 11.18, including dermatitis (*Shiitake* mushrooms), red burning extremities *(Clitocybe acromelagia)*, autoimmune haemolytic anaemia *(Paxillus involutus)* or encephalopathy *(Pleurocybella porrigens)*.

Management of mushroom poisoning includes identifying the species involved. Mycologists can be contacted via a poisons centre and may be able to identify the species if a specimen or photograph is available. Where and how the mushrooms were collected, stored and prepared, the interval since ingestion, the presenting symptoms and their latency should all be documented. Blood tests may identify renal or hepatic toxicity. Specialist laboratories may offer identification of amatoxins in urine.

There is limited evidence of benefits from antidotes for amatoxin poisoning, including silibinin and *N*-acetylcysteine, but for most types of mushroom poisoning treatment is symptomatic and supportive. This

11.18 Poisonous plants and fungi with clinical effects of poisoning

Species (common name)	Toxins	Important features of toxicity
Plants		
Abrus precatorius (jequirity bean) *Ricinus communis* (castor oil plant)	Abrin Ricin	Gastrointestinal effects, drowsiness, delirium, convulsions, multi-organ failure
Aconitum napellus (aconite, wolf's bane, monkshood) *Aconitum ferox* (Indian aconite, bikh)	Aconite	Gastrointestinal effects, paraesthesiae, convulsions, ventricular tachycardia
Atropa belladonna (deadly nightshade) *Datura stramonium* (Jimson weed, thorn apple) *Brugmansia* spp. (angel's trumpet)	Atropine, scopolamine, hyocyamine	Anticholinergic toxidrome (see Box 11.10)
Colchicum autumnale (autumn crocus)	Colchicine	Gastrointestinal effects, hypotension, cardiogenic shock
Conium maculatum (hemlock)	Toxic nicotinic alkaloids	Hypersalivation, gastrointestinal effects, followed by muscular paralysis
Digitalis purpurea (foxglove) *Nerium oleander* (pink oleander) *Cascabela thevetia* (yellow oleander)	Cardiac glycosides	Nausea, vomiting, bradycardia and heart block, supraventricular and ventricular tachyarrhythmias, visual disturbances, confusion (p. 262)
Laburnum anagyroides (laburnum)	Cytosine	Gastrointestinal effects; convulsions in severe cases
Taxus baccata (yew)	Taxane alkaloids	Hypotension, bradycardia, respiratory depression, convulsions, coma, arrhythmias
Mushrooms		
Amanita, *Galarina* and *Lepiota* species (especially *Amanita phalloides* (death cap)	Amatoxins	Gastrointestinal effects, progressing to liver failure
Cortinarius species	Orellanine	Gastrointestinal effects, fever, progressing to renal failure
Amanita smithiana, *Amanita pseudoporphyria*	Aminohexadienoic acid (AHDA)	Malaise followed by early renal failure
Psilocybe semilanceata (magic mushrooms)	Psilocybin, psilocin	Hallucinations
Clitocybe or *Inocybe* species	Muscarine	Muscarinic effects such as sweating, salivation and lacrimation
Amanita muscaria	Ibotenic acid/muscimol	Drowsiness, hallucinations, bizarre behaviour, confusion, coma
Morchella species (morel mushrooms)	Unknown	Neurological and GI effects ('morel neurological syndrome')
Russula species	Cycloprop-2-ene carboxylic acid	Rhabdomyolysis
Tricholoma species	Toxin unknown	Rhabdomyolysis
Gyromitra species	Gyromitrins	GI and neurological effects
Coprinus species	Coprines	Rash and facial flushing if ingested with alcohol
Podostroma species	Trichothecenes	Skin desquamation and multi-organ failure

(GI = gastrointestinal)

might include oral activated charcoal if ingestion was recent, fluid and electrolyte replacement, antiemetics for vomiting and atropine for muscarinic features. Haemodialysis may be needed for severe renal impairment and referral to a liver unit may be needed in the event of severe hepatotoxicity.

Multiple Choice Questions

11.1 Multiple doses of activated charcoal are useful in the treatment of patients with poisoning involving which one of the following:

A. Ferrous sulphate
B. Yellow oleander *(Thevetia peruviana)*
C. Pesticides
D. Lithium carbonate
E. Dapsone

Answer: E.

Ferrous sulphate and lithium are not adsorbed by activated charcoal. A clinical trial of multiple-dose activated charcoal for patients with yellow oleander or pesticide poisoning showed no benefit. The clearance of dapsone is enhanced by multiple-dose activated charcoal. This is also true for carbamazepine, phenobarbital, quinine and theophylline (Box 11.7).

11.2 A 2-year-old child is assessed because the parents are concerned he has swallowed some aspirin tablets. Which one of the following clinical features is NOT consistent with a diagnosis of salicylate poisoning in a child?

A. Respiratory alkalosis
B. Metabolic acidosis
C. Hypoprothrombinaemia
D. Hypothermia
E. Hypotension

Answer: D.

Respiratory alkalosis is a common feature of salicylate poisoning, especially in children. Metabolic acidosis can also occur and is associated with a worse prognosis. Hypoprothrombinaemia is typical of salicylate poisoning. Shock, including hypotension, and hyperpyrexia may also be seen in severe poisoning. Hypothermia is not a feature of salicylate toxicity.

11.3 An adult male is found unconscious after a suspected drug overdose. ECG findings are as follows: heart rate 78/min, PR interval 162 ms, QRS interval 162 ms and QT interval 363 ms. The corrected QT interval (QTc, using Bazett's formula) is 414 ms. Which ONE of the following statements is correct?

A. Severe cardiac potassium channel blockade is present
B. Conduction velocity is increased in the bundles of His
C. First-degree heart block is present
D. Overdose with flecainide could account for the ECG findings
E. Magnesium sulphate should be administered urgently

Answer: D.

The only abnormality identified is prolongation of the QRS interval, which is a feature caused by severe sodium channel blockade. This results in delayed phase 0 depolarisation and reduced conduction velocity in the bundles of His and in ventricular myocytes. Drugs that cause sodium channel blockade in overdose include class 1a (e.g. quinidine) and 1c (e.g. flecainide) anti-dysrhythmic drugs, tricyclic antidepressants, some β-blockers (e.g. propranolol), cocaine and diphenhydramine (Box 11.8). Cardiac sodium channel blockade is associated with an increased risk of monomorphic ventricular tachycardia and ventricular fibrillation. Treatment is with intravenous sodium bicarbonate. Potassium blockade is indicated by QTc prolongation and may culminate in torsades de pointes ventricular tachycardia, which is treated with magnesium sulphate; in this case, however, the QTc interval is normal, as is the PR interval, so first-degree heart block is also not present.

11.4 A homeless man aged 23 is found unconscious in the street after smoking an unidentified illicit drug. No further history is available. On examination his Glasgow Coma Scale (GCS) is 9, pupils are mid-sized and equal, heart rate is 110/min, blood pressure is 116/84 mmHg, and temperature is 36.8°C. Arterial blood gases show a mild respiratory acidosis. General physical examination is otherwise normal. No needle marks are found. Which of the following is the most likely substance causing this presentation?

A. Heroin
B. AMB-FUBINACA
C. Alprazolam
D. Ecstasy
E. Gamma hydroxybutyrate

Answer: B.

Ecstasy does not cause a reduction in level of consciousness, but this can be caused by any of the other four drugs listed. Alprazolam (a benzodiazepine) and gamma hydroxybutyrate (GHB) could both cause this clinical presentation but are not used by smoking. Heroin can be smoked ('chasing the dragon') but would usually cause small pupils. AMB-FUBINACA is a synthetic cannabinoid receptor agonist. These compounds, commonly referred to as 'spice', are usually smoked; they can cause reduced level of consciousness and respiratory acidosis, without pupillary changes.

11.5 Which of the following antidotes does NOT act by binding to the toxin it is used to treat?

A. Fomepizole
B. Digoxin-specific antibody fragments
C. Idarucizumab
D. Hydroxocobalamin
E. Desferrioxamine

Answer: A.

Fomepizole is an alcohol dehydrogenase inhibitor. It prevents the metabolism of ethylene glycol and methanol to the toxic metabolites responsible for the clinical features of poisoning. Digoxin-specific antibody fragments bind to digoxin (and other cardiac glycosides) and idarucizumab is a monoclonal antibody that binds to dabigatran etexilate. Hydroxocobalamin complexes with cyanide to form cyanocobalamin and desferrioxamine complexes with iron to form ferrioxamine. In all four of these examples, drug bound to the antidote no longer causes toxicity.

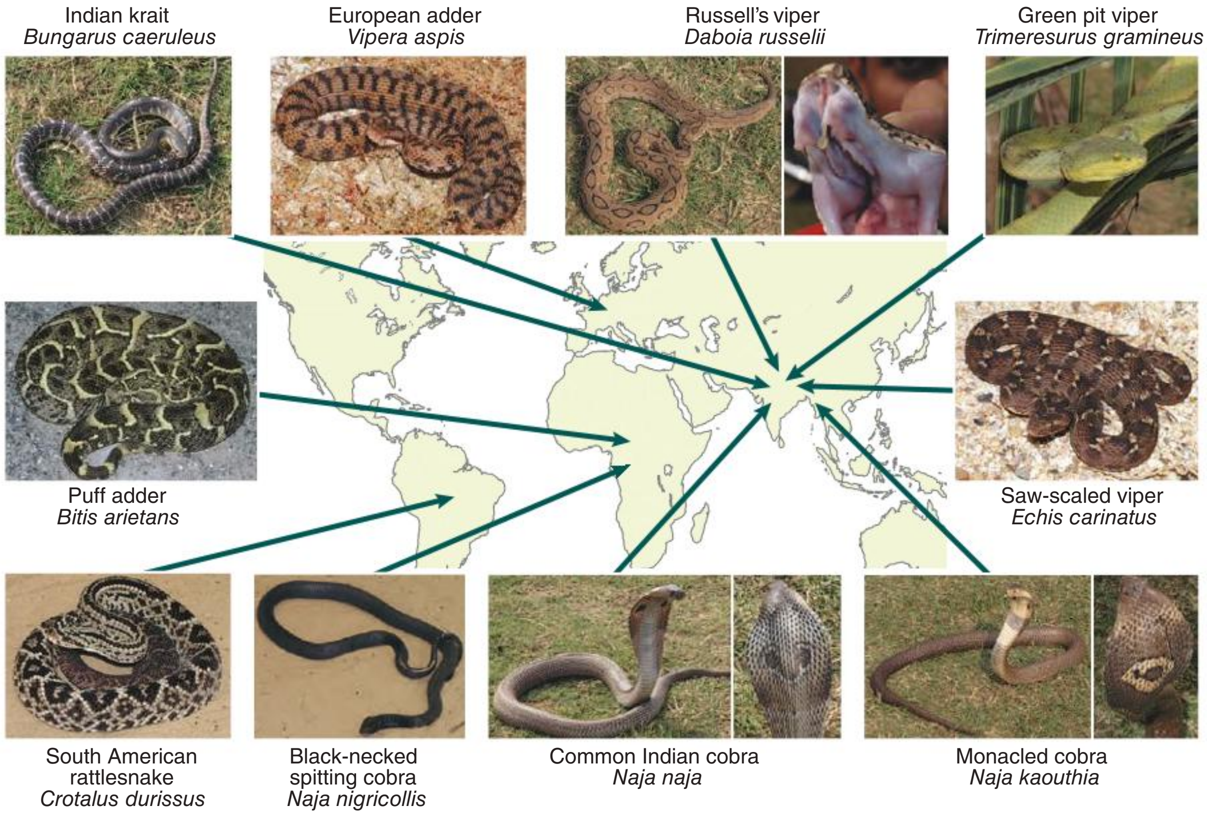
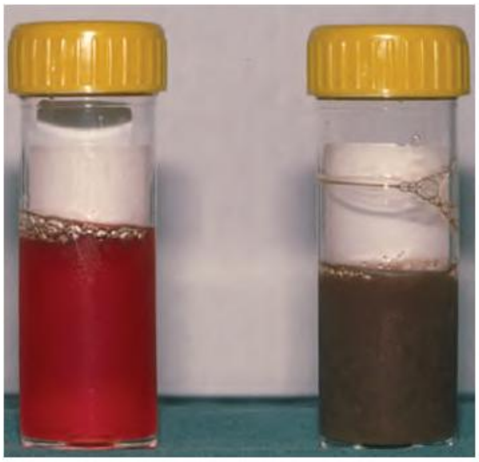
Geographical distribution of venomous snakes



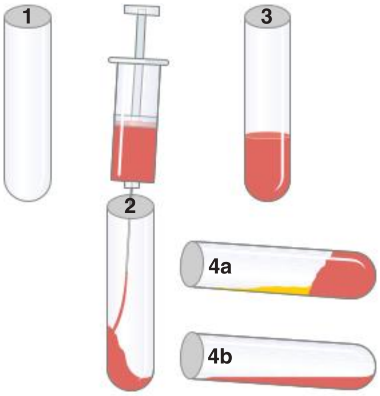
Indian krait
Bungarus caeruleus
European adder
Vipera aspis
Russell's viper
Daboia russelii
Green pit viper
Trimeresurus gramineus
Puff adder
Bitis arietans
Saw-scaled viper
Echis carinatus
South American rattlesnake
Crotalus durissus
Black-necked spitting cobra
Naja nigricollis
Common Indian cobra
Naja naja
Monacled cobra
Naja kaouthia

The geographical location of a snakebite determines the likely animal(s) involved and the nature and risks of the envenomation. Map lines delineate study areas and do not necessarily depict accepted national boundaries. *Copyright © Julian White.*

Bedside tests in the envenomed patient



Examination of urine. Haematuria may indicate a coagulopathy. Dark urine is suggestive of myoglobinuria, which is a sign of extensive rhabdomyolysis. *Copyright © Julian White.*



1 *Obtain a clean **glass** container (test tube or bottle) that is either new, or has only been washed with water (not detergent/soap)*

2 *Place 2–3 mL venous blood in the **glass** container*

3 *Allow to stand undisturbed for 20 mins*

4 *Gently invert/tip the glass container, checking for presence of a blood clot*

4a *Clot present = negative test (no coagulopathy present)*

4b *Clot absent = positive test (coagulopathy present)*

Twenty-minute whole-blood clotting test (20WBCT). The presence of coagulopathy is a key indicator of major envenoming for some species. While full laboratory coagulation studies may be the ideal, the 20WBCT has emerged as a simple standardised bedside test of coagulopathy, applicable even in areas with limited health facilities. *Copyright © Julian White.*

Overview of envenomation

Envenomation occurs when a venomous animal injects sufficient venom by a bite or a sting into a prey item or perceived predator to cause deleterious local and/or systemic effects. This is defined as a venom-induced disease (VID). Venomous animals generally use their venom to acquire and, in some cases, pre-digest prey, with defensive use a secondary function for many species. Where defensive use of venom is an important evolutionary driver, immediate and severe local pain is a common feature, though the toxin mechanisms causing pain are diverse. Accidental encounters between venomous animals and humans are frequent, particularly in the rural tropics, where millions of cases of venomous bites and stings occur annually. Globally, an increasing number of exotic venomous animals are kept privately, so cases of envenoming may present to hospitals where doctors have insufficient knowledge to manage potentially complex presentations. Doctors everywhere should thus be aware of the basic principles of management of envenomation and how to seek expert support. It is important for doctors to know what types of venomous animal are likely to occur in their geographical area (hospital hinterland; see p. 279) and the types of envenoming they may cause.

Venom

Venom is a complex mixture of diverse components, mostly with multiple separate toxins that can cause adverse effects in humans, with each potentially capable of multiple effects (Box 12.1). Venom is produced at considerable metabolic cost, so is used sparingly; only some bites/stings by venomous animals result in significant envenoming, the remainder are ‘dry bites’. The concept of dry bites is important in understanding approaches to first aid and medical management. It is important to remember that venom also has some positive implications for humanity, particularly as a source of new treatments. An increasing array of pharmaceuticals have been developed from venom toxins to treat varied diseases including hypertension, diabetes, chronic pain, obesity and, on the horizon awaiting clinical trial confirmation, stroke, myocardial infarction and other conditions.

Venomous animals

There are many animal groups that contain venomous species (Box 12.2). The epidemiological estimates of envenomation episodes reflect the importance of snakes and scorpions as causes of severe or lethal envenomation, but also the fragmentary nature of the data. For snakebites, recent studies have proposed widely varying estimates, but even the higher estimates may be too low. In India, studies indicate there are at least 58,000 snakebite-related deaths annually, far above both government figures and previous estimates. In many areas of the rural tropics, health resources are limited and few envenoming cases are either seen or recorded within the official hospital system, compared to the actual community burden of

i 12.2 Venomous animals and human envenoming

Phyla	Principal venomous animal groups	Estimated number of human cases/ year	Estimated number of human deaths/ year
Chordata	Snakes	> 2.5 million	> 100 000
	Spiny fish	> 100 000	Close to zero
	Stingrays	> 100 000	< 10
Arthropoda	Scorpions	> 1 million	< 5000
	Spiders	> 100 000	< 100
	Paralysis ticks	> 1000	< 10
	Insects	> 1 million	> 1000*
Mollusca	Cone snails	< 1000	< 10
	Blue-ringed octopus	< 100	< 10
Coelenterata	Jellyfish	> 1 million	< 10

*Social insect stings cause death by anaphylaxis rather than primary venom toxicity, except for massive multiple sting attacks.

i 12.1 Key venom effects*

Venom component	Clinical effects	Type of venomous animal
Neurotoxin		
Paralytic	Flaccid paralysis (may develop in a *descending* pattern, commencing first in cranial nerves, or in an *ascending* pattern, with early ataxia)	Some snakes (descending) Paralysis ticks (ascending) Cone snails (descending) Blue-ringed octopus (descending)
Excitatory	Neuroexcitation: autonomic storm, cardiotoxicity, pulmonary oedema	Some scorpions, spiders, jellyfish (irukandji)
Myotoxins	Systemic or local myolysis	Some snakes
Cardiotoxins	Direct or indirect cardiotoxicity; cardiac collapse, shock	Some snakes, scorpions, spiders and jellyfish (box jellyfish)
Haemostasis system toxins	Variation from rapid coagulopathy and bleeding to thrombosis, deep venous thrombosis and pulmonary emboli	Many snakes and a few scorpions *(Hemiscorpius)* Brazilian caterpillars *(Lonomia)*
Haemorrhagic toxins	Local vessel damage, fluid extravasation, blistering, ecchymosis, shock	Mainly some snakes
Nephrotoxins (direct or indirect)	Renal damage	Some snakes, massed bee and wasp stings
Necrotoxins	Local tissue injury/necrosis, shock	Some snakes, a few scorpions *(Hemiscorpius)*, spiders (recluse spiders), jellyfish and stingrays
Allergic toxins	Induction of acute allergic response (direct and indirect)	Almost all venoms but particularly those of social insects (i.e. bees, wasps, ants)

*All venom components have lethal potential.
Copyright © Julian White.

disease. While fatal cases may gain most attention, long-term disability from envenomation affects significantly more people and has a major social and economic cost. The World Health Organization (WHO) recognised snakebite as a 'neglected tropical disease' in 2017 and in 2019 released a plan to reduce the global snakebite burden by 50% by 2030. This may improve access to funding. Snakebite occurs frequently in low resource areas of the rural tropics and so is an important poverty trap; it is also a predominantly occupational disease, with farmers and other agricultural workers at particularly high risk. Although snakebite is undoubtedly the most impactful form of envenoming globally, there are some areas where scorpion stings have a higher impact on health systems than snakebite.

Other venomous animals may commonly envenom humans, but cause mostly non-lethal effects. Many venomous stings, particularly by social insects such as bees, wasps and some ants, though causing local pain, are more a nuisance than a medical threat, unless the victim has severe allergy resulting in anaphylaxis, or if there is a massed attack with many stings, causing major, even lethal envenomation (e.g. Africanised bees). A few animals only rarely envenom humans, but have a high potential for severe or lethal envenoming. These include box jellyfish, cone snails, blue-ringed octopus, paralysis ticks and Australian funnel web spiders. Within any given group, particularly snakes, there may be a wide range of clinical presentations. Some are described here, but for a more detailed discussion of the types of venomous animal, their venoms and their effects on humans, see toxinology.com.

Clinical effects

With the exception of dry bites, where no significant toxin effects occur, venomous bites/stings can result in three broad classes of effect.

Local effects

These vary from trivial to severe (Box 12.3). There may be minimal or no local effects with some snakebites (not even pain), yet lethal systemic envenoming may still be present (e.g. kraits in Asia). For other species, local effects predominate over systemic, and for some (e.g. certain snakes), both are important (p. 278). Some species commonly cause local necrosis, notably some snakes, brown recluse spiders, an Iranian scorpion *(Hemiscorpius lepturus)* and some stingrays. Globally, amputations secondary to snakebite are an important cause of long-term morbidity and social disadvantage, with an estimated 400000 cases/year (WHO).

12.3 Local and systemic effects of envenomation

Local effects

- Pain
- Sweating
- Erythema
- Major direct tissue trauma (e.g. stingray injuries)
- Blistering
- Necrosis
- Swelling
- Bleeding and bruising

Non-specific systemic effects

- Headache
- Nausea
- Vomiting and diarrhoea
- Abdominal pain
- Tachycardia or bradycardia
- Hypertension or hypotension
- Pulmonary oedema
- Dizziness
- Collapse
- Convulsions
- Shock
- Cardiac arrest

Specific systemic effects

- Neurotoxic flaccid paralysis (descending or ascending)
- Excitatory neurotoxicity (catecholamine storm-like and similar)
- Rhabdomyolysis (systemic or local)
- Coagulopathy (procoagulants, anticoagulants, fibrinolytics and platelet-active toxins)
- Cardiotoxicity (decreased/abnormal cardiac function or arrhythmia or arrest)
- Acute kidney injury (polyuria or oliguria or anuria or isolated elevated creatinine/urea)

Copyright © Julian White.

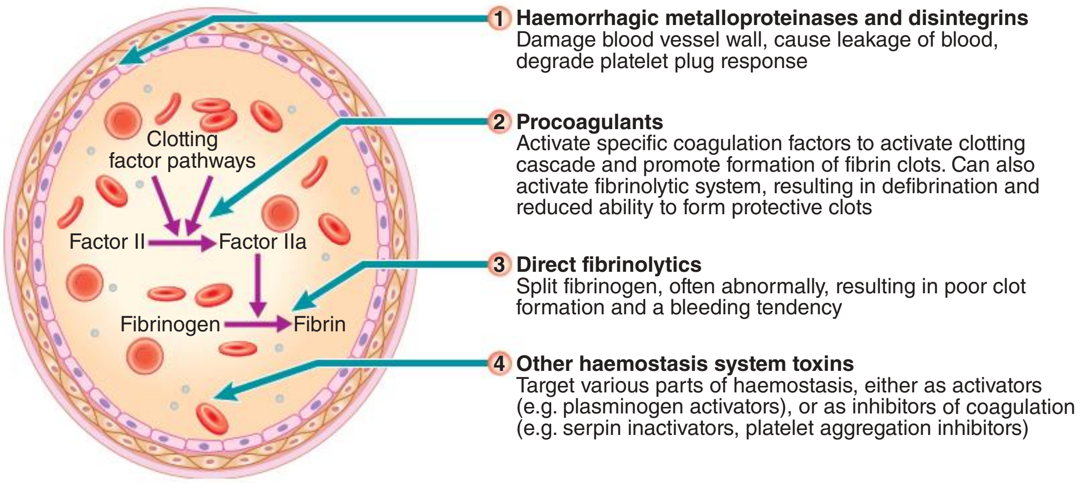
General systemic effects

By definition, these are non-specific (see Box 12.3). Shock is an important complication of major local envenoming by some snake species and if inadequately treated can prove lethal, especially in children.

Specific systemic effects

These are important in both diagnosis and treatment.

- *Neurotoxic flaccid paralysis* can develop very rapidly, progressing from mild weakness to full respiratory paralysis in less than 30 minutes (blue-ringed octopus bite, cone snail sting), or may develop far more slowly, over hours (e.g. kraits, some cobras) to days (paralysis tick). For neurotoxic snakes which cause a descending flaccid paralysis, the cranial nerves are usually involved first, with bilateral ptosis a common initial sign, often progressing to partial and later complete ophthalmoplegia, fixed dilated pupils, drooling and loss of upper airway protection (p. 278). Untreated, paralysis may then extend to the limbs, with weakness and loss of deep tendon reflexes, the neck ('broken neck' sign), then finally respiratory paralysis affecting the diaphragm.
- *Excitatory neurotoxins* cause an 'autonomic storm', often with profuse sweating (p. 278), variable cardiac effects and cardiac failure, sometimes with pulmonary oedema (notably, Australian funnel web spider bite, some scorpions such as Indian red scorpion). This type of envenomation can be rapidly fatal (many scorpions, funnel web spiders), or may cause distressing symptoms with a lesser risk of death (widow spiders, banana spiders).
- *Myotoxicity* can be localised in the bitten limb, or systemic, affecting mostly skeletal muscles. It can initially be silent, then present with generalised muscle pain, tenderness, myoglobinuria (p. 279) and substantial rises in serum creatine kinase (CK). Secondary renal failure can precipitate potentially lethal hyperkalaemic cardiotoxicity.
- *Cardiotoxicity* is often secondary, but symptoms and signs are non-specific in most cases. For some scorpions, envenomation can cause direct cardiac effects, including decreased cardiac output, arrhythmias and pulmonary oedema.
- *Haemostasis system toxins* cause a variety of effects, depending on the type of toxin (Fig. 12.1). Coagulopathy may present as bruising and bleeding from the bite site (p. 278), gums and intravenous sites. Surgical interventions are high risk in such cases. A few venoms cause thrombosis, usually presenting as deep venous thrombosis (DVT), pulmonary embolus or stroke (particularly Caribbean/Martinique vipers).
- *Haemorrhagic toxins* (associated with some snakebites) cause vascular damage, especially in the bitten limb, with extravasation of fluid and sometimes hypotensive shock. They may also cause internal bleeding such as retroperitoneal haemorrhage. The role of these toxins in causing late-developing capillary leak syndrome (p. 278) is uncertain (seen notably with Russell's viper).
- *Renal damage* in envenoming is mostly secondary, although some species (such as Russell's vipers) can cause primary renal damage. The presentation is similar in both scenarios, with changes in urine output (polyuria, oliguria or anuria), proteinuria, or rises in creatinine and urea. In cases with intravascular haemolysis, secondary renal damage is likely. The clinical effects of specific animals in different regions of the world are shown in Boxes 12.4–12.6.



① **Haemorrhagic metalloproteinases and disintegrins**
Damage blood vessel wall, cause leakage of blood, degrade platelet plug response

② **Procoagulants**
Activate specific coagulation factors to activate clotting cascade and promote formation of fibrin clots. Can also activate fibrinolytic system, resulting in defibrination and reduced ability to form protective clots

③ **Direct fibrinolytics**
Split fibrinogen, often abnormally, resulting in poor clot formation and a bleeding tendency

④ **Other haemostasis system toxins**
Target various parts of haemostasis, either as activators (e.g. plasminogen activators), or as inhibitors of coagulation (e.g. serpin inactivators, platelet aggregation inhibitors)

Fig. 12.1 **Sites of action of venoms on the haemostasis system.** *Copyright © Julian White.*

12.4 Selected important venomous animals in Asia

Scientific name[1]	Common name	Clinical effects	Antivenom/antidote/treatment
South Asia			
Bungarus spp. (E)	Kraits	Flaccid paralysis[2,3], myolysis[4], hyponatraemia[5]	Indian PV or specific
Naja spp. (E)	Cobras	Flaccid paralysis[3], local necrosis/blistering, shock	Indian PV or specific
Ophiophagus hannah (E)	King cobra	Flaccid paralysis[3], local necrosis, shock	Indian PV or specific
Echis spp. (Vv)	Saw-scaled vipers	Procoagulant coagulopathy, local necrosis/blistering, renal failure	Indian PV or specific
Daboia russelii (Vv)	Russell's viper	Procoagulant coagulopathy, local necrosis/blistering, myolysis, renal failure, shock, flaccid paralysis[2]	Indian PV or specific
Hypnale spp. (Vc)	Hump-nosed vipers	Procoagulant coagulopathy, shock, renal failure	No available AV; Indian PV unlikely to be effective
Trimeresurus[6] spp. (Vc)	Green pit vipers	Procoagulant coagulopathy, local necrosis, shock	Indian PV unlikely to be effective; consider specific AV from Thailand
Hottentotta spp. (Sc)	Indian scorpions	Neuroexcitation, cardiotoxicity	Indian specific AV Prazosin
East Asia			
Bungarus spp. (E)	Kraits	Flaccid paralysis[2,3]	Specific AV from country
Naja spp. (E)	Cobras (some spitters)	Flaccid paralysis[3], local necrosis/blistering, shock	Specific AV from country
Ophiophagus hannah (E)	King cobra	Flaccid paralysis[3], local necrosis, shock	King cobra AV
Calloselasma rhodostoma (Vc)	Malayan pit viper	Procoagulant coagulopathy, local necrosis/blistering, renal failure, shock	Specific AV from country
Daboia siamensis (Vv)	Russell's viper	Procoagulant coagulopathy, local necrosis/blistering, renal failure, capillary leak syndrome, shock, anterior pituitary haemorrhage and failure	Specific AV from country
Gloydius spp. (Vc)	Mamushis, pit vipers	Procoagulant coagulopathy, local necrosis/blistering, shock, renal failure, flaccid paralysis[2]	Specific AV from country
Trimeresurus[6] spp. (Vc)	Green pit vipers, habus	Procoagulant coagulopathy, local necrosis/blistering, shock	Specific AV from country
Hydrophis schistosus + other species	Sea snakes (all species globally)	Flaccid paralysis and/or myolysis	Seqirus sea snake AV

General approach to the envenomed patient

First aid

First aid can be crucial in determining the outcome for envenomed patients, yet throughout much of the world inappropriate and dangerous first aid is often administered.

A significant proportion of venom is transported from the bite/sting site via the lymphatic system, particularly for venoms with larger molecular weight toxins, such as many snake venoms. It is recommended that for most forms of envenoming, the patient should be kept still, the bitten limb immobilised with a splint and vital systems supported, where required. A patent upper airway should be ensured and respiratory support provided, if required. For some animals, notably snakes in certain regions, the use of a local pressure pad bandage over the bite site (Myanmar) or a pressure bandage and limb immobilisation (PBI) (Australia, New Guinea) is recommended.

Ineffective or dangerous first aid, such as suction devices, 'cut and suck', local chemicals, snake stones (stones of some sort placed over the snakebite), electric shock devices and tourniquets, should not be used. Tourniquets, in particular, have the potential to cause catastrophic ischaemic distal limb injuries in snakebite when applied too narrowly or too tightly, or left on too long. Caution is required when removing tourniquets or other constricting first aid, as there may be a sudden rush of venom into the circulation causing rapid effects and cardiorespiratory collapse.

12.6 Selected important venomous animals in Africa and Europe

Scientific name[1]	Common name	Clinical effects	Antivenom/antidote/treatment
Africa			
Naja spp. (E)	Cobras		
	Non-spitters	Flaccid paralysis[3] ± local necrosis/blistering	South African PV or other appropriate African-specific AV
	Spitters	Local necrosis/blistering (flaccid paralysis[3] uncommon)	South African PV or other appropriate African-specific AV
Dendroaspis spp. (E)	Mambas	Mamba neurotoxic flaccid paralysis and muscle fasciculation, shock, necrosis (uncommon)	South African PV or other appropriate African-specific AV
Hemachatus haemachatus (E)	Rinkhals	Flaccid paralysis[3], local necrosis, shock	South African PV
Atheris spp. (Vv)	Bush vipers	Procoagulant coagulopathy, shock, pain and swelling	No available AV (can try South African AV)
Bitis spp. (Vv)	Puff adders etc.	Procoagulant coagulopathy, shock, cardiotoxicity, local necrosis/blistering	South African PV or other appropriate African-specific AV
Causus spp. (Vv)	Night adders	Pain and swelling	No available AV
Echis spp. (Vv)	Carpet vipers	Procoagulant coagulopathy, shock, renal failure, local necrosis/blistering	Specific anti-*Echis* AV for species/geographical region or other appropriate African-specific AV
Cerastes spp. (Vv)	Horned desert vipers	Procoagulant coagulopathy, local necrosis, shock	Specific or polyspecific AV covering *Cerastes* from country of origin
Dispholidus typus (C)	Boomslang	Procoagulant coagulopathy, shock	Boomslang AV
Androctonus spp.	North African scorpions	Neuroexcitation	Specific scorpion AV (Algeria, Tunisia, Sanofi Pasteur Scorpifav)
Leiurus quinquestriatus	Yellow scorpion	Neuroexcitation, shock	Specific scorpion AV (Algeria, Tunisia, Sanofi Pasteur Scorpifav)
Europe			
Vipera spp. (Vv)	Vipers and adders	Shock, local necrosis/blistering, procoagulant coagulopathy (flaccid paralysis[2] rare)	ViperaTab AV or Zagreb AV or Sanofi Pasteur Viperfav AV

If the biting/stinging organism has been killed, if possible, bring it with the patient, but be careful to avoid accidental envenoming by touching fangs, stings etc. Do not try and kill the animal, however, as this may cause further bites/stings. Photographs of the animal, perhaps taken using a mobile smart phone, may be helpful instead of bringing the dead animal. In some countries, such as India, doctors are encouraged to try and identify the culprit snake and distinguish between dangerous species and harmless species with a similar appearance (e.g. krait versus wolf snake).

Transporting patients

Where possible, transport should be brought to the patient. It is vital to obtain medical assessment and intervention at the earliest opportunity, so any delay in transporting the patient to a medical facility should be avoided. Severely envenomed patients may develop life-threatening problems during transport, such as shock or respiratory failure, so ideally the transport method should allow for management of these problems en route.

In resource-poor environments, simple solutions for rapid transport have been successfully employed, such as motorbikes or similar with the patient supported between the driver in front and another person behind the patient. However, this method cannot cope with a patient developing airway compromise or respiratory failure, such as from developing neurotoxicity.

Assessment and management in hospital

On arrival at a health station or hospital, there are two immediate priorities:

- identifying and treating any life-threatening problems (e.g. circulatory shock, respiratory failure; see Ch. 16)
- determining whether envenomation has occurred and if that requires urgent treatment.

Assessment and management of life-threatening problems

Patients who are seriously envenomed must be identified early so that appropriate management is not delayed. Critically ill patients must be resuscitated (Ch. 10) and this takes precedence over administration of any antivenom. Clinicians should look for signs of:

- shock/hypotension
- airway and/or respiratory compromise (likely to be secondary to flaccid paralysis)
- major bleeding, including internal bleeding (especially intracranial, intra- or retro-peritoneal)
- impending limb compromise from inappropriate first aid (e.g. a tourniquet).

In a patient with severe neurotoxic flaccid paralysis, who is still able to maintain sufficient respiratory function for survival, clinical assessment may erroneously suggest irretrievable brain injury (fixed dilated pupils, absent reflexes, no withdrawal response to painful stimuli, no movement of limbs, fixed forward gaze with gross ptosis; p. 278) when, in fact, the patient is conscious and terrified.

Assessment for evidence of envenoming

As in other areas of medicine, comprehensive assessment of a patient bitten/stung by a venomous animal requires a good history, a careful targeted examination and, where appropriate, 'laboratory' testing (though the latter may just consist of simple bedside tests performed by the doctor; p. 279). Animals that are unlikely to cause serious envenomation in humans should be identified so that inappropriate admission and intervention are avoided. Occasionally, patients may be unaware they have been bitten/stung and thus provide a misleading history. In regions of the world where keeping or handling venomous animals is illegal, patients may be reticent in giving a truthful history. Multiple bites or stings are more likely to cause major envenoming.

The following key questions should be asked:

- When was the patient exposed to the venomous bite/sting?
- Was the organism causing it seen and what did it look like (size, colour)?
- What were the circumstances (on land, in water etc.)?
- Was there more than one bite/sting? (multiple bites/stings are more likely to be severe)
- What first aid was used, how quickly was it applied and how long has it been in place?
- What symptoms has the patient had (local and systemic)?
- Are there symptoms suggesting systemic envenomation (paralysis, rhabdomyolysis, coagulopathy etc.)?
- Is there any significant past medical history and medication use?
- Is there a past exposure to antivenom/venom and allergies?

If patients state that they have been bitten by a particular species, ensure this information is accurate. Private keepers of venomous animals may not have accurate knowledge of what they are keeping and misidentification of a snake, scorpion or spider can have dire consequences if the wrong antivenom is used.

An outline of some principal findings on examination of the envenomed patient is shown on p. 278. The patient may have a cluster of clinical features suggestive of a particular type of envenoming (see Box 12.1). There are documented envenoming syndromes for some groups of snakes that, in some regions, can guide diagnosis and treatment (Box 12.7). Detail of this syndromic approach is available in free WHO guides on snakebite in Asia and in Africa.

Even with dangerously venomous animals, some bites/stings will be dry bites and will not require antivenom. The time to onset of first symptoms and signs of envenomation is variable, depending on both animal and patient factors. It may range from a matter of minutes post-bite/sting to 24 hours later in some cases. Therefore, if the initial assessment is normal, it must be repeated multiple times during the first 24 hours. Some types of envenomation will not cause symptoms or signs at all, or may appear very late, long after the optimum time for treatment has passed. Evidence of envenomation may become apparent only through laboratory testing.

Laboratory investigations

Specific tests for venom are currently commercially available only for Australian snakebites, but may be developed for snakebites in other regions. They are not available for other types of envenomation, where venom concentrations are low. For snakebite, a screen for envenomation includes full blood count, coagulation screen, urea and electrolytes, creatinine, CK and electrocardiogram (ECG). Lung function tests, peripheral oximetry or arterial blood gases may be indicated in cases with potential or established respiratory failure, notably in bites by animals causing neurotoxic flaccid paralysis. In areas without access to routine laboratory tests, the 20-minute whole-blood clotting test (20WBCT) is potentially useful (p. 279).

12.7 Snakebite envenomation syndromes for South-east Asia

Clinical definition/characteristics of syndrome	Likely snakes causing the syndrome
Syndrome 1	
Local envenoming (swelling etc.) + bleeding, clotting disturbances	Viper bite (many possible species)
Syndrome 2	
Local envenoming (swelling etc.) + bleeding, clotting disturbances + shock or AKI	Russell's viper
2a – ± conjunctival oedema and acute pituitary insufficiency	2a – Russell's viper in Myanmar and South India
2b – ± bilateral ptosis, external ophthalmoplegia, flaccid paralysis, dark urine (myoglobinuria)	2b – Russell's viper in Sri Lanka and South India
Syndrome 3	
Local envenoming (swelling etc.) + flaccid paralysis (bilateral ptosis, ophthalmoplegia etc.)	Cobra or king cobra
Syndrome 4	
Minimal or no local envenoming + flaccid paralysis (bilateral ptosis, ophthalmoplegia, etc.)	
4a – If bitten on land (patient sleeping on ground at night) ± abdominal pain	4a – krait
4b – If bitten in water (sea, some lakes) ± dark urine (myoglobinuria)	4b – sea snake
4c – If bitten on land in New Guinea ± coagulopathy	4c – Australasian Elapid (taipan, small-eyed snake, etc.)
Syndrome 5	
Variable local effects + flaccid paralysis + dark urine (myoglobinuria) and AKI	
5a – If bitten on land (sleeping on ground)	5a – krait
5b – If bitten in water (sea, some lakes) + no coagulopathy	5b – sea snake
5c – If bitten on land + coagulopathy/bleeding	5c – Russell's viper (Sri Lanka and South India)

(AKI = acute kidney injury)
After World Health Organization, Regional Office for South-East Asia. Guidelines for the management of snake-bites. 2nd ed; 2016.

Treatment

Once a diagnosis of likely envenoming has been made, the next and urgent decision is whether to give antivenom. However, antivenom may not be the only crucial treatment required. For a snakebite by a potentially lethal species such as Russell's viper, the patient may have local effects with oedema, blistering, necrosis and resultant fluid shifts causing shock, and at the same time have systemic effects such as intractable vomiting, coagulopathy, paralysis and secondary renal failure. Specific treatment with antivenom will be required to reverse the coagulopathy and may prevent worsening of the paralysis and reduce the vomiting, but will not greatly affect the local tissue damage or the renal failure or shock. The latter will require intravenous fluid therapy, possibly respiratory support, renal dialysis and local wound care, perhaps including antibiotics. In Myanmar at least, each hour of delay in giving antivenom after Russell's viper bite markedly increases the likelihood of developing renal failure.

Each venomous animal will cause a particular pattern of envenomation, requiring a tailored response (envenoming syndrome). Listing all of these is beyond the scope of this chapter (see 'Further information').

Antivenom

Antivenom, sometimes inappropriately labelled as 'anti-snake venom' (ASV), is the most important tool in treating envenomation. Currently it is made by hyperimmunising an animal, usually horses, to produce antibodies against venom. Once refined, these bind to venom toxins and render them inactive or allow their rapid clearance. Research is progressing on an alternative production approach using biotechnology and engineered combination venom antigens that offers hope for improved future antivenoms, but this remains to be proven practical and effective. Antivenom is available only for certain venomous animals and cannot reverse all types of envenomation. With a few exceptions, it should be given intravenously, with adrenaline (epinephrine) ready in

12.8 Indications for antivenom

General indications

- Shock/cardiac collapse
- Respiratory compromise
- Rapidly increasing swelling of the bitten limb
- Active bleeding
- Intractable non-specific symptoms, including recurrent vomiting

Specific indications

- Developing paralytic features (ptosis etc.)
- Developing rhabdomyolysis
- Developing coagulopathy
- Developing renal failure
- Developing neuroexcitatory envenoming

Copyright © Julian White.

case of anaphylaxis. It should be used only when clearly indicated and indications will vary between venomous animals (Box 12.8). It is critical that the correct antivenom is used at the appropriate dose. Doses vary widely between antivenoms. In some situations (such as South Asia), pre-treatment with subcutaneous adrenaline may reduce the chance of anaphylaxis to antivenom.

Antivenom may be given either as a continuous intravenous (IV) infusion diluted in normal saline or a similar IV fluid, or as a slow IV push injection, undiluted, but in both methods it is essential that the patient be continuously observed during the administration of antivenom and for at least an hour after, to ensure that any adverse reaction, particularly anaphylaxis, is promptly detected and appropriately treated. If anaphylaxis develops during antivenom administration, immediately stop the antivenom and treat the anaphylaxis, but once controlled, cautiously restart the antivenom at a slow rate. In selected patients it may be necessary to run a diluted adrenaline infusion IV in tandem with a restarted diluted antivenom infusion to control the anaphylaxis, with the expectation that the rate of IV adrenaline may be progressively reduced to zero. It is critically important in such cases to ensure the dose of IV adrenaline is correct, as this treatment is potentially lethal if a too high dose is given or the infusion rate is too rapid.

Antivenom can sometimes reverse post-synaptic neurotoxic paralysis (α-bungarotoxin-like neurotoxins), but will not usually reverse established pre-synaptic paralysis (β-bungarotoxin-like neurotoxins), so should be given before major paralysis has occurred (Fig. 12.2). Coagulopathy is best reversed by antivenom, but even after all venom is neutralised, there may be a delay of hours before normal coagulation is restored. More antivenom should not be given because coagulopathy has failed to normalise fully in the first 1–3 hours (except in very particular circumstances). Thrombocytopenia may persist for days despite antivenom. The role of antivenom in reversing established rhabdomyolysis and renal failure is uncertain. Antivenom may help limit local tissue effects or injury in the bitten limb, but this is quite variable and time-dependent. Neuroexcitatory envenoming can respond very well to antivenom (Australian funnel web spider bites and Mexican, South American and Indian scorpion stings), but there is controversy about the effectiveness of antivenom for some species (some North African and Middle Eastern scorpions). The role of antivenom in limiting local venom effects, including necrosis, is also controversial; it is most likely to be effective when given early.

All patients receiving antivenom are at risk of both early and late adverse reactions, including anaphylaxis (early; not always related to immunoglobulin E (IgE)) and serum sickness (late).

Non-antivenom treatments

Anticholinesterases are used as an adjunctive treatment for post-synaptic paralysis.

Prazosin, an α-adrenoceptor antagonist (α-blocker) has been used in the management of hypertension or pulmonary oedema in scorpion sting cardiotoxicity, particularly for Indian red scorpion stings, with significant success according to some proponents, though antivenom is now the preferred treatment according to other clinicians, but combining antivenom and prazosin may offer optimal results.

Fig. 12.2 Principal snake venom neurotoxins acting at the neuromuscular junction (NMJ). The pre-synaptic neurotoxins (β-bungarotoxin-like) bind to the cell membrane of the terminal axon (1), form a synaptosome (2) and enter the cell, where they disrupt acetylcholine (ACh) production (3) and damage intracellular structures, including ion channels (4). On initial entry, they cause release of excess ACh, followed by cessation of all ACh release, causing irreversible paralysis until the cell is repaired (days to weeks later). The post-synaptic neurotoxins (α-bungarotoxin-like) bind adjacent to the ACh receptor on the external surface of the muscle end plate and block ACh binding (5), thereby ceasing neurotransmission. Because this action is external to the cell and does not cause cell damage, it is potentially a reversible paralysis. *Copyright © Julian White.*

Antibiotics are not routinely required for most bites/stings, though a few animals, such as some South American pit vipers and stingrays, regularly cause significant wound infection or abscess. Tetanus is a risk in some types of bite or sting, such as snakebite, but intramuscular toxoid should not be given until any coagulopathy is reversed.

Mechanical ventilation (p. 244) is vital for established respiratory paralysis that will not reverse with antivenom and may be required for prolonged periods (up to several months in some cases).

Fasciotomy as a treatment for potential compartment syndrome or severe limb swelling is an overused and often disastrous surgical intervention in snakebite and is associated with poor functional outcomes. It should be reserved as a treatment of last resort and used only in cases where compartment syndrome is confirmed by intra-compartment pressure measurement and after first trying limb elevation, antivenom and ensuring that any coagulopathy has resolved.

New non-antivenom pharmaceutical treatments to reduce the effects of envenomation are being studied, with some reaching clinical trial evaluation, such as anti-phospholipase A2 drugs, but their place in treating envenomation remains unproven and they are likely to be adjuncts to antivenom rather than replacements.

Follow-up

Cases with significant envenomation and those receiving antivenom should be followed up to ensure any complications have resolved and to identify any delayed envenoming. Patients receiving antivenom should be advised about the symptoms of serum sickness before they are discharged from hospital and advised to return if these symptoms develop.

Prevention

Community education promoting prevention should be an important part of health delivery, particularly in low resource nations where access to health care may be suboptimal. For snakebite, avoiding sleeping on the ground, walking barefoot or without illumination at night should be emphasised. Use of mosquito netting over raised beds may prevent both mosquito-borne diseases and nocturnal snakebite (kraits in Asia). Use of boots in paddy fields may reduce the risk of snakebite. Installation of glossy tiles around the base of buildings may discourage scorpion entry in endemic areas.

The WHO identified snakebite as a neglected tropical disease (NTD) in 2017 and has published a roadmap aiming to substantially improve outcomes for snakebite patients globally by 2030. Clinicians wishing to improve outcomes for their patients should consult this document for guidance.

Envenomation by specific animals

Venomous snakes

Venomous snakes represent the single most important cause of envenomation globally, affecting millions of humans annually and resulting in large numbers of deaths and patients left with long-term disability. Of the 3000-plus snake species, more than 1000 either are venomous or produce oral toxins. The most important venomous snake families are the Viperidae (vipers; includes typical vipers (subfamily Viperinae) and pit vipers, with heat-sensing pit organs (subfamily Crotalinae)) and the Elapidae (cobras, kraits, mambas, coral snakes, sea snakes, Australian snakes). However, there are also dangerous species among the Atractaspididae (side-fanged burrowing vipers of Africa and the Middle East) and the non-front-fanged colubroids (NFFC snakes; several families, including the 'back-fanged' boomslang and vine snakes of Africa and the keelbacks of Asia).

A selection of important species is included in Boxes 12.4–12.6.

Clinical features and management

As with other forms of envenomation, the management of snakebite follows the standard assessment guidelines described previously (p. 278). The nature of the risks posed will depend on the specific snake fauna in a given region (p. 279). For example, in South Asia, the major snakebite risks are claimed to come from the 'big four': cobras, kraits, Russell's viper and saw-scaled vipers. This list is misleading, though, as it omits other important snakes, including the hump-nosed vipers, king cobra and green pit vipers, all of which can cause severe or lethal envenoming and may not be covered by current Indian antivenoms. Even for those snakes recognised as causing envenoming, there may be major geographical variation in venom and features of envenoming. For Russell's viper (*Daboia* spp.), Sri Lankan specimens can cause rhabdomyolysis and flaccid paralysis, in addition to classic severe coagulopathy, haemorrhage, local bite site injury and acute kidney injury (AKI). Most Indian populations of the same snake are not associated with either rhabdomyolysis or paralysis, but in parts of Southern India may cause anterior pituitary haemorrhage and/or capillary leak syndrome (hypotensive shock plus vascular leakage resulting in pulmonary oedema). Capillary leak syndrome is also encountered with populations of Burmese Russell's viper (Myanmar), where AKI is especially common and severe.

Antivenom raised against venom from one population of snakes may be poorly effective against bites from snakes from other regions; this is particularly true for Russell's vipers. Similarly, each of the several species of saw-scaled vipers (*Echis* spp.) spread from West Africa across the Middle East to South Asia (including Sri Lanka) has specific venoms that may not be neutralised by antivenoms raised against other species in the genus; Indian antivenoms are ineffective against African species. It follows that, in managing snakebite envenomation, it is critically important to choose the appropriate antivenom and to understand that this may not include every antivenom claimed to cover a given species.

It is unwise to assume that everything is known about envenoming by snakes because new clinical information and syndromes are emerging as more detailed studies are carried out. For instance, krait bites (*Bungarus* spp.), long associated with 'painless' bites, later development of devastating flaccid paralysis and a high mortality rate, are now known to have some venom diversity. At least some species can cause rhabdomyolysis (black krait, Bangladesh) and/or severe hyponatraemia, and while bites may be painless, systemic envenomation can cause severe abdominal pain in at least some patients. Among cobra bites, the previous division into 'non-spitting', neurotoxic species and 'spitting', less neurotoxic species that cause local necrosis is less clear. Non-spitters are now known to spit in parts of their range (e.g. *Naja kaouthia* in West Bengal) and may cause local necrosis in addition to paralysis. Previously clear diagnostic indicators for envenomation by particular types of snakes, such as Russell's vipers and saw-scaled vipers causing coagulopathy, have also become less sure, as other snakes, such as hump-nosed vipers (*Hypnale* spp.) and green pit vipers (*Trimeresurus* spp.), found in similar regions, can also cause marked coagulopathy and yet are often not covered by available antivenoms. The ability to cause life-threatening coagulopathy, associated with snakes previously considered harmless, such as the keelbacks in Asia (*Rhabdophis* spp.), can further complicate the diagnostic and management process, as antivenom against these snakes is currently available only in Japan.

Scorpions

Scorpions are second only to snakes in their venomous impact on humankind. Most medically important scorpions are in the family Buthidae and have complex neuroexcitatory venoms with highly specific ion-channel toxins. Classically, stings by these scorpions (some key genera listed in Boxes 12.4–12.6) cause moderate to severe local pain and rapid-onset systemic envenoming with development of a catecholamine storm-like syndrome as the toxins target the nervous system. There may be tachycardia or bradycardia, hyper- or hypotension, profuse sweating, salivation, cardiac dysfunction and pulmonary oedema. Cardiac collapse can occur, especially in children. Other clinical features may vary, depending on the scorpion species.

The Iranian scorpion, *Hemiscorpius lepturus* (principally south-west Iran), causes a quite different presentation, with an initial minor sting, followed by progressive development of bite site or limb necrosis and a potentially lethal systemic envenoming, characterised by intravascular haemolysis, disseminated intravascular coagulation (DIC), secondary renal failure and shock.

Clinical features and management

The approach to management varies with species and region. In South America, specific antivenoms are routinely used and associated with improved outcomes and reduced mortality. In India, the past reliance on prazosin has been supplemented or replaced with use of specific antivenom, again with improved outcomes. In contrast, in parts of North Africa, past reliance on antivenom has been replaced with use of cardiac support and arguably poorer outcomes.

In Iran, *H. lepturus* stings are treated with antivenom, though as presentation is often delayed because the sting initially appears to be minor, the role of late antivenom is unclear.

Spiders

There are vast numbers and great species diversity of spiders, with two broad taxonomic groupings: the more 'primitive' Mygalomorphs (several medically important species, especially Australian funnel web spiders (*Atrax, Hadronyche* and *Illawarra*)) and the far more diverse Araneomorphs (main clinically important species in the genera *Latrodectus* (widow spiders), *Loxosceles* (brown recluse spiders) and *Phoneutria* (banana or wandering spiders)).

Clinical features and management

While spiders and spider bites are common, only those genera noted above commonly cause medically significant effects. In most cases this is a neuroexcitatory envenoming, sometimes similar to severe scorpion envenoming (notable from Australian funnel web spiders), but the recluse spiders cause an often painless bite that develops into local skin necrosis and sometimes a systemic illness similar to that caused by the Iranian scorpion, *H. lepturus*, and with similar lethal potential. Widow spiders cause 'latrodectism', with initial local pain and sweating. In some, the pain becomes severe, sometimes spreading regionally followed by generalised pain, sweating, with associated hypertension, nausea and malaise.

For most of these spiders, antivenom remains the key treatment and is life-saving in some cases. A study in Australia suggesting that anti-*Latrodectus* antivenom is ineffective has not been confirmed by independent studies, is only applicable to adult patients and is in contrast to decades of positive clinical experience in Australia and globally confirming the value of antivenom.

Paralysis ticks

Most ticks are vectors for disease but a few species in Australia, North America and parts of Africa can cause flaccid paralysis. Toxins in the saliva act as potent pre-synaptic neurotoxins that can cause gradual-onset ascending flaccid paralysis.

There are no antivenoms for tick paralysis. Treatment is based on removal of all ticks and supportive care, including intubation/ventilation where required. The paralysis usually resolves by about 48 hours following removal of all ticks, although embedded ticks may be hard to find, hiding in the scalp, ears and skin folds.

Venomous insects

A number of insects are venomous, but very few cause significant envenoming in humans.

Venomous lepidopterans

The *Lonomia* caterpillars of South America, especially Brazil, have numerous protective venomous spines that, on contact with the skin, can discharge a potent procoagulant venom that can cause a progressive and sometimes fatal consumptive coagulopathy, with terminal haemorrhagic and/or organ failure events. Treatment includes use of a Brazilian specific antivenom and supportive care.

Venomous hymenopterans

Many bees, wasps, hornets and some ants have modified ovipositors in the abdomen that act as stings, attached to venom glands. The quantity of venom injected in a single sting is insufficient to cause significant envenomation, but as many of these venoms are potently allergenic, it can cause severe and sometimes fatal anaphylaxis in sensitised persons (p. 219). Massed stings by hundreds of these insects in a swarm, however, can cause life-threatening systemic envenoming, often with intravascular haemolysis, DIC, shock and multi-organ failure. 'Africanised' bees are a particular risk for such attacks in South America and now in parts of North America. The giant wasps and hornets of Asia can similarly cause systemic envenoming with multiple attacks, even from a few individual insects. Invasive ants, such as *Solenopsis* spp., are colonising new regions and can cause both allergic reactions and unpleasant local reactions.

Marine venomous and poisonous animals

The marine environment is dominated by animal life, and many species utilise toxins, either self-produced or taken up from the environment, to arm themselves for either defence or predation. Many of these animals can cause adverse effects in humans, either as a direct venom effect on bites/stings (venomous spiny fish, sea snakes, stingrays, jellyfish, sea urchins, some starfish, cone snails, selected octopuses etc.), or through poisoning if eaten (fugu, ciguatera, scombroid, several types of shellfish poisoning; p. 273).

For venomous marine animals, there is antivenom available only for sea snakes, which can cause rhabdomyolysis and/or paralytic neurotoxicity; box jellyfish, which can cause very rapid cardiac collapse; and stonefish, which cause intense sting-site pain and sometimes local necrosis. In general, marine venoms respond to heat; thus, a hot water immersion or shower (about 45°C) is effective at reducing local pain, particularly for jellyfish, stinging fish and stingray stings. For stingray stings, the venom may cause local tissue damage both through sting trauma and a venom effect. Wounds penetrating the abdomen or chest are potentially lethal and should be adequately explored, cleaned and allowed to heal by secondary intention, with antibiotic treatment of secondary infection if indicated. For bites by the blue-ringed octopus and stings by cone snails, rapid-acting venom can cause early cardiovascular collapse and flaccid paralysis. Supportive care is crucial in ensuring survival from these potentially lethal and seemingly trivial local wounds. Sea urchin and venomous starfish wounds can result in multiple penetrating spines, which cause pain and act as a nidus for secondary infection, but surgical removal of spines can be difficult and unrewarding. Contact with venomous sessile animals (coral, anemones, some sponges etc.) can result in painful local envenoming.

Multiple Choice Questions

12.1. Snakebite has been classified as a major neglected tropical disease, but venomous snakes are not the most common and important cause of envenoming in some regions. In those regions, such as North Africa, which of these animal groups is the most important?

A. Spiders
B. Hymenopteran insects (bees, wasps and ants)
C. Scorpions
D. Jellyfish
E. Stingrays

Answer: C.

While there are far more spider species than scorpions, and many scorpions are not dangerous for humans, scorpion sting can be severe and life-threatening. Scorpion sting causes more hospitalisations than snakebite in some regions, such as North Africa, parts of the Middle East and parts of Latin America, including Mexico. Globally hymenopteran insect stings causing major allergy are also important, but with fewer hospitalisations. Jellyfish stings and stingray injuries are important in some regions, but again with comparatively fewer hospitalisations.

12.2. Descending neurotoxic flaccid paralysis is a feature of envenoming by a number of animals, both terrestrial and marine, but most notably some species of snakes. Which is the common key first sign to look for as evidence of developing neurotoxicity?

A. Limb weakness
B. Ophthalmoplegia
C. Difficulty speaking and swallowing
D. Loss of deep tendon reflexes
E. Bilateral ptosis

Answer: E.

All of the listed signs can occur with neurotoxic descending flaccid paralysis, but cranial nerves are usually affected first and bilateral ptosis is usually the first clear sign and should be a standard part of repeated examinations of patients with suspected snakebite, as important and frequently tested as pulse, blood pressure and respiratory rate. Ophthalmoplegia often first manifests as partial paralysis affecting medial gaze and generally occurs after ptosis becomes apparent. As neurotoxicity progresses, the patient may develop difficulty with speech, swallowing and may start drooling and at this point pharyngeal airway protection may become imperilled and require airway support. Limb weakness and loss of deep tendon reflexes usually occur later in the progression of neurotoxicity. Ideally, as soon as ptosis develops, the patient should receive an appropriate antivenom to try to prevent paralysis progressing through to full respiratory paralysis.

12.3. Procoagulants in some snake venoms can cause consumption of clotting factors, particularly fibrinogen, resulting in a bleeding tendency. In West Africa, which of the following snakes is most likely to cause this type of coagulopathy?

A. Puff adder
B. Night adder
C. Spitting cobra
D. Saw-scaled viper
E. Forest cobra

Answer: D.

Saw-scaled vipers are a classic cause of procoagulant-mediated consumptive coagulopathy throughout their range, including West Africa, where they pose a major hazard to humans. Their venom also contains potent haemorrhagins, and severe local and systemic bleeding effects can occur. Cobras do not cause coagulopathy. Puff adders and night adders can cause local bleeding, but not this severe systemic coagulopathy.

12.4. Which of the following common causes of snakebite in parts of India and Sri Lanka is not covered by current polyvalent antivenoms available in this region?

A. Common cobra
B. Saw-scaled viper
C. Hump-nosed viper
D. Russell's viper
E. Common krait

Answer: C.

Hump-nosed vipers, *Hypnale* spp., are common in some parts of India and Sri Lanka, causing a significant number of bites and can cause coagulopathy and acute kidney injury in addition to local effects at the bite site. Envenoming by these snakes can appear similar to envenoming caused by Russell's viper and saw-scaled vipers; however, their venom is distinct and not used in production of current antivenoms. Therefore, these antivenoms are unlikely to provide benefit in treating hump-nosed viper bites. A new antivenom is being developed for Sri Lanka that will include venom from these snakes in the immunising mix, and this may become a better treatment option in future, if clinical trials prove both effectiveness and safety.

12.5. Most scorpions causing medically significant envenoming have potent neuroexcitatory venoms that cause rapid development of both local pain and systemic envenoming, which can, in some cases, cause a catecholamine storm–like effect, but one scorpion causes a quite different type of envenoming, with minimal initial pain and development over many hours to days of local sting site necrosis, with a systemic illness. Which of the following scorpions causes this local necrotic effect?

A. *Tityus serrulatus* (Brazil)
B. *Hemiscorpius lepturus* (Iran)
C. *Leiurus quinquestriatus* (Middle East)
D. *Hottentotta tamulus* (India)
E. *Androctonus australis* (North Africa)

Answer: B.

Most medically significant scorpions globally are in the family Buthidae and cause local pain and systemic neuroexcitatory envenoming and do not cause sting site tissue injury/necrosis. The Iranian scorpion *Hemiscorpius lepturus* is in the family Hemiscorpiidae and is unique amongst scorpions in having a locally necrotic and systemically haemolytic and tissue-damaging venom, similar in clinical presentation to recluse spider (*Loxosceles* spp.) envenoming. In parts of SW Iran, it is the most important cause of scorpion stings and despite antivenom, probably because presentation is often delayed until after the optimum time to use antivenom, stings can cause sometimes fatal envenoming, especially in children.

Medicine in austere environments

Extremes of temperature 290
- The cold environment 290
- Heat-related illness 292

Acute high altitude illness 294
- Illness at high altitude 295

Subaquatic medicine 296

'Wilderness medicine' can be defined as medical care delivered in environments greater than 1 hour away from definitive care; however, in practice it often represents the care of patients that are multiple hours, if not days, away from the nearest hospital. This covers a broad range of scenarios from expeditions to commercial work and research projects, often in austere conditions. Adventure tourism is also becoming increasingly popular and is projected to grow further.

Delivery of exemplary care in this context is summarised in Box 13.1. It involves a core understanding of the interaction between the environment and human health, alongside strong situational awareness and consideration of human factors. As the environment continually alters, whether through population growth, economic development or climate change, it plays an important role in disease causation – one that may increase over time. This chapter deals principally with the acute effects of environmental hazards on individuals and should be read in conjunction with the chapters on Acute Medicine and Critical Illness (Ch. 10) and Poisoning (Ch. 11).

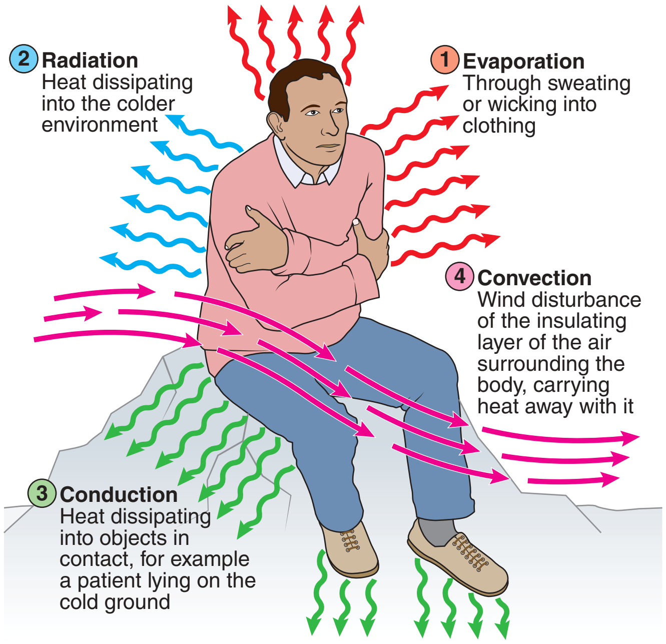
13.1 Key factors in the delivery of exemplary wilderness medicine

- Optimise participant fitness (e.g. pre-departure health screening)
- Understand the patterns of injury and anticipate issues
- Appropriate technical equipment, medical kit and drugs
- Effective logistical support
- Multiple communication options (awareness of limitations of each)
- Understand environmental factors that affect ingress and egress
- Proactive rather than reactive approach (e.g. daily skin checks/blister care)
- Established standard operating procedures (SOPs)

Extremes of temperature

Thermoregulation

Body heat is generated by basal metabolic activity and muscle movement and lost by four main mechanisms: conduction, convection, evaporation and radiation (Fig. 13.1). Body temperature is controlled by the hypothalamus, which is directly sensitive to changes in core temperature and indirectly responds to temperature-sensitive neurons in the skin.



② Radiation
Heat dissipating into the colder environment
① Evaporation
Through sweating or wicking into clothing
④ Convection
Wind disturbance of the insulating layer of the air surrounding the body, carrying heat away with it
③ Conduction
Heat dissipating into objects in contact, for example a patient lying on the cold ground

Fig. 13.1 Mechanisms of heat loss.

13.2 Thermoregulation in old age

- **Age-associated changes**: impairments in vasomotor function, skeletal muscle response and sweating mean that older people react more slowly to changes in temperature.
- **Increased comorbidity**: thermoregulatory problems are more likely in the presence of pathology such as atherosclerosis and hypothyroidism, and medication such as sedatives and hypnotics.
- **Hypothermia**: this may arise as a primary event, but more commonly complicates other acute illness, e.g. pneumonia, stroke or fracture.
- **Ambient temperature**: financial pressures and older equipment may result in inadequate heating during cold weather.

The normal 'set-point' of core temperature is tightly regulated within the range 37 ± 0.5°C, which is necessary to preserve the normal function of many enzymes and metabolic processes. Aspects of thermoregulation specific to old age are detailed in Box 13.2.

The cold environment

Protective mechanisms in a cold environment include activation of the sympathetic nervous system with cutaneous vasoconstriction, shivering and increases in both heart rate and cardiac contractility. Shivering, an involuntary contraction and relaxation of muscles, is an early adaptive cold response that results in a two- to fivefold increase in heat generation. As core temperature drops, these protective mechanisms fail; shivering stops between 29°C and 31°C.

Physiological effects

The cold environment has six main effects on physiological systems:

Metabolism

Regional organ blood flow is reduced in the cold environment with marked variation; the kidneys demonstrate the most significant change, similar in response to that seen with haemorrhage or sepsis. The stress response results in glycogenolysis and gluconeogenesis with a relatively defective insulin efficacy resulting in hyperglycaemia.

Fluid and electrolytes

As the body cools there is a relative decrease in plasma volume as fluid moves intracellularly with subsequent inadequate tissue perfusion. There is a decrease in intracellular potassium below a core temperature of 25°C, which is linked to the risk of arrhythmias.

Respiratory

For every 1°C reduction in core temperature there is a 6% drop in oxygen consumption. The initial increased respiratory rate declines with ongoing cooling, with animal studies suggesting a cessation of breathing at a core temperature of 24°C. There is direct respiratory centre depression from a reduction in both oxygen expenditure and production of carbon dioxide.

Cardiovascular

As the core temperature falls there is a reduction in cardiac output with initial maintenance of stroke volume. At around 28°C the heart rate is reduced by 50% with a subsequent increased risk of arrythmias. Initial conduction abnormalities include a sinus bradycardia, progressing to slow atrial fibrillation (AF) and then to ventricular fibrillation (VF). VF may be induced below 30°C with excessive stimulation/movement, which is why handling of a hypothermic patient needs to be performed with great care.

Haematological

There is an increased plasma viscosity, with a 150% rise in haematocrit documented at a core temperature of 25°C. Enzymatic reactions within the coagulation cascade are prolonged, alongside platelet trapping within the liver and spleen, resulting in an increased bleeding risk.

Neurological

There is a decline in cognitive function in the cold environment, with unconsciousness occurring at a core temperature around 28–30°C. Slurred speech, ataxia and paradoxical undressing are all described with lowering core temperatures. Absence of brain electrical activity is seen below 20°C; this is generally considered to be neuroprotective. It is believed that the cold stabilises the blood–brain barrier and cerebral cell membranes that would otherwise be disrupted by hypoxia.

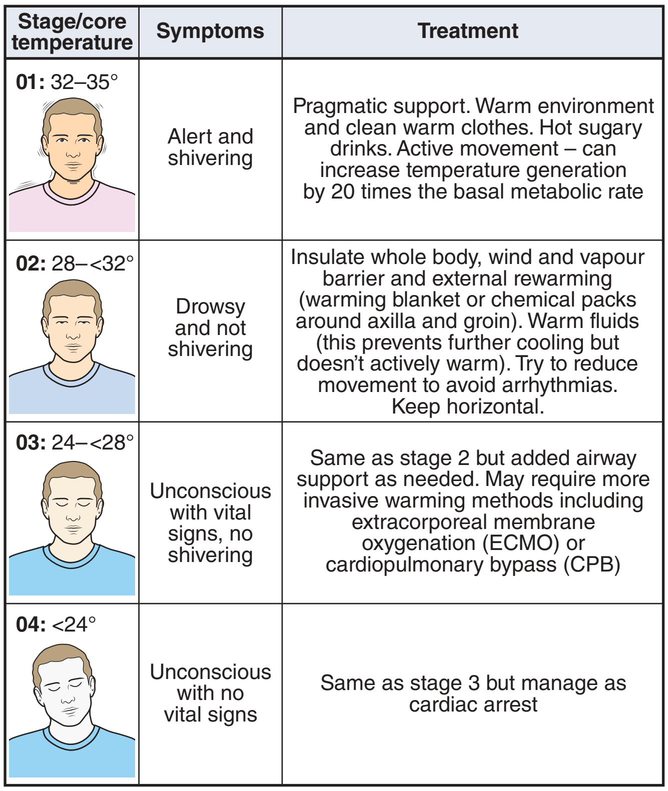
Hypothermia

Hypothermia is defined as a core temperature below 35°C and can be subcategorised into primary hypothermia due to environmental exposure and secondary hypothermia due to abnormal thermoregulatory mechanisms due to an underlying altered physiological state. Measurement of core temperature can be challenging, with tympanic measurements often considered inaccurate; monitors are often not calibrated below 35.5°C. Alternatives such as oesophageal temperature can be difficult to achieve in practice, and rectal measurements (considered the gold standard measurement) can lag behind the true core temperature.

Traditionally, hypothermia is categorised as mild (32–35°C), moderate (28–32°C) and severe (< 28°C); however, newer staging systems, such as the Swiss Staging System, define the level of hypothermia based on symptoms (Fig. 13.2). This has been shown to overestimate the degree of hypothermia in around 20% of cases but remains a helpful classification when an accurate core temperature cannot be obtained.

Management

Following resuscitation, the objectives of management are to rewarm the patient in a controlled manner whilst treating associated hypoxia (by oxygenation and ventilation if necessary), fluid and electrolyte disturbance, and cardiovascular abnormalities. Careful handling is essential to avoid precipitating arrhythmias. The Swiss Staging System can be used to guide treatment at various levels of hypothermia (see Fig. 13.2).



Stage/core temperature	Symptoms	Treatment
01: 32–35°	Alert and shivering	Pragmatic support. Warm environment and clean warm clothes. Hot sugary drinks. Active movement – can increase temperature generation by 20 times the basal metabolic rate
02: 28–<32°	Drowsy and not shivering	Insulate whole body, wind and vapour barrier and external rewarming (warming blanket or chemical packs around axilla and groin). Warm fluids (this prevents further cooling but doesn't actively warm). Try to reduce movement to avoid arrhythmias. Keep horizontal.
03: 24–<28°	Unconscious with vital signs, no shivering	Same as stage 2 but added airway support as needed. May require more invasive warming methods including extracorporeal membrane oxygenation (ECMO) or cardiopulmonary bypass (CPB)
04: <24°	Unconscious with no vital signs	Same as stage 3 but manage as cardiac arrest

Fig. 13.2 Swiss Staging System and the treatment of hypothermia.

Mild hypothermia

Continued heat loss can be prevented by sheltering the patient from the cold, replacing wet clothing, covering the head and insulating the patient from the ground. Hibler's method is the best available technique for packaging a patient, which involves wrapping the patient in an insulating layer, followed by an outer vapour-tight layer. Active movement can raise the core temperature by 2°C per hour. Forced-air re-warming blankets and heat packs can increase core temperature by 0.1–3.4°C per hour. Warmed intravenous fluids have been shown to provide no active warming, but they do prevent further cooling.

Severe hypothermia

For severe hypothermia a number of invasive warming methods can be instigated in hospital. This includes bladder lavage, which involves flushing the bladder with 300 mL of warm saline resulting in a 1–2°C rise in core temperature per hour. Thoracic lavage through two unilateral chest drains (anterior and lateral) can result in a 2–3°C rise per hour. A single chest drain approach can be used by clamping a 32–36 French tube for 2–3 minutes after flushing in 300 mL of warm saline, then allowing it to drain.

Extracorporeal membrane oxygenation (ECMO) and cardiopulmonary bypass (CPB) are performed in specialist hospitals and represent the best warming strategies, with increases in core temperature of 6–10°C per hour.

Cardiac arrest

There are a number of adaptations to resuscitation algorithms for hypothermic patients in cardiac arrest (Box 13.3). There is an old adage that 'you're not dead until you're warm and dead', with documented cases of full recovery following extended periods of ECMO and CPB (Box 13.4). There are, however, some markers of futility. These include: obvious lethal injury, prolonged asphyxia (mouthful of snow etc.), incompressible thorax (distinct from a stiff chest, which is common), frozen abdomen, or potassium > 12 mmol/L.

13.3 Management of cardiac arrest in hypothermic patients

- Assessment for signs of life should be extended to 1 minute
- Ventricular fibrillation and ventricular tachycardia can be defibrillated; however, if after three shocks there is no response, additional shocks should be delayed until core temperature is > 30°C (3-shock 'stacked' sequences are not recommended)
- Withhold adjunctive medications (adrenaline, amiodarone etc.) if the temperature is below 30°C; or double the interval between doses when temperature is 30–35 °C

13.4 Cases of full recovery following extended periods of ECMO and CPB

- In 1999 a 29-year-old Norwegian radiology registrar fell whilst skiing into an ice waterfall gully. She was cut out after 1 hour and 20 minutes with a core temperature of 13.7°C. Following 9 hours of CPR and CPB, she survived with no neurological impairment.
- In 2011 a 7-year-old Swedish girl fell from a cliff into the sea and was found in the water after 3–4 hours with a core temperature of 13.2°C. Following CPR and warming, she survived with no neurological impairment.

(CPB = cardiopulmonary bypass; CPR = cardiopulmonary resuscitation; ECMO = extracorporeal membrane oxygenation)

Cold injury

Freezing cold injury ('frostbite')

Hypothermia-induced vasoconstriction results in tissue cooling, and frostbite refers to ice formation and freezing within the tissue, most commonly affecting the hands and feet (around 90% of cases). Risk factors include alcohol consumption (which impairs decision-making and results in peripheral vasodilatation), previous frostbite, drug use, inappropriate clothing, fatigue and dehydration. There are two distinct phases to cold injury: a 'cooling–supercooling–freezing' stage during exposure; and a vascular stage during re-warming. When skin tissues cool to below 0°C, ice crystal formation causes microvascular and cell damage. During warming, this results in a degree of circulatory failure and fluid loss. The release of inflammatory mediators causes ischaemia and clot production. Re-freezing following warming is particularly destructive, resulting in massive cell inflammatory changes; therefore, re-warming should only be initiated if there is no risk of further re-freezing.

Patients often describe an initial numbness and woody sensation followed by a severe pain during warming, with a persistent throbbing sensation. Pain can endure for months alongside potentially permanent sensory changes. The skin can look waxy, discoloured or blistered (Fig. 13.3); however, prognostication using initial skin changes can be very challenging.

Management

If concerned about the possibility of cold injury, immediate pre-hospital treatment is to try to shelter from the environment, remove wet clothing and jewellery and re-dress in warm, dry clothing. If there is absolutely no risk of re-freezing, then warming the area can be achieved by placing the area into a companion's armpit or groin. Aspirin 75 mg and ibuprofen 400 mg 8 hourly are recommended. Do not rub the area and do not place heat sources directly onto the area. Evacuation for formal medical review should be obtained. Warmed areas need to be made non-load-bearing and therefore prior thought about extraction needs to be considered. Aloe vera gel has anti-prostaglandin effects and can be applied before application of a non-adherent dressing, splinting and elevation of the affected region.

Definitive warming involves placing the affected area into circulating water between 37°C and 42°C with small amounts of antiseptic for around an hour, avoiding contact with the sides of the container. Additional treatment involves fluid replacement with warmed fluids (due to cold diuresis), strong analgesia and blister care. Blisters may present as clear, cloudy or haemorrhagic. Blister management remains controversial, with current evidence recommending debridement of all blisters in hospital (likely under a general anaesthetic) to improve wound healing. There is no evidence for prophylactic antibiotics and tetanus prophylaxis should be given according to local protocols; frostbite wounds are not considered tetanus-prone.

In-hospital management includes specialist imaging, e.g. angiography and technetium bone scanning to inform prognosis; however, access to these may be limited. A combination of thrombolysis and vasodilators (such as nitroglycerin), given within 24 hours, has evidence of good outcomes. Iloprost, a prostacyclin analogue that causes vasodilation and reduces the requirement for amputation, can be given intravenously. There is substantial variability between international protocols for both initiation of iloprost (commonly from point of injury to within 72 hours, with some case reports documenting use up to 9 days from thawing) and for duration of treatment (between 1 hour to 56 days). Early amputations have a higher morbidity, and surgery should be delayed unless there is evidence of sepsis. There is also a potential role for hyperbaric oxygen treatment, and this is an area of current research.

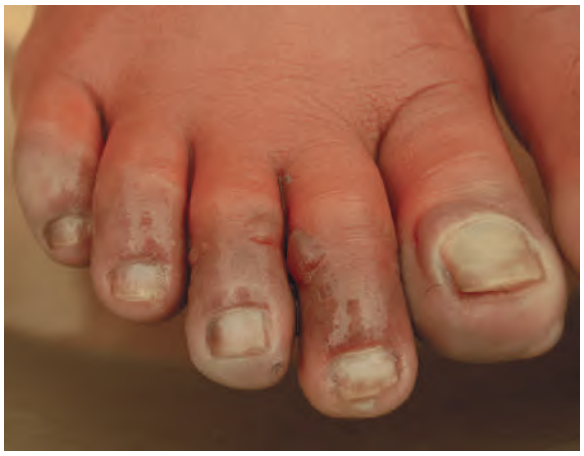


Fig. 13.3 Frostbite in a female Everest sherpa.

Non-freezing cold injury

This results from prolonged exposure to cold, damp conditions and is often seen in individuals who become wet but are unable to dry out. The important distinction from frostbite is that the tissues do not freeze. It is almost exclusively seen in the lower limbs and feet; however, concomitant injury to the hands is sometimes seen. It is often described as a patch of numbness, which when rewarmed, changes in colour from pale to red, with associated swelling and pain. These symptoms can last for months or indefinitely; often far longer than an equivalent freezing injury. The pathology remains uncertain but probably involves endothelial injury. Gradual re-warming is associated with less pain than rapid re-warming. The pain and associated paraesthesia are difficult to control with conventional analgesia and may benefit from early use of amitriptyline. The patient is at risk of further damage on subsequent exposure to the cold.

Heat-related illness

Heat-related illness defines a spectrum of pathology from benign heat oedema to lethal heat stroke, the definitions of which are found in Box 13.5. There is a growing risk of heat-related illness with global temperatures predicted to rise by between 1.7°C and 5.6°C within this century alone; the World Health Organization predicts over 250 000 additional deaths a year from 2050 as a result of heat exposure.

Heat-related illness is often categorised as either environmental or exertional heat illness depending on the primary underlying mechanism.

13.5 Definitions of heat-related illness

Heat-related illness	Definition
Heat oedema	Mild swelling to the limbs during the first few days of heat exposure due to increased plasma volume, peripheral vasodilation and interstitial pooling of blood
Heat cramps	Muscle spasms related to sodium loss. Generally occur after exercise in non-acclimatised individuals who sweat freely and replace losses with water or other hypotonic solutions, so they become salt depleted. Salt supplementation reduces the incidence
Heat syncope	Heat syncope refers to a multi-factorial syndrome involving transient loss of consciousness in the context of heat exposure with a relatively rapid return to normal function and baseline. Contributing factors may include peripheral vasodilation, orthostatic pooling of blood, prolonged standing, advanced age and dehydration, as well as coexisting medical conditions such as ischaemic heart disease that reduce cardiac output
Heat exhaustion	Characterised by volume and salt depletion. It is an inability to continue an activity due to heat stress. It presents with thirst, lethargy, headache, nausea but importantly a normal mental status. Some literature describes it as benign as it may be protective in the development of heat stroke, causing an individual to stop an activity and thus the generation of heat
Heat stroke	Neurological impairment with core body temperature $\geq$ 40°C (rectal temperature is gold standard in a pre-hospital environment). Symptoms can involve a coarse muscle tremor, confusion, aggression and loss of consciousness. Sweating may be absent due to dehydration and failure of thermoregulatory mechanisms

Environmental heat illness results from elevated ambient temperatures, with increased incidence seen at the extremes of age, due to suboptimal homeostatic thermoregulation. Peaks of incidence are common during heatwaves, exemplified by the 70 000 heat-related deaths reported during the 2003 European heatwave. Conversely, exertional heat illness predominantly affects young, physically fit individuals (such as soldiers and athletes), reflecting a failure to dissipate intrinsic heat production from physical activity.

Risk factors for the development of heat illness are well established (Box 13.6).

Pathophysiology of heat stroke

The pathophysiology of heat stroke can be summarised as organ dysfunction from the high temperature itself and end-organ ischaemia from diminished blood flow. Increased sweating results in dehydration, and blood pools in vasodilated peripheral vasculature resulting in a decreased effective blood volume. The blood viscosity increases resulting in heart strain. Enzymes denature at 40°C, and at 41°C mitochondrial activity stops; the subsequent loss of oxidative phosphorylation results in organ ischaemia. The muscles and gastrointestinal tract are affected first, followed by the central nervous system, circulatory and clotting systems. The pathophysiology is similar to sepsis, severe trauma and extensive burns (Box 13.7).

Management

Mortality of heat illness is around 30% and is directly proportional to the duration and magnitude of hyperthermia; therefore, immediate cooling should begin on scene, before transfer to hospital. The aim should be to reduce core temperature to approximately 39°C.

A patient should be removed from the heat source and put into shade to reduce radiant heat gain. Resting in an air-conditioned room has cooling rates of 0.03–0.06°C/min. Clothes should be removed, a rectal temperature taken and intravenous access established. Supplemental oxygen may be required if respiratory distress is present. If temperature measurement is unavailable but the history and clinical findings are consistent with heat illness, initiation of treatment with cooling techniques should not be delayed.

A number of cooling strategies exist (Box 13.8), and their implementation will depend on what is feasible within each particular environment. Meta-analyses have concluded that ice water immersion is the most effective treatment strategy, with cooling rates of 0.20–0.35°C/min for iced water and 0.11°C/min for wet towels. Immersion is unlikely to be feasible in the wilderness environment and many hospitals, with further consideration of the potential dangers of immersing a patient with

13.6 Risk factors for the development of heat-related illness

Risk factor	Mechanism
High ambient temperatures	Increased radiant heat gain
High humidity	Ineffective evaporative heat loss at humidities > 75%
Little shade	Increased radiant heat gain
Intercurrent illness	Raised core temperature
Extremes of age	Suboptimal homeostatic thermoregulation
Overweight/unfit	The main identifiable risk factor for heat illness during military training was a body mass index (BMI) ≥ 30 kg/m^2
Effects of alcohol and medication (diuretics, ACE inhibitors, β-adrenoceptor antagonists (β-blockers), vasodilators, antidepressants, anticholinergics, antihistamines and stimulants)	Through dehydration, decreased cardiovascular and peripheral response to dissipate heat, reduced sweating or increased metabolic rate
Inappropriate clothing	Reduced heat loss through combination of radiation, convection and evaporation
Dehydration	Regardless of body habitus or fitness level, fluid losses that result in a 2%–3% decrease in body weight correlate with decreased aerobic performance, increased perception of fatigue and greater core temperatures at a given workload
Previous heat-related illness	Impaired homeostatic thermoregulation
No acclimatisation	Body fluid deficits are reduced by around 30% in acclimatised individuals, despite increased sweat rates of up to 18%, as a result of a more accurate thirst response
Intense work/duration	Increased heat generation

(ACE = angiotensin-converting enzyme)

13.7 Pathophysiology of heat stroke

	Increased heart rate and an increase in cardiac output by 3 L/min for each 1°C rise in core temperature. Increased peripheral blood flow from 0.2 L/min up to 8 L/min. Dehydration with sweat rates increasing from 0.5 L/day up to 15 L/day. Risk of heart failure if pre-existing cardiac disease
	Ischaemia and cerebral oedema due to the high temperature itself and vascular endothelial damage
	Intestinal mucosal impairment results in toxins entering the portal vein and circulating systemically, resulting in sepsis
	Tachypnoea and pulmonary vasodilatation result in acute respiratory distress syndrome (ARDS) (p. 238)
	Acute renal failure due to ischaemia, dehydration and rhabdomyolysis (p. 235)
	Acute liver injury from ischaemia and high levels of circulating inflammatory cytokines (p. 897)
	Microthrombus formation causing further ischaemia and disseminated intravascular coagulation (p. 1013)
	Multiple electrolyte abnormalities including hypokalaemia, hypomagnesaemia, hypoglycaemia and metabolic acidosis

13.8 Summary of cooling rates

Cooling technique (target < 39°C)	Cooling rate
Ice water immersion	0.20–0.35°C/min
Wet towels	0.11°C/min
Evaporative and convective combined	0.034–0.31°C/min
Air-conditioned room	0.03–0.06°C/min
Intravenous cold saline	0.03°C/min
Intravenous room-temperature saline	0.015°C/min

a reduced conscious level. Immersing the hands and forearms in cold water results in reduction of heat stress in normal subjects, but has not been evaluated in the treatment of heat stroke patients.

The placement of ice/cold packs in the axillae, groin and neck has been recommended as an easy method to use in the field, but when compared with evaporative cooling in healthy subjects, cooling times were longest when the ice packs were used alone and shortest when both methods were used simultaneously. Evaporative cooling involves the removal of clothing, spraying tepid or cool water over the patient, and facilitating evaporation and convection with the use of a fan.

The role of invasive cooling methods such as gastric, bladder or peritoneal lavage has not been fully established. Neither hyperhydration nor dantrolene (used in the treatment of malignant hyperthermia) have evidence of benefit. Cold intravenous fluids may supplement cooling. In a study of healthy volunteers, infusion of 4°C saline over 30 minutes cooled the body by 1°C, compared to 0.5°C with room-temperature saline.

Prevention

Cooling in a wilderness setting may be incredibly challenging, with likely no access to ice or cold fluids. Prevention of heat illness is therefore paramount. Strategies include:

1. Ensuring adequate hydration. The 2024 Wilderness Medical Society heat illness guidelines identify hydration as the ‘most readily modifiable physiologic risk factor’. Ingestion of either isotonic or hypertonic fluids is also identified as the most effective approach to mitigate the rise in core temperature amongst athletes. Military guidelines recommend a 0.25–1.25 L/hr hydration strategy that varies for work rates (low/medium/high/very high) at a given wet bulb globe temperature (WBGT) (Box 13.9).
2. Consider accepted WBGT cut-offs for activities (see Box 13.9).
3. Expedition participants should receive high-level education pre-departure on the dangers of heat-related illness with evidence-based advice on risk reduction. Increased hydration and cooling strategies have been documented following educational material targeting older people prior to heatwaves.
4. Implementing a period of acclimatisation is the most powerful strategy. Guidelines vary, but an acclimatisation of around 80% can be achieved with 7 days of moderate exertion in the heat. Body fluid deficits are reduced by around 30% in acclimatised individuals as a result of a more accurate thirst response.

i 13.9 Wet bulb globe temperature (WBGT)

Meteorological conditions affect environmental temperatures, and a widely used index to calculate this is the WBGT, originally developed by the US Marines. WBGT is an apparent temperature measurement taking into account temperature, humidity, wind speed and solar radiation. This gives a much more accurate representation of the degree of heat stress experienced. WBGT is used to formulate a set of guidelines that guide activity levels, hydration and rest periods. For example, a ‘do not start’ WBGT of 21°C has been suggested for American marathons based on an unsuccessful attempt of 160 per 1000 finishers above this level, although the incidence of heat-related illness is not well described.

Acute high altitude illness

Illness due to high altitudes represents over a quarter of all serious medical incidents from reviews of expeditions in a range of environments. High altitude is generally considered to be over 2500 m and extreme altitude over 5500 m. The summit of Mount Everest stands at 8848 m, where the barometric pressure and atmospheric partial pressure of oxygen (PO_2) is around one-third of that at sea level; the percentage of oxygen remains the same at 20.9%.

Unconsciousness secondary to hypoxia normally occurs within 3 minutes if the body is exposed to an altitude over 8000 m. However, with a period of acclimatisation, the body is able to adapt and overcome even profound hypoxaemia with arterial partial pressures of oxygen (PaO_2) of 2.55 kPa recorded at 8400 m in a healthy climber (normally > 10.6 kPa at sea level).

Physiological effects of high altitude

A number of physiological systems are affected by altitude, which change over time (Fig. 13.4).

Respiratory

Reduction in oxygen tension results in a fall in arterial oxygen saturation (Fig. 13.5). This varies widely between individuals, depending on the shape of the sigmoid oxygen–haemoglobin dissociation curve

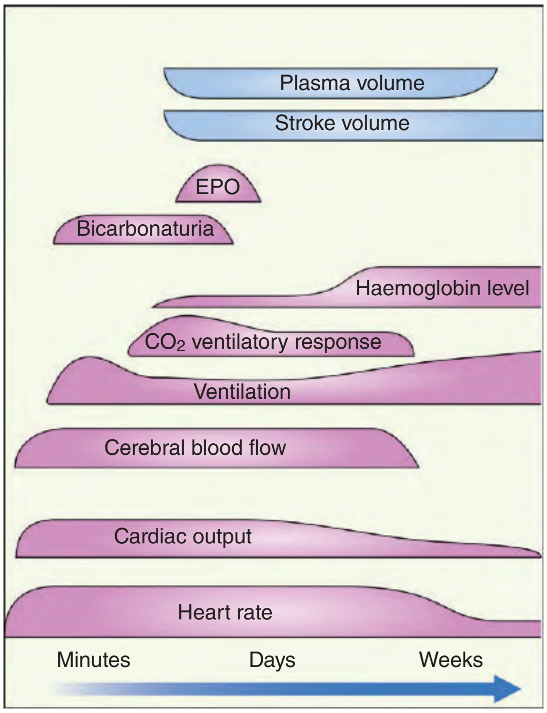

Fig 13.4 Physiological response to hypoxia over time. (EPO = erythropoietin)

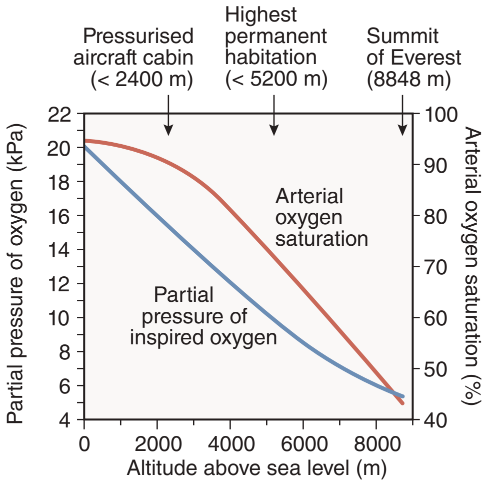

Fig. 13.5 Change in inspired oxygen tension and blood oxygen saturation at altitude. The blue curve shows changes in oxygen availability at altitude and the red curve shows the typical resultant changes in arterial oxygen saturation in a healthy person. Oxygen saturation varies between individuals according to the shape of the oxygen–haemoglobin dissociation curve and the ventilatory response to hypoxaemia. (To convert kPa to mmHg, multiply by 7.5.)

(see Fig. 24.5) and the ventilatory response. Alveolar ventilation increases with altitude, lowering carbon dioxide and resulting in a respiratory alkalosis, with metabolic compensation via renal bicarbonate loss. At high altitude, individuals are at the steep section of the oxygen dissociation curve, whereby a small fall in PaO_2 can result in a substantial decrease in oxygen saturation. The initial respiratory alkalosis shifts the curve to the left, but with a period of acclimatisation, increased production of 2,3-diphosphoglycerate moves the curve rightwards towards a sea-level position.

Haematological

Measured haemoglobin concentration increases with acclimatisation – a 20% fall in plasma volume causes haemoconcentration, and erythropoietin release (stimulated by hypoxia) leads to increased production of haemoglobin.

Cardiovascular

There is an initial increase in cardiac output due to increased sympathetic activity and heart rate. The reduction in plasma volume causes a fall in preload and stroke volume. Cardiac output returns to baseline over several weeks, but the stroke volume remains lowered.

Illness at high altitude

Neurological and respiratory complications from high altitude occur in individuals who ascend rapidly and are not acclimatised. Acute mountain sickness (AMS) is seen in over a third of people who ascend to 3000 m. Serious illness includes high altitude pulmonary oedema (HAPE) and high altitude cerebral oedema (HACE), occurring in 0.1%–4% of people climbing over 4000 m. Prevention is essential and achievable through controlled ascents.

Acute mountain sickness

AMS is a syndrome comprised principally of non-specific symptoms including headache, fatigue, anorexia, nausea and vomiting, insomnia and dizziness. The pathophysiology of AMS is not fully understood, but it is thought that hypoxia results in vasodilation and increased capillary hydrostatic pressure causing a fluid leak and a raised intracranial venous volume with risk of raised intracranial pressure. There is believed to be an increase in cerebrospinal fluid (CSF production with a reduced buffering capacity. Non-acclimatised individuals show impaired gas exchange and a lower degree of hyperventilation, alongside fluid retention and a heightened sympathetic activation. Symptoms can occur within 4 hours, with the diagnostic definition specifying an ascent to > 2500 m within the prior 4 days. The symptoms can vary in severity, from trivial to completely incapacitating.

Management

Treatment of mild cases consists of rest and symptomatic control with simple analgesia; symptoms usually resolve after 1–3 days at a stable altitude, but may recur with further ascent. Occasionally there is progression to cerebral oedema (HACE). Persistent symptoms indicate the need to descend, which is considered the definitive treatment.

Medication options include acetazolamide and dexamethasone. Acetazolamide is used in both the prophylaxis of AMS and as a treatment option. It works as a carbonic anhydrase inhibitor in the kidneys, increasing bicarbonate excretion and inducing a metabolic acidosis, thereby offsetting the hyperventilation-induced alkalosis seen at altitude. It also decreases CSF production, reducing intracranial pressure and risk of progression to HACE. Ideal dosing strategies are 125 mg twice daily for prophylaxis in low/moderate risk ascent profiles with consideration for 250 mg twice daily for high risk profiles. Treatment dose is 250 mg twice daily. Dexamethasone (4 mg 6 hourly) moderates capillary leak and reduces the inflammatory response, improving symptoms to allow for a safe descent.

High altitude cerebral oedema

HACE is considered a severe sequela of AMS, presenting as ataxia or cognitive impairment in addition to the symptoms described above. It very rarely occurs without being preceded by milder AMS symptoms, making early recognition and treatment of AMS essential. Untreated HACE can progress to coma and death within 24 hours.

Management

Management is directed at improving oxygenation with supplemental oxygen, aiming to raise SpO_2 to > 90%. Descent is essential and dexamethasone (8 mg immediately, followed by 4 mg four times daily) should be given. If descent is impossible, descent can be simulated with the use of portable hyperbaric chambers, such as a Gamow bag. Use of these devices, however, can be difficult in patients with vomiting or a reduced level of consciousness.

High altitude pulmonary oedema

HAPE is a life-threatening condition that usually occurs in the first 4 days after ascent above 2500 m and is the leading cause of mortality from high altitude illness. It is defined as an imbalance of hydrostatic pressure within the alveoli with no evidence of inflammatory changes. Hypoxic pulmonary vasoconstriction causes alveolar capillary stress failure and subsequent pulmonary hypertension. This results in capillary fluid leak, which is exacerbated by exercise and compounded by impaired epithelial sodium transport, normally essential for fluid reabsorption. Initial symptoms include a dry cough, exertional dyspnoea and extreme fatigue. Later, the cough becomes wet with haemoptysis and orthopnoea. Tachycardia and tachypnoea occur at rest and crepitations may often be heard in both lung fields. Fever may also be present. There may be profound hypoxaemia and radiological evidence of diffuse alveolar oedema (Fig. 13.6). HAPE may occur without the preceding signs of AMS, although around 50% of patients with HAPE have concurrent AMS and 14% have HACE.

Management

Treatment is directed at reversal of hypoxia, with immediate descent (by a minimum of 1000 m) and oxygen administration targeting saturations > 90%. A portable hyperbaric chamber should be used if descent is

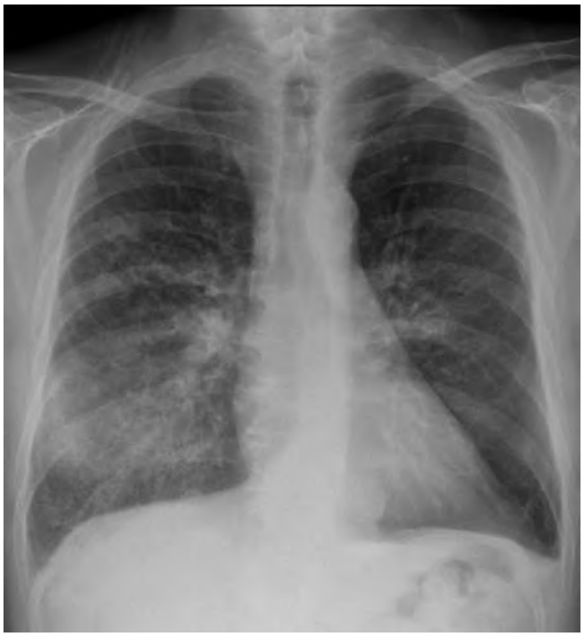

Fig. 13.6 X-ray of a climber with high altitude pulmonary oedema.

delayed. Nifedipine (30 mg modified release twice daily) is recommended prophylactically, only for those with a history of HAPE, starting 1 day before ascent above 2500 m and continued until the individual has spent 4 days at highest elevation or descends. The Wilderness Medical Society guidelines 2024 state that nifedipine (20 mg modified release 6 hourly) can be considered as an adjunct only when descent is delayed or access to oxygen and hyperbaric chambers is unavailable.

Subaquatic medicine

Drowning

Drowning remains a leading cause of death globally and is defined as 'the process of experiencing respiratory impairment from submersion or immersion in liquid'. Immersion refers to the upper airway being above the water surface and submersion below. The definition of drowning does not require death, and therefore the terms 'fatal' and 'non-fatal' drowning should be used. The drowning process involves initial breath holding, followed by a period of laryngospasm. Gas exchange is prevented resulting in hypoxia, hypercarbia and acidosis. Respiratory movements are stimulated by the respiratory centre due to hypercarbia; however, the laryngospasm results in obstruction of the airway. The laryngospasm eventually falters with continued hypoxia resulting in the aspiration of liquid of a variable amount, usually < 4 mL/kg.

Aspiration of either saltwater or freshwater results in changes to the alveolar surfactant and the alveolar capillary barrier causing atelectasis, ventilation–perfusion mismatch and hypoxia. Saltwater is hypertonic, resulting in bronchoconstriction, inflammation and pulmonary oedema; aspiration of 2.5 mL/kg of seawater results in a 75% increase in right-to-left shunting of deoxygenated blood. Fresh water is hypotonic and generally absorbed through the pulmonary circulation, entering the systemic circulation and damaging the alveolar capillary membrane. This can also generate foam, which further decreases ventilation efficiency. The clinical significance of swallowing water into the stomach during the drowning process remains unclear. Clinically significant electrolyte abnormalities from aspiration and swallowing of both hypotonic and hypertonic fluids are uncommon, requiring > 22 mL/kg of fluid, although both hyper- and hyponatraemia have been described.

Most drownings occur in cold water, resulting in body cooling; water is thermoneutral around 35°C. The historical term 'dry-drowning' refers to the 10% of fatal drownings that are documented to have 'macroscopically dry lungs' on examination, attributed to laryngospasm. This remains controversial but is no longer felt to be true, with newer evidence demonstrating the presence of microscopic liquid in the lungs of all fatal drownings. 'Secondary drowning', referring to patients who develop acute respiratory distress syndrome (ARDS), is now also considered a misnomer, as ARDS is a recognised complication of the drowning process.

Cold shock

The cold shock response is believed to be responsible for many drowning deaths. Sudden cold-water immersion results in an uncontrolled reflex inspiratory gasping, hyperventilation with profound hypocapnia and tachycardia from activation of peripheral subepidermal cold receptors. There is a 75% reduction in breath-hold time, which can therefore result in the aspiration of water. The response is maximal at water temperatures of 10–15°C and peaks within the first 30 seconds of immersion, waning over 2–3 minutes. Continued immersion then results in physical incapacitation from neuromuscular cooling, with peripheral paralysis occurring at regional limb temperatures of 5–15°C. Hypothermia develops after around 30 minutes in cold water but has many variables, such as body habitus, clothing and water state as examples.

Autonomic conflict

Simultaneous positive and negative chronotropic triggers are considered arrhythmogenic. Bradycardia from vagal stimulation (initiated when face down in water – dive reflex) coupled with a tachycardia from sympathetic activation (cold, stress or exercise) can generate arrhythmias in previously healthy individuals and can be fatal in those with structural cardiac abnormalities.

Pre-hospital management

In-water CPR and rescue breaths are no longer recommended. In-water rescue is not recommended for untrained individuals – remember 'Reach, Throw, Row, Don't Go'. If extracting someone from the water following prolonged immersion, the patient should be kept horizontal to prevent post-immersion hypotension; the loss of hydrostatic pressure that the water was applying can result in venous pooling and a sudden circulatory collapse. The patient should be kept warm, with life support commenced at the earliest opportunity. Cervical spine precautions should be considered, as there may be a traumatic precursor to the drowning incident (e.g. tombstoning), although these injuries are uncommon (0.5% of cases). Postural drainage techniques to try to clear fluid from the lungs have no proven benefit.

In-hospital management

Treatment is often focused on re-warming and organ support, including non-invasive ventilation (continuous positive airway pressure, CPAP) and protective lung ventilation strategies for acute lung injury/ARDS. Prolonged immersion can result in hypovolaemia due to the hydrostatic pressure effect of water, and the patient may require intravenous fluid. Prophylactic antibiotics are not recommended unless submersion was in grossly contaminated water. Guidelines suggest that asymptomatic patients with no respiratory compromise, a normal chest X-ray and normal arterial blood gas can be discharged home after 6–8 hours' observation. The arterial blood gas in an asymptomatic patient is arguably excessive, and discharge on scene criteria are described in the literature but are beyond the scope of this chapter.

CPR modifications

Five initial rescue ventilations are recommended given the hypoxic nature of a cardiac arrest in drowning. The patient's chest should be dried before application of defibrillation pads; however, less than 5% of drowned patients are in a shockable rhythm. The common progression of cardiac rhythm is from bradycardia, to pulseless electrical activity, to asystole. Submersion in ice-cold water (less than 6°C) may confer improved survival due to neuroprotection from rapid brain cooling before the onset of severe hypoxia; children in particular appear to have greater protection, believed in part to be due to a greater surface area to mass ratio allowing quicker cooling. For submersion times greater than 30 minutes in water warmer than 6°C, resuscitation is likely to be futile. If water temperature is below 6°C, resuscitation is likely to be futile following a submersion over 90 minutes long. Submersion within a vehicle may prolong these times due to the potential presence of an air bubble. International guidelines do vary on the futility associated with submersion duration. The overall mortality of drowned patients who present in cardiac arrest is 93%.

Decompression illness

Changes in environmental pressure (as seen in diving) can result in decompression illness due to intravascular or extravascular bubbles, the clinical manifestations of which include both arterial gas embolism and decompression sickness. Diagnosis of decompression illness is based on the history and clinical features in patients following a dive; 90% of cases are symptomatic within 6 hours; however, delays up to 72 hours are described.

A brief review of the physics and physiology of diving is essential in understanding the medical issues encountered. The two most important gas laws are Boyle's law and Henry's law (Fig. 13.7).

Decompression sickness

Nitrogen bubble formation on ascent can cause direct mechanical damage to the vascular endothelium and an inflammatory response. The bubbles occur almost anywhere in the body; therefore, the clinical presentation is broad, ranging from malaise and headache to paraesthesiae,

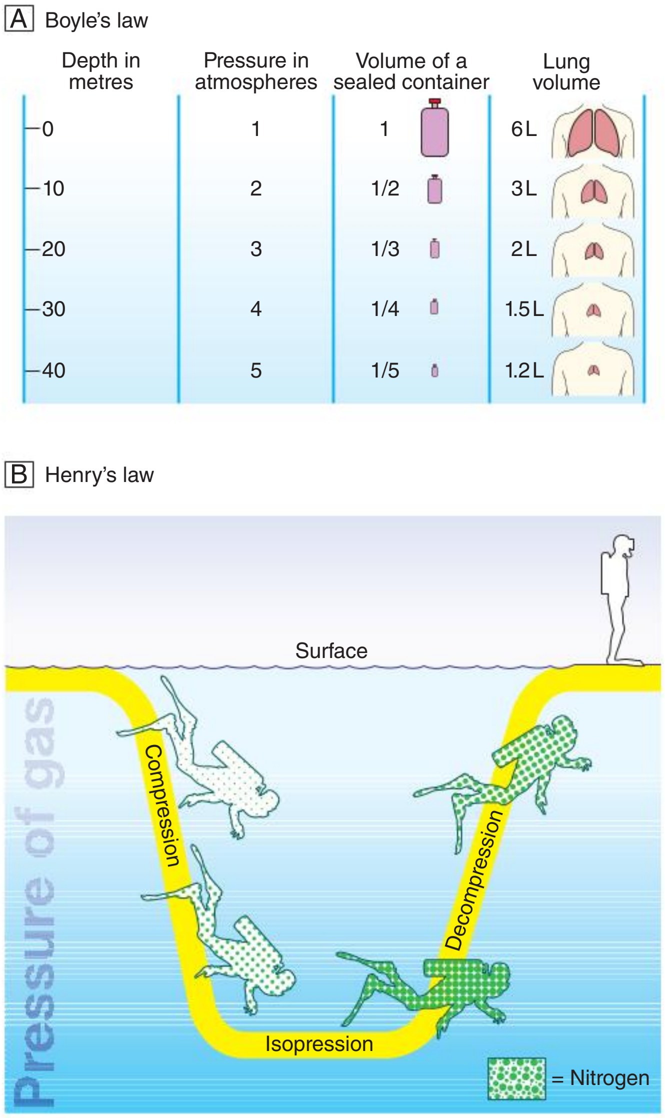

Fig. 13.7 **Boyle's law and Henry's law.** **A** Boyle's law: The volume of a gas is inversely proportional to the pressure. Atmospheric pressure increases with depth, increasing by 1 atmosphere for each 10 m of depth in water. During diving this increasing pressure compresses the gas within the human body, including the lungs, ears, sinuses and bowels. During ascent this gas expands and can cause barotrauma if the ascent is too rapid. **B** Henry's law: The amount of gas that dissolves in a liquid is proportional to the partial pressure of the gas. Nitrogen is not metabolised by the body and increasingly dissolves into the blood on descent. The reverse occurs on ascent, which if ascending too quickly can cause bubbles to form, resulting in decompression sickness.

lymphoedema, rash, joint pain and neurological manifestations including ataxia, paralysis and altered mentation. The overall incidence is low (0.03%) for recreational divers. Decompression sickness is very uncommon for diving depths less than 10 m and is normally seen following multiple dives.

Arterial gas embolism

Expanding gases during ascent from diving, from depths as little as 1 m, can rupture the alveolar capillary membrane (barotrauma), introducing alveolar gas into the arterial circulation. The brain is the most commonly affected organ. Small venous gas emboli are common with diving and usually are of no clinical consequence due to pulmonary capillary filtering. A patent foramen ovale is seen in around a quarter of the population, which can result in these emboli transferring to the arterial circulation, causing neurological sequelae. Overall, the risk of arterial gas embolism is rare, representing only around 4% of documented decompression illnesses. Risks include rapid ascents, breath holding and pre-existing pulmonary disease. If there is rapid onset of neurological signs, including seizures or a reduced consciousness following ascent, arterial gas embolism should be suspected.

Management

Any obtunded patient should have appropriate first aid. Definitive treatment for decompression illness is providing 100% oxygen to wash out gas from the tissues to the lungs and remove bubbles. This should be instigated for all patients regardless of their oxygen saturations.

Chamber recompression is the gold standard therapy and should be performed as soon as possible, causing a theoretical crushing of bubbles (as per Boyle's law) and providing improved oxygenation to damaged tissues. Extraction to a recompression chamber may require aeromedical retrieval, and helicopters at low altitude (less than 300 m) or those with cabins pressurised to 1 atmosphere are recommended. In-water recompression is controversial and is recommended only for divers, including the patient, with specific training in decompression procedures underwater. Previous recommendations of a head-down position to stop cranial spread of bubbles is no longer recommended due to the increased risk of cerebral oedema; patients should be kept horizontal. One litre of intravenous fluid should be given to correct the intravascular fluid loss from endothelial bubble injury and dehydration associated with immersion. Analgesia should be avoided; non-steroidal anti-inflammatory drugs can result in haemorrhage whilst opiates raise the risk of oxygen toxicity. The Divers Alert Network can be contacted for international advice and support.

Immersion pulmonary oedema

Immersion pulmonary oedema can affect surface swimmers as well as divers and is believed to be a leading cause of death during the swim stage of triathlons, previously felt to be due to drowning. Immersion results in exposure to hydrostatic pressure, which collapses veins and redistributes blood to the thorax, causing increased preload, cardiac contractility and stroke volume. Rising pulmonary alveolar capillary pressure results in a fluid shift into the lung interstitium initially, followed by the alveoli. This is normally balanced by the release of natriuretic peptides (ANP and BNP) causing a natriuresis and diuresis; however, in immersion pulmonary oedema this compensation is overwhelmed. Risk factors include overhydration, overexertion, heart disease, hypertension and cold water, all resulting in raised ventricular filling pressures. Breathing into a snorkel or scuba equipment can result in higher negative pressures in the alveoli with a subsequent greater fluid transudation into them (the opposite of positive pressure ventilation used to treat pulmonary oedema). Symptoms range from shortness of breath to haemoptysis and frothy sputum, generally occurring within 10 minutes of starting swimming, and of variable onset with diving. Treatment involves extraction from the water to remove the hydrostatic pressure, which in turn decreases ventricular filling pressures. Patients should be kept warm to prevent vasoconstriction, sat upright and given 100% oxygen. In-hospital management involves a combination of vasodilators (nitrates), diuretics and positive-pressure ventilation (CPAP). Recurrence rates are around 30%.

Shallow-water blackout

This condition refers to the loss of consciousness underwater when hyperventilation is followed by breath holding. It generally occurs in water less than 5 m in depth and can affect even experienced swimmers. Hyperventilation (as rapid shallow breaths before diving) preceding a breath hold lowers the arterial CO_2 and delays the hypercarbic stimulus to breathe, which may not occur before hypoxaemia and unconsciousness develop. Unconsciousness usually occurs on ascent as the hydrostatic pressure decreases, reducing the thoracic shunting of blood and gas exchange, coupled with a decreasing partial pressure of oxygen (Boyle's law) and resulting in a significant hypoxaemia.

Multiple Choice Questions

13.1 You are part of a search and rescue team looking for a trapped skier following an avalanche 20 minutes prior. On finding the patient you are instructed by the team leader to move them very carefully, to not induce a cardiac arrhythmia. Below what core temperature can ventricular fibrillation be induced from excessive movement?
A. 36°C
B. 32°C
C. 35°C
D. 30°C
E. 33°C

Answer: D.

As the core temperature falls, there is a reduction in cardiac output with initial maintenance of stroke volume. At around 28°C the heart rate is reduced by 50%. Initial conduction abnormalities include a sinus bradycardia, progressing to slow atrial fibrillation (AF) and then to ventricular fibrillation (VF). VF may be induced below 30°C with excessive stimulation/movement, which is why handling of hypothermic patients needs to be performed with great care.

13.2 You are working as a medic for a 100-mile ultramarathon. Environmental conditions are wet (moderate rain), with a temperature of 8°C. You are asked to see a competitor who has come into the medical tent after 12 hours of running. The competitor is drowsy, confused and is not shivering. Blood sugar is normal. You do not have access to a rectal thermometer. Using the Swiss Staging System, quantify the possible degree of hypothermia for this patient.
A. < 24°C
B. 28–31°C
C. 24–27°C
D. 32–35°C
E. 35–36°C

Answer: B.

Traditionally, hypothermia is categorised as mild (32–35°C), moderate (28–32°C) and severe (< 28°C); however, newer staging systems, such as the Swiss Staging System, adopted by some ambulance services, define the level of hypothermia based on symptoms (see Fig. 13.2). This has been shown to overestimate the degree of hypothermia in around 20% of cases but remains a helpful classification when an accurate core temperature cannot be obtained.

13.3 Which of the following statements is true for adaptations to resuscitation algorithms for hypothermic patients in cardiac arrest?
A. Withhold all shocks – chance of shockable rhythm < 5%
B. Signs of life should be checked for 30 seconds rather than 10 seconds
C. Do not warm hypothermic patients in cardiac arrest – the hypothermia is neuroprotective
D. Withhold medications (adrenaline, amiodarone etc.) until core temperature > 30°C and double the interval time between doses for core temperatures between 30°C and 35°C
E. A potassium level of 7 mmol/L is diagnostic of resuscitation futility

Answer: D.

There are a number of adaptations to resuscitation algorithms for hypothermic patients in cardiac arrest. Assessment for signs of life should be extended to 1 minute. Ventricular fibrillation and ventricular tachycardia can be defibrillated; however, if after three shocks there is no response, additional shocks should be delayed until core temperature is greater than 30°C. Stacked shocks are not recommended. Withhold adjunctive medications (adrenaline, amiodarone etc.) if the patient is below 30°C, and double the interval time between doses between 30°C and 35°C. Markers of futility include: obvious lethal injury, prolonged asphyxia (mouthful of snow etc.), incompressible thorax (distinct from a stiff chest which is common), frozen abdomen or potassium > 12 mmol/L.

13.4 With regards to freezing cold injury (frostbite), which of the following statements around management is correct?
A. The affected area should always be rewarmed immediately in the pre-hospital environment
B. Early amputation is the gold standard therapy
C. Rubbing of the area with direct application of heat pads to thaw the affected region is recommended
D. Analgesia is not required; freezing injuries are not painful
E. Aspirin 75 mg and ibuprofen 400 mg 8 hourly are recommended

Answer: E.

If concerned about the possibility of cold injury, immediate pre-hospital treatment is to try to shelter from the environment, consume warm drinks, remove shoes, wet clothing and jewellery and re-dress in warm, dry clothing. If there is absolutely no risk of re-freezing then warming the area can be achieved by placing the area into a companion's armpit or groin. Aspirin 75 mg and ibuprofen 400 mg 8 hourly are recommended. Do not rub the area and do not place heat sources directly onto the area. Evacuation for formal medical review should be obtained. Warmed areas need to be made non-load-bearing and therefore prior thought about extraction needs to be considered. Aloe vera gel has anti-prostaglandin effects and can be applied before application of a non-adherent dressing, splinting and elevation of the affected region.

Definitive warming involves placing the affected area into circulating water between 37°C and 42°C with small amounts of antiseptic for around an hour, avoiding contact with the sides of the container. Additional treatment involves fluid replacement with warmed fluids (due to cold diuresis), strong analgesia and blister care. Blisters may present as clear, cloudy or haemorrhagic. Blister management remains controversial, with current evidence recommending débridement of all blisters in hospital (likely under a general anaesthetic) to improve wound healing. There is no evidence for prophylactic antibiotics, and tetanus should be given following local protocols; frostbite wounds are not considered tetanus-prone.

13.5 The most readily modifiable physiological risk factor for the development of heat illness is:
A. Obesity
B. Hydration
C. Acclimatisation
D. Use of β-blockers
E. Aerobic fitness

Answer: B.

The 2024 Wilderness Medical Society heat illness guidelines identify hydration as the 'most readily modifiable physiologic risk factor'. Fluid ingestion is also identified as the most effective approach to mitigate the rise in core temperature amongst athletes. Military guidelines recommend a 0.25–1.25 L/hr hydration strategy that varies for work rates (low/medium/high/very high) at a given wet bulb globe temperature (WBGT).

13.6 The definition of heat stroke is:
- A. Mild swelling to the limbs during the first few days of heat exposure due to increased plasma volume
- B. Neurological impairment with core body temperature ≥ 40°C
- C. A transient loss of consciousness in the context of heat exposure with a relatively rapid return to normal function and baseline
- D. An inability to continue an activity due to heat stress
- E. Body spasms related to sodium loss

Answer: B.

Heat-related illness defines a spectrum of pathology from benign heat oedema to lethal heat stroke. The definition of heat stroke is: neurological impairment with core body temperature ≥ 40°C (rectal temperature is gold standard in a pre-hospital environment). Symptoms can involve a coarse muscle tremor, confusion, aggression and loss of consciousness. Sweating may be absent due to dehydration and failure of thermoregulatory mechanisms.

13.7 You are working on an expedition in the Costa Rican jungle. The expedition leader asks you theoretically what the best cooling strategy is for patients with heat stroke. In your current location you only have access to cold water. You suggest:
- A. Removing the patient into the shade
- B. Calling for a helicopter to use the downwash from the blades
- C. Forcing the patient to drink cold water
- D. Spraying the patient with cool water and using a combination of evaporative and convective heat loss
- E. Ice water immersion

Answer: D.

A number of cooling strategies exist and their implementation will depend on what is feasible within each particular environment. Two meta-analyses have concluded that ice water immersion is the most effective treatment strategy, with cooling rates of 0.20°C–0.35°C/min for iced water and 0.11°C/min for wet towels. Immersion is unlikely to be feasible in the wilderness environment and in many hospitals, with further consideration for the dangers of potentially immersing a patient with a reduced conscious level.

The placement of ice/cold packs in the axillae, groin and neck has been recommended as an easy method to use in the field, but when compared with evaporative cooling in five healthy subjects, cooling times were longest when the ice packs were used alone and shortest when both methods were used simultaneously. Evaporative cooling involves the removal of clothing, spraying tepid or cool water over the patient, and facilitating evaporation and convection with the use of a fan.

13.8 You are working on an expedition on Mont Blanc and are asked to see a patient who at 3500 m has developed a wet cough with frothy sputum. The patient is tachycardic with a high respiratory rate, and you hear bibasal crepitations in both lungs. The patient insists they have mild acute mountain sickness, which they have had previously, and wants to continue to summit. They have taken no prophylactic medications. What is the most appropriate plan?
- A. The patient likely has high altitude pulmonary oedema and should immediately descend by at least 1000 m alongside giving high-flow oxygen
- B. The patient is most likely correct and has mild acute mountain sickness and should be allowed to summit
- C. The patient has high altitude cerebral oedema and should be given 8 mg of dexamethasone and then start to descend
- D. The patient has no evidence of high altitude illness, and the findings are consistent with normal physiological changes at altitude. No action is required
- E. The patient has severe acute mountain sickness and should remain at their current altitude for 2–3 days

Answer: A.

HAPE is a life-threatening condition that usually occurs in the first 4 days after ascent above 2500 m and is the leading cause of mortality from high altitude illness. Hypoxic pulmonary vasoconstriction causes alveolar capillary stress failure and subsequent pulmonary hypertension. This results in capillary fluid leak, which is exacerbated by exercise and compounded by impaired epithelial sodium transport, normally essential for fluid reabsorption. Initial symptoms include a dry cough, exertional dyspnoea and extreme fatigue. Later, the cough becomes wet with haemoptysis and orthopnoea. Tachycardia and tachypnoea occur at rest and crepitations may often be heard in both lung fields. Fever may also be present. There may be profound hypoxaemia and radiological evidence of diffuse alveolar oedema. HAPE may occur without the preceding signs of AMS, although around 50% of patients with HAPE have concurrent AMS and 14% have HACE.

Treatment is directed at reversal of hypoxia, with immediate descent (by a minimum of 1000 m) and oxygen administration targeting saturations > 90%. A portable hyperbaric chamber should be used if descent is delayed. Nifedipine (30 mg modified release twice daily) is recommended prophylactically, only for those with a history of HAPE, starting 1 day before ascent above 2500 m and continued until the individual has spent 4 days at highest elevation or descends. The Wilderness Medical Society guidelines 2024 state that nifedipine (20 mg modified release 6 hourly) can be considered as an adjunct only when descent is delayed or access to oxygen and hyperbaric chambers is unavailable.

13.9 You are working in an emergency department and are asked to review a 17-year-old male patient who 1 hour prior aspirated some water whilst swimming in the sea and was rescued by members of the public, who described initial panicking and respiratory impairment. The patient appears well, with normal observations. The most appropriate plan is:
- A. The patient is suitable for discharge with no evidence of ongoing respiratory distress
- B. The patient is suitable for discharge following a normal chest X-ray
- C. The patient is suitable for discharge following 6–8 hours' observation if his observations remain normal, with a normal chest X-ray ± normal arterial blood gas
- D. The patient should be admitted for 72 hours to observe for delayed acute respiratory distress syndrome (ARDS)
- E. The patient does not need to be seen in an emergency department and should be discharged home without review

Answer: C.

Drowning is defined as 'the process of experiencing respiratory impairment from submersion/immersion in liquid'. Asymptomatic patients with no respiratory compromise, a normal chest X-ray and normal arterial blood gas can be discharged home after 6–8 hours' observation.

13.10 You are on holiday on a beach and see a 50-year-old female swimmer in difficulty. She is dragged from the water by a first aider on scene and is currently lying on her back in the shallow water with small waves breaking over her. She is alert but is coughing frequently, with a fast respiratory rate. The first aider does not wish to move the patient due to the risk of a cervical spine injury. The most appropriate plan is:

A. Assist the first aider by applying cervical spine immobilisation and wait for an ambulance to arrive with a scoop
B. Drag the patient up the beach out of the water to prevent further aspiration or development of hypothermia
C. Acknowledge the first aider's concern, but reassure that the risks are low (0.5%) for a cervical injury, and it would be safest to ask the patient to move with help up the beach
D. Do nothing, the patient is clearly alert and breathing and no further intervention is required
E. Administer 5 rescue breaths, followed by raising the patient's body above their head to allow for postural drainage of water from the lungs

Answer: C.

The safest option is to remove the patient from the water due to the ongoing risk of further aspiration and ongoing cooling with subsequent hypothermia. Risk of cervical spine injury is low (0.5%). Asking the patient if they are able to move up the beach with support is the most appropriate initial step. Postural drainage techniques are not recommended, with no evidence of benefit.

i Fever

Documentation of fever

- Symptoms of feeling 'hot', 'feverish' or 'sweaty' do not necessarily signify fever – diagnose only when a body temperature of over 38.0°C is recorded
- Axillary and aural measurement is less accurate than oral or rectal
- Outpatients may be trained to keep a home temperature chart

Rigors

- Shivering (followed by excessive sweating) occurs with a rapid rise in body temperature from any cause

Night sweats

- Associated with particular infections (e.g. TB, infective endocarditis); sweating from any cause is worse at night

Excessive sweating

- Alcohol, anxiety, thyrotoxicosis, diabetes, acromegaly, lymphoma and excessive environmental heat all cause sweating without temperature elevation

Recurrent fever

- There are various causes, e.g. *Borrelia recurrentis*, bacterial abscess

Accompanying features

- Severe headache and photophobia, although characteristic of meningitis, may accompany other infections, including parameningeal infections such as sinusitis or mastoiditis
- Delirium during fever is more common in young children and older people
- Myalgia may occur with viral infections, such as influenza, and with sepsis including meningococcal sepsis
- Shock may accompany severe infections and sepsis

i History-taking in suspected infectious disease*

Presenting complaint

- Diverse manifestations of infectious disease make accurate assessment of features and duration critical; e.g. fever and cough lasting 2 days imply an acute respiratory tract infection but raise suspicion of TB if they last 2 months

Review of systems

- Must be comprehensive

Past medical history

- Define the 'host', comorbidities and likelihood of infection(s)
- Assessment of 'host' and comorbidities will suggest elements of the immune response that are dysfunctional, e.g. impaired neutrophil function with chemotherapy or diabetes. Defining comorbidities may highlight the system most likely to be the source of infection, e.g. spontaneous bacterial peritonitis in decompensated cirrhosis
- Include surgical and dental procedures involving prosthetic materials
- Document previous infections and antimicrobial-resistant infections

Medication history

- Include non-prescription drugs, use of antimicrobials and immunosuppressants
- Identify medicines that interact with antimicrobials or that may cause fever

Allergy history

- Esp. to antimicrobials, noting allergic manifestation (e.g. rash versus anaphylaxis)

Family and contact history

- Note infections and their duration
- Sensitively explore exposure to key infections, e.g. TB and HIV

Travel history

- Include countries visited (and transited through) and where previously resident (relevant to exposure and likely vaccination history, e.g. likelihood of BCG vaccination in childhood)

Occupation

- e.g. Anthrax in leather tannery workers

Recreational pursuits

- e.g. Leptospirosis in canoeists and windsurfers

Animal exposures

- Include pets, e.g. dogs/hydatid disease

Dietary history

- Consider under-cooked meats, shellfish, unpasteurised dairy products or well water
- Establish who else was exposed, e.g. to food-borne pathogens

History of intravenous drug injection or receipt of blood products

- Risks for blood-borne viruses, e.g. HIV-1, HBV and HCV

Sexual history

- Explore in a confidential manner (Ch. 15); remember, HIV-1 transmission is most frequently heterosexual

Vaccination history and use of prophylactic medicines

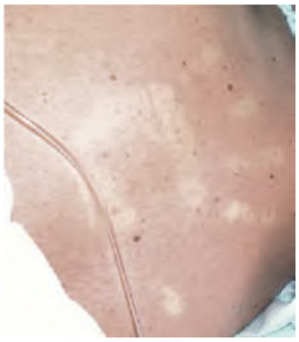
- Consider occupation- or age-related vaccines
- In a traveller or infection-predisposed patient, establish adherence to prophylaxis

*Always consider non-infectious aetiologies in the differential diagnosis.
(HBV/HCV = hepatitis B/C virus; HIV-1 = human immunodeficiency virus-1; TB = tuberculosis)

1 Skin lesions in infectious diseases

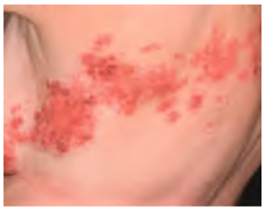
- Diffuse erythema, e.g. A
- Migrating erythema, e.g. enlarging rash of erythema migrans in Lyme disease (see Fig. 14.37)
- Purpuric or petechial rashes, e.g. B
- Macular or papular rashes, e.g. primary infection with HIV (see Box 14.34)
- Vesicular or blistering rash, e.g. C
- Erythema multiforme (see Fig. 26.54 and Box 26.32)
- Nodules or plaques, e.g. Kaposi sarcoma
- Erythema nodosum (D and Box 26.33)

A



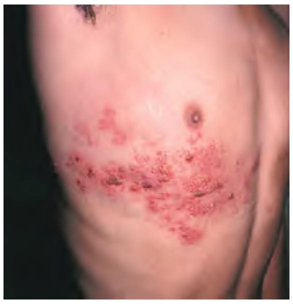
Streptococcal toxic shock syndrome.

B



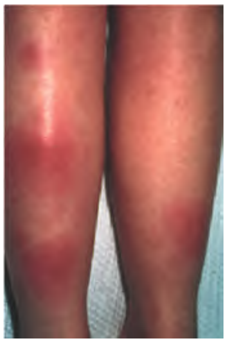
Herpes zoster. *From Michelettie RG, James WD, Elston DM, McMahon PJ. Andrews' diseases of the skin clinical atlas. 2nd ed. Elsevier; 2023.*

C



Herpes zoster on the anterior chest. *From James WD, Berger TG, Elston DM. Andrews' diseases of the skin. 11th ed. Saunders; 2011.*

D



Erythema nodosum.

(HIV = human immunodeficiency virus)

The principles of infection and its investigation and therapy are described in Chapter 7. This chapter, including human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) and the following chapter (Ch. 15) on sexually transmitted infection (STI), describe the approach to patients with potential infectious disease, the individual infections and the resulting syndromes.

Presenting problems in infectious diseases

Infectious diseases present with a myriad of clinical manifestations. Systems-based presentations and investigations are described in other chapters.

Fever

'Fever' implies an elevated core body temperature of more than 38.0°C. Fever is a response to cytokines and acute phase proteins (pp. 60 and 66), and occurs both in infections and non-infectious conditions.

Clinical assessment

The differential diagnosis is broad so clinical features are used to guide the most appropriate investigations. The systematic approach described in this chapter should be followed. Box 14.1 describes the assessment of older patients.

Investigations

If the clinical features do not suggest a specific infection, then initial investigations should include:

- a full blood count (FBC) with differential, including eosinophil count
- urea and electrolytes, liver function tests (LFTs), blood glucose and muscle enzymes (e.g. creatine kinase (CK))
- inflammatory markers: erythrocyte sedimentation rate (ESR), C-reactive protein (CRP) and/or procalcitonin (PCT) (depending on local use and availability)
- an HIV-1 antigen/antibody test
- autoantibodies, including antinuclear antibodies (ANA)
- chest X-ray (CXR) and electrocardiogram (ECG)
- urinalysis and urine culture
- blood culture
- throat swab for culture or respiratory pathogen nucleic acid detection (usually by polymerase chain reaction (PCR))
- other specimens, as indicated by history and examination, e.g. wound swab; sputum culture; stool culture, microscopy for ova and parasites, and *Clostridioides* (formerly *Clostridium*) *difficile* toxin assay
- specific tests and their priority, indicated by geographical location and travel: e.g. a malaria rapid diagnostic test (RDT) or malaria films on three consecutive days; a test for dengue (antigen detection) non-structural protein 1 (NS1); blood cultures for *Salmonella* Typhi, as well as abdominal ultrasound, would be standard initial tests in many areas where these geographically restricted infections are prevalent.

14.1 Fever in old age

- **Temperature measurement**: fever may be missed because oral temperatures are unreliable. Rectal measurement may be needed but core temperature is increasingly measured using eardrum reflectance.
- **Delirium**: common with fever, especially in those with underlying cerebrovascular disease or dementia.
- **Prominent causes of pyrexia of unknown origin**: include tuberculosis and intra-abdominal abscesses, complicated urinary tract infection and infective endocarditis. Non-infective causes include polymyalgia rheumatica/temporal arteritis and tumours. A smaller fraction of cases remain undiagnosed than in young people.
- **Diagnostic pitfalls**: conditions such as stroke or thromboembolic disease can cause fever, but every effort must be made to exclude concomitant infection.
- **Common infectious diseases in the very frail** (e.g. nursing home residents): pneumonia, urinary tract infection, soft tissue infection and gastroenteritis.

Subsequent investigations in patients with nosocomial or travel-related infections, immunocompromised patients or people with HIV are influenced by the principles in the sections that follow.

Management

Fever and its associated systemic symptoms can be treated with paracetamol, and tepid sponging to cool the skin. Replacement of salt and water is important in patients with drenching sweats either orally or intravenously. Further management is focused on the underlying cause.

Fever with localising symptoms or signs

In most patients, the site of infection is apparent after clinical evaluation, and the likelihood of infection is reinforced by investigation results (e.g. neutrophilia with raised CRP in bacterial infections). Not all apparently localising symptoms are reliable; however, headache, breathlessness and diarrhoea can occur in systemic infection, such as sepsis or malaria, without localised infection in the central nervous system (CNS), respiratory tract or gastrointestinal tract. Abdominal pain may be a feature of basal pneumonia. Careful interpretation of the clinical features is vital (e.g. severe headache associated with photophobia, rash and neck stiffness suggests meningitis, whereas moderate headache with cough and rhinorrhoea is consistent with a viral upper respiratory tract infection).

Common infections that present with fever are shown in Figure 14.1. Further investigation and management are specific to the cause but may include empirical antimicrobial therapy (Fig. 7.16) pending confirmation of the microbiological diagnosis.

Pyrexia of unknown origin

Pyrexia of unknown origin (PUO) was classically defined as a temperature above 38.0°C on multiple occasions for more than 3 weeks, without diagnosis, despite initial investigation in hospital for 1 week. The definition has been relaxed to allow for investigation over 3 days of inpatient care, three outpatient visits or 1 week of intensive ambulatory investigation. Subsets of PUO are described as HIV-1 related, immune-deficient or nosocomial.

Clinical assessment

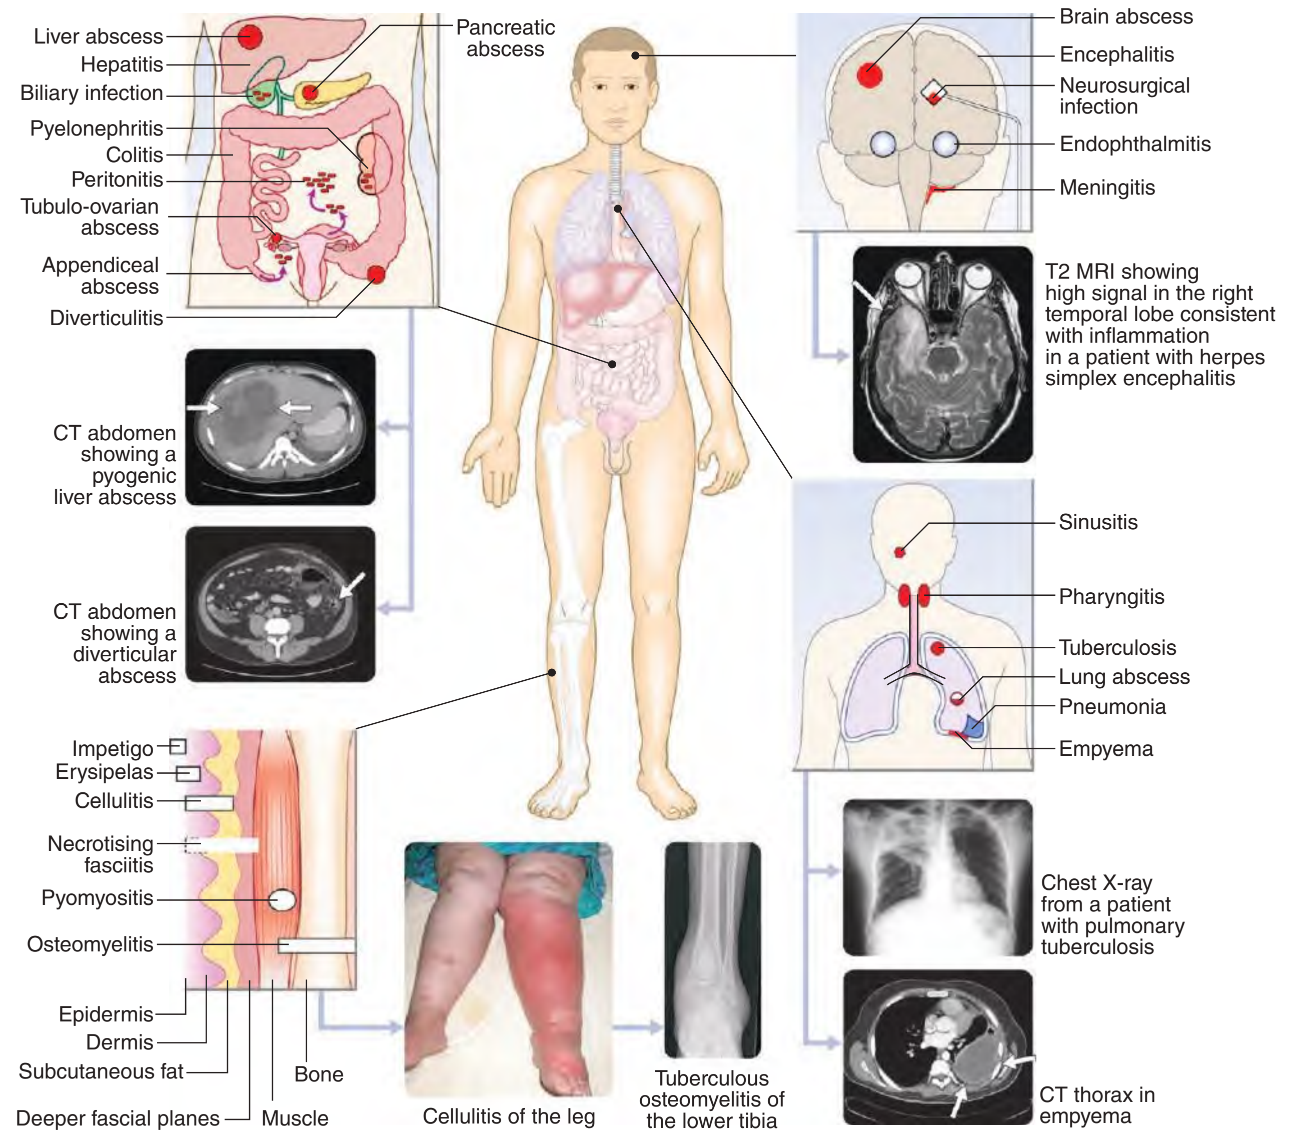
Major causes of PUO are outlined in Box 14.2. Periodic fever syndromes are rare causes that should be considered in those with a family history. Children and younger adults are more likely to have infectious causes. Older adults are more likely to have certain infectious and non-infectious causes (see Box 14.1). Detailed history and examination should be repeated at regular intervals to detect emerging features (e.g. rashes, signs of infective endocarditis or features of vasculitis). In men, the prostate should be considered as a potential source of infection.

Clinicians should be alert to the possibility of factitious fever, in which high temperature recordings are engineered by the patient (Box 14.3).

Investigations

If initial investigations are negative, further microbiological and non-microbiological investigations should be considered (Boxes 14.4, 14.5). As with initial investigation of fever described above, the prioritisation of tests will be influenced by the geographical location of potential exposure to pathogens (see Box 14.4). These will usually include:

- sputum or other specimens for mycobacterial stains and culture
- serological tests
- ferritin estimation
- imaging of the abdomen by ultrasonography or computerised tomography (CT)
- echocardiography (transthoracic and transoesophageal if indicated).



Liver abscess
Hepatitis
Biliary infection
Pyelonephritis
Colitis

Fig. 14.1 Common infectious syndromes presenting with fever and localised features. Major causes are grouped by approximate anatomical location and include central nervous system infection; respiratory tract infections; abdominal, pelvic or urinary tract infections; and skin and soft tissue infections (SSTIs) or osteomyelitis. For each site of infection, particular syndromes and their common causes are described elsewhere in the book. The causative organisms vary, depending on host factors, which include whether the patient has lived in or visited a tropical country or particular geographical location, has acquired the infection in a health-care environment or is immunocompromised. *Insets (cellulitis of the leg) Courtesy of Dr Ravi Gowda, Royal Hallamshire Hospital, Sheffield; (pulmonary tuberculosis) Courtesy of Dr Ann Chapman, Royal Hallamshire Hospital, Sheffield; (empyema, pyogenic liver abscess, diverticular abscess, tuberculous osteomyelitis) Courtesy of Dr Robert Peck, Royal Hallamshire Hospital, Sheffield.*

Estimation of ferritin can be informative. Levels > 1000 ng/mL can suggest adult-onset Still disease (characterised by fever, salmon-coloured macular rash and often arthralgia; see Ch. 25), and even higher levels with macrophage activation syndrome and the related condition haemophagocytosis lymphohistiocytosis (HLH), which is associated with certain connective tissue disorders, haematological malignancy and viral infections, e.g. Epstein–Barr virus infection (Ch. 24). Macrophage activation syndrome can present as fever accompanied by hepatosplenomegaly, lymphadenopathy, sepsis and disseminated coagulopathy.

Lesions identified on imaging should usually be biopsied using sterile technique in order to seek evidence of relevant pathogens by culture, histopathology or nucleic acid detection. Particularly in patients who have received prior antimicrobials, 16S rRNA analysis (Box 7.2) may aid diagnosis if a microorganism is not cultured. The chance of a successful diagnosis is greatest if procedures for obtaining and transporting the correct samples in the appropriate media are carefully planned between the clinical team, the radiologist or surgeon performing the procedure, and the local microbiologist and histopathologist. Fluorodeoxyglucose (FDG)-positron emission tomography (PET) scans may aid diagnosis of vasculitis or help selection of biopsy sites. Non-focused liver biopsy may be justified – for example, to identify idiopathic granulomatous hepatitis – if there are biochemical or radiological abnormalities. Bone marrow biopsies have a diagnostic yield of up to 15%, most often revealing haematological malignancy, myelodysplasia or tuberculosis, and also identifying brucellosis, typhoid fever or visceral leishmaniasis. Bone marrow should be sent for culture, as well as microscopy. Laparoscopy is occasionally undertaken with biopsy of abnormal tissues including peritoneum. Splenic aspiration in specialist centres is the diagnostic test of choice for suspected visceral leishmaniasis. Diagnostic tests for giant cell arteritis should be considered in patients over the age of 50 years even in the absence of physical signs or a raised ESR. 'Blind' biopsy of other structures in the absence of localising signs or laboratory or radiology results is usually unhelpful.

Prognosis

No cause is found in up to one-half of PUO cases, but as long as there is no significant weight loss or signs of another disease, the long-term mortality is low.

14.2 Aetiology of pyrexia of unknown origin (PUO)

Infections (~30%)

Specific locations
- Abscesses: hepatobiliary, diverticular, urinary tract (including prostate), pulmonary, CNS
- Infections of oral cavity (including dental), head and neck (including sinuses)
- Bone and joint infections
- Infective endocarditis

Specific organisms
- TB (particularly extrapulmonary)*
- HIV-1 infection
- Other viral infections: cytomegalovirus (CMV), Epstein–Barr virus (EBV)
- Fungal infections (e.g. *Aspergillus* spp., *Candida* spp. or dimorphic fungi)
- Infections with fastidious organisms (e.g. *Bartonella* spp., *Tropheryma whipplei*)

Specific patient groups
- Recently spent time in a region with geographically restricted infection:
  - Malaria*, dengue, rickettsial infections, *Brucella* spp., amoebic liver abscess, enteric fevers (Africa, Asia, Oceania, Central and South America), *Leishmania* spp. (southern Europe, India, Africa and Latin America), *Burkholderia pseudomallei* (South-east Asia), Middle East respiratory syndrome coronavirus (MERS-CoV; Arabian Peninsula)
- Residence in or travel to a region with endemic infection:
  - TB* (Africa, Asia, Central and South America), extensively drug-resistant TB (XDR-TB; South Africa), *Brucella* spp. (Africa, Asia, Central and South America), HIV-1 (Africa, Asia), *Trypanosoma cruzi* (Central and South America)
- Nosocomial infections:
  - Pneumonia*, infections related to prosthetic materials and surgical procedures, urinary tract infections, central venous catheter infections
- HIV-positive individuals:
  - Acute retroviral syndrome
  - AIDS-defining infections (disseminated *Mycobacterium avium* complex (DMAC), *Pneumocystis jirovecii* pneumonia, CMV and others)

Malignancy (~20%)

Haematological malignancy
- Lymphoma*, leukaemia and myeloma

Solid tumours
- Renal, liver, colon, stomach, pancreas

Connective tissue disorders (~15%)

Older adults
- Temporal arteritis/polymyalgia rheumatica*

Younger adults
- Still disease (juvenile rheumatoid arthritis)*
- Systemic lupus erythematosus (SLE)
- Vasculitic disorders, including polyarteritis nodosa, microscopic polyangiitis, rheumatoid disease with vasculitis and granulomatosis with polyangiitis (formerly known as Wegener granulomatosis)
- Polymyositis
- Behçet disease
- Rheumatic fever (in regions where still endemic, e.g. Asia, Oceania and parts of Africa)
- Macrophage activation syndrome

Miscellaneous (~20%)

Cardiovascular
- Atrial myxoma, aortitis, aortic dissection

Respiratory
- Sarcoidosis, pulmonary embolism and other thromboembolic disease, extrinsic allergic alveolitis

Gastrointestinal
- Inflammatory bowel disease, granulomatous hepatitis, alcoholic liver disease, pancreatitis

Endocrine/metabolic
- Thyrotoxicosis, thyroiditis, hypothalamic lesions, phaeochromocytoma, adrenal insufficiency, hypertriglyceridaemia

Haematological
- Haemolytic anaemia, paroxysmal nocturnal haemoglobinuria, thrombotic thrombocytopenic purpura, myeloproliferative disorders, Castleman disease, graft-versus-host disease (after allogeneic haematopoietic stem cell transplantation)

Inherited
- Familial Mediterranean fever and periodic fever syndromes

Drug reactions*
- e.g. Antibiotic fever, drug hypersensitivity reactions etc.

Factitious fever

Idiopathic (~15%)

*Most common causes within each group.
(AIDS = acquired immunodeficiency syndrome; CNS = central nervous system; HIV-1 = human immunodeficiency virus-1; TB = tuberculosis; XDR = extensively drug-resistant)

14.3 Clues to the diagnosis of factitious fever

- A patient who looks well
- Bizarre temperature chart with absence of diurnal variation and/or temperature-related changes in pulse rate
- Temperature > 41°C
- Absence of sweating during defervescence
- Normal erythrocyte sedimentation rate and C-reactive protein despite high fever
- Evidence of self-injection or self-harm
- Normal temperature during supervised (observed) measurement
- Infection with multiple commensal organisms (e.g. enteric or mouth flora)

Positive blood culture

Blood-stream infection (BSI) is a frequent presentation of infection. This can be community-acquired or hospital-acquired ('nosocomial'). Common causes are shown in Figure 14.2. In immunocompromised hosts, a wider range of microorganisms may be isolated, e.g. fungi.

Primary BSI refers to cases in which an extravascular source of infection (e.g. pneumonia or urinary tract infection) is not identified and is commonly caused by *Staphylococcus aureus*. In community-acquired *Staphylococcus aureus* bacteraemia, 20%–30% of cases are associated with infectious endocarditis and up to 10% with osteomyelitis. Peripheral and central venous catheters are an important source of nosocomial BSI.

BSI has an associated mortality of 15%–40%, depending on the setting, host and microbial factors.

Clinical assessment

The history should determine the setting in which BSI has occurred. Host factors predisposing to infection include skin disease, diabetes, injection drug use, the presence of a central venous, urinary or haemodialysis catheter, and surgical procedures, especially those involving the implantation of prosthetic materials (in particular, endovascular prostheses).

Physical examination should focus on signs of infective endocarditis (p. 498), evidence of bone (especially spinal) or joint infection (tenderness or restriction of movement), and abdominal or flank tenderness. Central venous catheters should be examined for erythema or purulence at the exit site. Particularly in cases with *Candida* spp. infection or suspected infectious endocarditis, fundoscopy after pupil dilatation should be performed.

Investigations

Positive blood cultures may be caused by contamination. When isolated from only one bottle, or from all bottles from one venesection, coagulase-negative staphylococci often represent contamination. Repeated isolation of coagulase-negative staphylococci, however, should raise suspicion of infective endocarditis or, in a patient with any form of prosthetic material, prosthesis infection. Viridans streptococci occasionally cause transient non-significant bacteraemia or blood culture contamination but,

14.4 Microbiological investigation of pyrexia of unknown origin[1]

Location-independent investigations

Microscopy

- Blood for atypical lymphocytes (EBV, CMV, HIV-1, hepatitis viruses or *Toxoplasma gondii*)
- Respiratory samples for mycobacteria and fungi
- Stool for ova, cysts and parasites
- Biopsy for light microscopy (bacteria, mycobacteria, fungi) and/or electron microscopy (viruses, protozoa (e.g. microsporidia) and other fastidious organisms (e.g. *Tropheryma whipplei*))
- Urine for white or red blood cells and mycobacteria (early morning urine ×3)

Culture

- Aspirates and biopsies (e.g. joint, deep abscess, débrided tissues)
- Blood, including prolonged culture and special media conditions
- Sputum for mycobacteria
- CSF
- Gastric aspirate for mycobacteria
- Stool
- Swabs
- Urine ± prostatic massage in older men

Antigen detection

- Blood, e.g. HIV p24 antigen (usually combined with an antibody test), cryptococcal antigen, *Aspergillus* galactomannan ELISA and (1,3)-β-D-glucan (for fungi other than mucoraceous moulds and *Cryptococcus*)
- CSF for cryptococcal antigen
- Bronchoalveolar lavage fluid for *Aspergillus* galactomannan
- Nasopharyngeal aspirate/throat swab for respiratory viruses, e.g. IAV or RSV
- Urine, e.g. for *Legionella* antigen

Nucleic acid detection

- Blood for *Bartonella* spp. and viruses
- CSF for viruses and key bacteria (meningococcus, pneumococcus, *Listeria monocytogenes*)
- Nasopharyngeal aspirate/throat swab for respiratory viruses
- Sputum for *Mycobacterium tuberculosis* (MTB) and rifampicin (RIF) resistance with geneXpert MTB/RIF cartridge-based nucleic acid amplification test (NAAT)
- Bronchoalveolar lavage fluid, e.g. for respiratory viruses
- Tissue specimens, e.g. for *T. whipplei*
- Urine, e.g. for *Chlamydia trachomatis*, *Neisseria gonorrhoeae*
- Stool, e.g. for norovirus, rotavirus

Immunological tests

- Serology (antibody detection) for viruses, including HIV-1, and some bacteria
- Interferon-gamma release assay for diagnosis of exposure to tuberculosis (but note this will not distinguish latent from active disease and can only be used to trigger further investigations of active disease)

Geographically restricted tests[2]

Microscopy

- Blood for trypanosomiasis, malaria and *Borrelia* spp.
- Stool for geographically restricted ova, cysts and parasites
- Biopsy for light microscopy (dimorphic fungi, *Leishmania* spp. and other parasites)
- Urine for red blood cells and schistosome ova

Antigen detection

- Blood, e.g. dengue virus NS1 antigen, *Histoplasma* antigen (restricted availability) and malaria antigen (e.g. HRP-2 for *Plasmodium falciparum* or parasite-specific LDH for *P. falciparum* and *P. vivax*)

Nucleic acid detection

- Blood for causes of viral haemorrhagic fever
- CSF for geographically restricted viruses, e.g. Japanese encephalitis virus
- Nasopharyngeal aspirate/throat swab or bronchoalveolar lavage fluid for geographically restricted respiratory viruses, e.g. MERS-CoV

Immunological tests

- Serology (antibody detection) for viruses, dimorphic fungi and protozoa

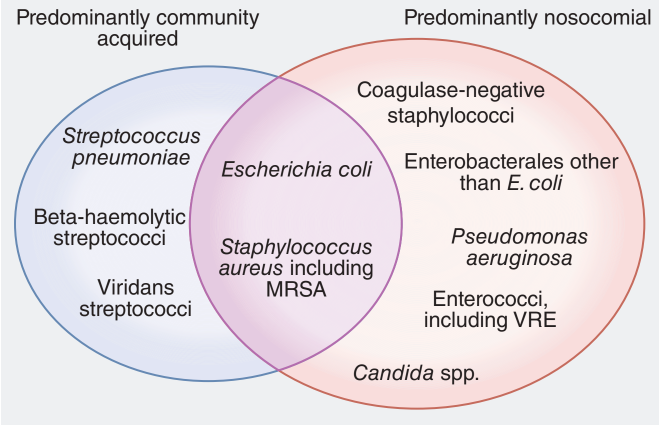
[1] This list does not apply to every patient with a pyrexia of unknown origin. Appropriate tests should be selected in a stepwise manner, according to specific predisposing factors, epidemiological exposures and local availability, and should be discussed with a microbiologist.

[2] Addition of these tests should be guided by the location of presentation or travel history.

(CMV = cytomegalovirus; CSF = cerebrospinal fluid; EBV = Epstein–Barr virus; ELISA = enzyme-linked immunosorbent assay; HIV-1 = human immunodeficiency virus-1; HRP-2 = histidine-rich protein 2; IAV = influenza A virus; LDH = lactate dehydrogenase; MERS-CoV = Middle East respiratory syndrome coronavirus; NS1 = non-structural 1; RSV = respiratory syncytial virus)

14.5 Additional investigations to be considered in pyrexia of unknown origin (PUO)

- Serological tests for connective tissue disorders:
  - Autoantibody screen
  - Complement levels
  - Immunoglobulins
  - Cryoglobulins
- Ferritin
- Echocardiography
- Ultrasound of abdomen
- CT/MRI of thorax, abdomen and/or brain
- Imaging of the skeletal system:
  - Plain X-rays
  - CT/MRI spine
  - Isotope bone scan
- Labelled white cell scan
- Fluorodeoxyglucose-positron emission tomography (FDG-PET)/single-photon emission computed tomography (SPECT)
- Biopsy:
  - Bronchoscopy and lavage ± transbronchial biopsy
  - Lymph node aspirate or biopsy
  - Biopsy of radiological lesion
  - Biopsy of liver
  - Bone marrow aspirate and biopsy
  - Lumbar puncture
  - Laparoscopy and biopsy
  - Temporal artery biopsy



Predominantly community acquired
Predominantly nosocomial
Streptococcus pneumoniae
Beta-haemolytic streptococci
Viridans streptococci
Escherichia coli
Staphylococcus aureus including MRSA
Coagulase-negative staphylococci
Enterobacterales other than *E. coli*
Pseudomonas aeruginosa
Enterococci, including VRE
Candida spp.

Fig. 14.2 Common causes of blood-stream infection. Causes of community- and hospital-acquired blood-stream infection are subject to significant regional and geographic location. (MRSA = meticillin-resistant *Staphylococcus aureus*; VRE = vancomycin-resistant *Enterococcus* spp.)

in view of their association with infective endocarditis, significant infection must always be excluded. *Bacillus* spp. ('aerobic spore bearers') and *Clostridium* spp. often represent incidental transient bacteraemia or contamination, but certain species (e.g. *C. septicum*) are more likely to be genuine pathogens.

Further investigations are influenced by the causative organism and setting. Initial screening tests are similar to those for fever and should include CXR, urine culture and, in many cases, ultrasound or other imaging of the abdomen. Imaging should also include any areas of bone or joint pain and any prosthetic material, e.g. a prosthetic joint or an aortic graft.

Echocardiography should be considered for those patients with BSI who have valvular heart disease or clinical features of endocarditis, those whose cultures reveal an organism that is a common cause of endocarditis (e.g. *Staphylococcus aureus*, viridans streptococci or enterococci), those in whom multiple blood cultures are positive for the same organism, and those with a rapid positive result on culture. The sensitivities of transthoracic echocardiography (TTE) and transoesophageal echocardiography (TOE) for the detection of vegetations are 50%–90% and over 95%, respectively. Therefore, if TTE is negative, TOE should be considered.

Certain rare causes of BSI have specific associations that warrant further investigation. Endocarditis caused by *Streptococcus gallolyticus* subsp. *gallolyticus* (formerly *Strep. bovis* biotype I) and BSI with *C. septicum* are both associated with colonic carcinoma and should lead to appropriate investigation.

Management

BSI is treated with antimicrobial therapy and, where possible, source control (surgical drainage, joint washout etc.). Two weeks of therapy may be sufficient for *Staphylococcus aureus* BSI from central and peripheral venous catheter infections when the source is identified and removed, for uncomplicated skin and soft tissue infections, and for uncomplicated right-sided infective endocarditis. Other *Staph. aureus* BSIs are usually treated for 4–6 weeks although evidence is accumulating that shorter courses of antibiotics are appropriate in some clinical settings when supported by clinical trial data.

Central venous catheter infections

Infections of central venous catheters typically involve the catheter lumen and are associated with fever, positive blood cultures and, in some cases, signs of purulence or exudate at the site of insertion. Infection is more common in temporary catheters inserted into the groin or jugular vein than in those in the subclavian vein. Tunnelled catheters, e.g. Hickman catheters, may also develop tunnel site infections.

Staphylococci account for 70%–90% of catheter infections, with coagulase-negative staphylococci more common than *Staphylococcus aureus*. Other causes include enterococci and gram-negative bacilli. Unusual gram-negative organisms, such as *Citrobacter freundii* and *Pseudomonas fluorescens*, raise the possibility of non-sterile infusion equipment or infusate. *Candida* spp. are a common cause of line infections, particularly in association with total parenteral nutrition. Non-tuberculous mycobacteria may cause tunnel infections.

Investigations and management

In bacteraemic patients with fever and no other obvious source of infection, a catheter infection is likely. Local evidence of erythema, purulence or thrombophlebitis supports the diagnosis, but microbiological confirmation is essential. If the line is removed, a semi-quantitative culture of the tip may confirm the presence of 15 or more colony-forming units, but this technique is retrospective and does not detect luminal infection. If the catheter remains in place, paired blood cultures (with approximately equal volumes) should be taken through the catheter and from a peripheral vein. A differential time to positive culture of 2 hours or more, with the catheter sample coming up positive first, suggests a luminal catheter infection.

For coagulase-negative staphylococcal line infections, the options are to remove the line and provide 5–7 days' therapy or, particularly in the case of tunnelled catheters, to treat empirically with a glycopeptide antibiotic, e.g. vancomycin, with or without the use of antibiotic-containing lock therapy to the catheter for approximately 14 days. For *Staphylococcus aureus* infection, the chance of curing an infection with the catheter in situ is low and the risks from infection are high. Therefore, unless the risks of catheter removal outweigh the benefits, treatment involves catheter removal, followed by 14 days of antimicrobial therapy; the same applies to infections with *Pseudomonas aeruginosa*, *Candida* spp., atypical mycobacteria or *Bacillus* spp. Infections complicated by endocarditis, thrombophlebitis, metastatic infection or tunnel infection also require catheter removal.

14.6 How to assess an intravenous (IV) cannula using the visual infusion phlebitis (VIP) score

Clinical features	Score	Assessment and management
IV site appears healthy	0	**No signs of phlebitis** Observe cannula
One of the following is evident: Slight pain near IV site Slight redness near IV site	1	**Possible first signs of phlebitis** Observe cannula
Two of the following are evident: Pain near IV site Erythema Swelling	2	**Early stage of phlebitis** Resite cannula
ALL of the following are evident and extensive: Pain along path of cannula Erythema Induration	3	**Medium stage of phlebitis** Resite cannula Consider treatment
ALL of the following are evident and extensive: Pain along path of cannula Erythema Induration Palpable venous cord	4	**Advanced stage of phlebitis or start of thrombophlebitis** Resite cannula Consider treatment
ALL of the following are evident: Pain along path of cannula Erythema Induration Palpable venous cord Pyrexia	5	**Advanced stage of thrombophlebitis** Initiate treatment Resite cannula

Adapted from Jackson A. Infection control: a battle in vein infusion phlebitis. Nursing Times 1997; 94:68–71.

Infection prevention is a key component of the management of vascular catheters. Measures include strict attention to hand hygiene, optimal siting, full aseptic technique on insertion and subsequent interventions, skin antisepsis with chlorhexidine and isopropyl alcohol, daily assessment of catheter sites (e.g. with visual infusion phlebitis (VIP) score; see Box 14.6), and daily consideration of the continuing requirement for catheterisation. The use of catheters impregnated with antimicrobials, such as chlorhexidine or silver, is advocated in some settings.

Sepsis

Sepsis is discussed on page 235 and there are many causes (Box 14.7). The results of blood cultures and pre-existing host factors guide initial investigations. Patients who are immunocompromised may have a broader range of causal pathogens that may be harder to culture, including mycobacteria and fungi. In many regions, malaria and dengue must also be excluded. The leading causes of sepsis include gram-positive organisms such as *Staphylococcus aureus*, streptococci (particularly invasive Group A streptococci and *Streptococcus pneumoniae*) and gram-negative bacteria related to biliary, intra-abdominal or renal infections.

The likely cause may be suggested by an underlying site of infection, e.g. sepsis with community-acquired pneumonia may suggest potential *Streptococcus pneumoniae* infection. *Staphylococcus aureus* and streptococcal infections are suggested by the presence of skin and soft tissue

14.7 Causes of sepsis

Infection	Setting
Bacterial	
Staph. aureus, coagulase-negative staphylococci	Bacteraemia may be associated with endocarditis, intravascular cannula infection, or skin or bone foci
Streptococcus pneumoniae	Invasive pneumococcal disease, usually with pneumonia or meningitis; asplenia
Other streptococci	Invasive streptococcal disease, especially necrotising fasciitis Viridans streptococci in neutropenic host with severe mucositis
Staphylococcal or streptococcal toxic shock syndrome	Toxin-mediated, blood cultures negative; clues include erythrodermic rash and epidemiological setting
Enterococci	Most often with abdominal focus
Neisseria meningitidis	Sepsis in children or young adults with petechial rash and/or meningitis
Escherichia coli, other gram-negative bacteria	Urinary or biliary tract infection, or other abdominal infections
Pseudomonas aeruginosa, multidrug-resistant gram-negative bacteraemia	Nosocomial infection
Salmonella Typhi or Paratyphi	In countries with a high incidence of enteric fever
Yersinia pestis	In plague
Burkholderia pseudomallei	Endemic in areas of Thailand; more likely to involve patients with diabetes or immunocompromised
Capnocytophaga canimorsus	Associated with dog bites and asplenic individuals
Clostridioides difficile	Severe colitis, particularly in older adults
Polymicrobial infection with gram-negatives and anaerobes	Bowel perforation, bowel ischaemia
Mycobacterium tuberculosis, *M. avium* complex (MAC)	HIV-positive or immunocompromised with miliary tuberculosis or disseminated MAC
Fungal	
Candida spp.	Line infection or post-operative complication, nosocomial or immunocompromised host
Histoplasma capsulatum, other dimorphic fungi	Immunocompromised host
Parasitic	
Falciparum malaria	Malaria with high-level parasitaemia and multi-organ failure or as a complication of bacterial superinfection
Babesia microti	Asplenic individual
Strongyloides stercoralis hyperinfection syndrome	Gram-negative infection complicating Strongyloides infection in immunocompromised host

(HIV = human immunodeficiency virus)

infection (SSTI). *Staphylococcus aureus* may be associated with intravascular cannula or central venous catheter infections, with deep-seated endovascular infection (e.g. endocarditis, permanent pacemaker infections or vascular graft infections) or with bone and joint infections. It is a leading cause of sepsis in people who inject drugs. Staphylococcal or streptococcal toxic shock syndrome may be suggested when there is no obvious localising source of infection but a widespread blanching erythematous rash is present. A widespread non-blanching petechial rash is observed in meningococcaemia, seen particularly in children or young adults, but which is now rarer when all meningococcal vaccines have been administered. Alternative non-vaccine-related strains may now cause disease including in older adults. Gram-negative sepsis is likely when there is a potential abdominal perforation, as may occur with diverticulitis. It may also occur with biliary sepsis or with pyelonephritis. Recent critical illness or the history of a long-hospitalisation with prior antimicrobials and the presence of indwelling drains or catheters increases the risks these infections may be due to multidrug-resistant strains.

Candida species may cause infection in the presence of long lines, especially during total parenteral nutrition, in those who have received broad-spectrum antimicrobials for other infections or in immunocompromised groups. *Plasmodium falciparum*, typhoid or dengue can cause sepsis in travellers and miliary tuberculosis can cause sepsis, in particular in immunocompromised groups. Sepsis was commonly observed in patients with COVID-19.

These infections (and the rarer causes in Box 14.7) are covered in the pathogen-specific sections of this chapter or in other chapters that deal with system-specific infections.

Skin and soft tissue infections causing sepsis

Skin and soft tissue infections (SSTIs) are an important cause of sepsis. Severe necrotising SSTI can be classified as in Box 14.8, according to the clinical features and microbiological findings. In some cases, severe systemic features may be out of keeping with mild local features.

Necrotising fasciitis

In necrotising fasciitis, cutaneous erythema and oedema progress to bullae or areas of necrosis. Unlike in cellulitis, extreme pain may be disproportionate to the visible cutaneous features or may spread beyond the zone of erythema. The infection spreads quickly along the fascial plane. Type 1 necrotising fasciitis is a mixed infection with gram-negative bacteria and anaerobes, often seen post-operatively in diabetic or immunocompromised hosts. Subcutaneous gas may be present. Type 2 necrotising fasciitis is caused by Group A or other streptococci. Approximately 60% of cases are associated with streptococcal toxic shock syndrome (p. 355). Type 3 infection involves organisms such as *Aeromonas hydrophila* and *Vibrio vulnificus*, which is found in tropical to subtropical regions and is associated with marine exposure. Type 4 is caused by fungi such as mucoraceous moulds and may also vary geographically in incidence, with increased cases in India and other regions.

Necrotising fasciitis is a medical emergency, requiring immediate surgical débridement with inspection of the involved muscle groups, in addition to antimicrobial therapy (Fig. 14.3). Empirical treatment is

14.8 Severe necrotising soft tissue infections

- Necrotising fasciitis (primarily confined to subcutaneous fascia and fat)
- Clostridial anaerobic cellulitis (confined to skin and subcutaneous tissue)
- Non-clostridial anaerobic cellulitis
- Progressive bacterial synergistic gangrene (*Staph. aureus* + micro-aerophilic streptococcus) ('Meleney gangrene', primarily confined to skin)
- Pyomyositis (discrete abscesses within individual muscle groups)
- Clostridial myonecrosis (gas gangrene)
- Anaerobic streptococcal myonecrosis (non-clostridial infection mimicking gas gangrene)
- Group A streptococcal necrotising myositis

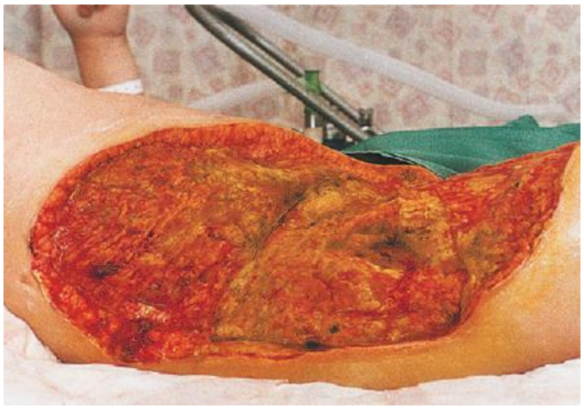


Fig. 14.3 Excision following necrotising fasciitis in an injection drug-user.

with broad-spectrum agents (e.g. co-amoxiclav plus clindamycin). Ceftazidime or ciprofloxacin with doxycycline may be used where marine exposure is a factor, and antifungals for suspected fungal necrotising fasciitis, but it is important to combine these with effective coverage against streptococcal infection. MRSA-associated necrotising fasciitis has emerged in some regions, where glycopeptides or linezolid should be added to the empirical regimen to cover MRSA until microbiological results allow focused therapy. Hyperbaric oxygen therapy may be considered for polymicrobial infection. Group A streptococcal infection is treated with benzylpenicillin plus clindamycin, and often intravenous immunoglobulin (IVIG), although there is conflicting evidence for this.

Gas gangrene

Although *Clostridium* spp. may colonise or contaminate wounds, no action is required unless there is evidence of spreading infection.

Anaerobic cellulitis occurs when *C. perfringens*, or other clostridia, infect devitalised tissue, usually following a wound. Gas forms locally and extends along tissue planes but bacteraemia does not occur. Prompt surgical débridement of devitalised tissue and therapy with penicillin or clindamycin is usually effective.

Gas gangrene (clostridial myonecrosis) is defined as acute invasion of healthy living muscle undamaged by previous trauma and is most commonly caused by *C. perfringens*. In at least 70% of cases, it follows deep penetrating injury sufficient to create an anaerobic (ischaemic) environment, allowing clostridial proliferation. Severe pain at the site of the injury progresses rapidly over 18–24 hours. Skin colour changes from pallor to bronze/purple discoloration and the skin is tense, swollen, oedematous and exquisitely tender. Gas in tissues may be obvious, with crepitus on clinical examination, or visible on X-ray, CT or ultrasound. Signs of systemic toxicity develop rapidly, with high leucocytosis, multi-organ dysfunction, raised CK and evidence of disseminated intravascular coagulation (DIC; Ch. 24) and haemolysis. Antibiotic therapy with high-dose intravenous penicillin and clindamycin is recommended, coupled with aggressive surgical débridement of the affected tissues. Alternative agents include cephalosporins and metronidazole. Hyperbaric oxygen has a putative but controversial role.

Other severe SSTIs associated with sepsis

'Synergistic gangrene' is a polymicrobial infection with anaerobes and other bacteria (*Staphylococcus aureus* or gram-negatives). When this affects the genital/perineal area, it is known as 'Fournier gangrene' and can be a complication of use of sodium-glucose co-transporter 2 (SGLT2) inhibitors in diabetics. Severe gangrenous cellulitis in immunocompromised hosts may involve gram-negative bacteria or fungi. *Entamoeba histolytica* can cause soft tissue necrosis following abdominal surgery in areas of the world where infection is common. Contact with sea water or shellfish consumption in tropical to subtropical regions worldwide, such as the Gulf of Mexico, can lead to infection with *Vibrio vulnificus*. This infection causes soft tissue necrosis and bullae and may lead to necrotising fasciitis. Patients with chronic liver disease are particularly susceptible to this infection and can develop sepsis.

Acute diarrhoea and vomiting

Acute diarrhoea, sometimes with vomiting, is the predominant symptom in infective gastroenteritis (Box 14.9). Acute diarrhoea may also be a symptom of other infectious and non-infectious diseases (Box 14.10). Stress, whether physical or psychological, can also produce loose stools.

Global Burden of Disease 2021 estimates suggest acute diarrhoea causes 1.2 million deaths annually, a third in children under 5. In high-income countries older people are most susceptible (Box 14.11). The majority of episodes are due to infections spread by the faecal–oral route and transmitted either on fomites, on contaminated hands or in food or water. Provision of clean drinking water, appropriate disposal of human and animal sewage, and the application of simple principles of food hygiene all limit gastroenteritis (water, sanitation and hygiene – *WASH*).

14.9 Causes of infectious gastroenteritis

Toxin in food: < 6 hrs incubation

- *Bacillus cereus*
- *Staph. aureus*
- *Clostridium* spp. enterotoxin

Bacterial: 12–72 hrs incubation

- Enterotoxigenic *Escherichia coli* (ETEC)
- Shiga toxin-producing *E. coli* (EHEC)*
- Entero-invasive *E. coli* (EIEC)*
- _Vibrio cholerae_
- _Salmonella_
- _Shigella_*
- _Campylobacter_*
- _Clostridioides difficile_*

Viral: short incubation

- Rotavirus
- Norovirus

Protozoal: long incubation

- Giardiasis
- Cryptosporidiosis
- Microsporidiosis
- Amoebic dysentery*
- Cystoisosporiasis

*Associated with bloody diarrhoea.

14.10 Differential diagnosis of acute diarrhoea and vomiting

Infectious causes

- Gastroenteritis
- *Clostridioides difficile* infection
- Acute diverticulitis (p. 850)
- Sepsis (p. 235)
- Pelvic inflammatory disease (p. 411)
- Meningococcaemia
- Pneumonia (especially 'atypical disease', p. 551)
- Malaria

Non-infectious causes

Gastrointestinal

- Inflammatory bowel disease (p. 853)
- Bowel malignancy (p. 844)
- Overflow from constipation (p. 851)
- Enteral tube feeding

Metabolic

- Diabetic ketoacidosis (p. 764)
- Thyrotoxicosis (p. 694)
- Uraemia (p. 629)
- Neuroendocrine tumours releasing (e.g.) VIP or 5-HT

Drugs and toxins

- NSAIDs
- Cytotoxic agents
- Antibiotics
- Proton pump inhibitors
- Dinoflagellates (p. 273)
- Plant toxins (p. 275)
- Heavy metals
- Ciguatera fish poisoning (p. 274)
- Scombrotoxic fish poisoning (p. 274)

(5-HT = 5-hydroxytryptamine, serotonin; NSAIDs = non-steroidal anti-inflammatory drugs; VIP = vasoactive intestinal peptide)

14.11 Infectious diarrhoea in old age

- **Incidence**: not increased but the impact is greater.
- **Mortality**: most deaths due to gastroenteritis in high-income countries are in adults aged over 70. Most are presumed to be caused by dehydration leading to organ failure.
- ***Clostridioides difficile* infection (CDI)**: more common, especially in hospital and nursing home settings, usually following antibiotic exposure.

Some organisms (*Bacillus cereus*, *Staphyloccocus aureus* and *Vibrio cholerae*) elute exotoxins that cause vomiting and/or so-called 'secretory' diarrhoea (watery diarrhoea without blood or faecal leucocytes, reflecting small bowel dysfunction). In general, the time from ingestion to the onset of symptoms is short and, other than dehydration, little systemic upset occurs. Other organisms, such as *Shigella* spp., *Campylobacter* spp. and enterohaemorrhagic *Escherichia coli* (EHEC, which includes

i 14.12 Foods associated with infectious illness, including gastroenteritis

Raw seafood

- Norovirus
- *Vibrio* spp.
- Hepatitis A

Raw eggs

- *Salmonella* serovars

Under-cooked meat or poultry

- *Salmonella* serovars
- *Campylobacter* spp.
- EHEC
- Hepatitis E (pork products)
- *Clostridium perfringens*

Unpasteurised milk or juice

- *Salmonella* serovars
- *Campylobacter* spp.
- EHEC
- *Yersinia enterocolitica*

Unpasteurised soft cheeses

- *Salmonella* serovars
- *Campylobacter* spp.
- ETEC
- *Yersinia enterocolitica*
- *Listeria monocytogenes*

Home-made canned goods

- *Clostridium botulinum*

Raw hot dogs, pâté

- *Listeria monocytogenes*

(EHEC = enterohaemorrhagic *Escherichia coli*; ETEC = enterotoxigenic *E. coli*)

shigatoxigenic and verotoxigenic *E. coli*), may directly invade the mucosa of the small bowel or produce cytotoxins that cause mucosal ulceration, typically affecting the terminal small bowel and colon. The incubation period is longer and more systemic upset occurs, with prolonged bloody diarrhoea. *Salmonella* spp. are capable of invading enterocytes and of causing both a secretory response and invasive disease with systemic features. This is seen with *Salmonella* Typhi and *Salmonella* Paratyphi (enteric fever without diarrhoea) but may occasionally be seen with other non-typhoidal *Salmonella* spp., particularly in the immunocompromised host and older people.

Clinical assessment

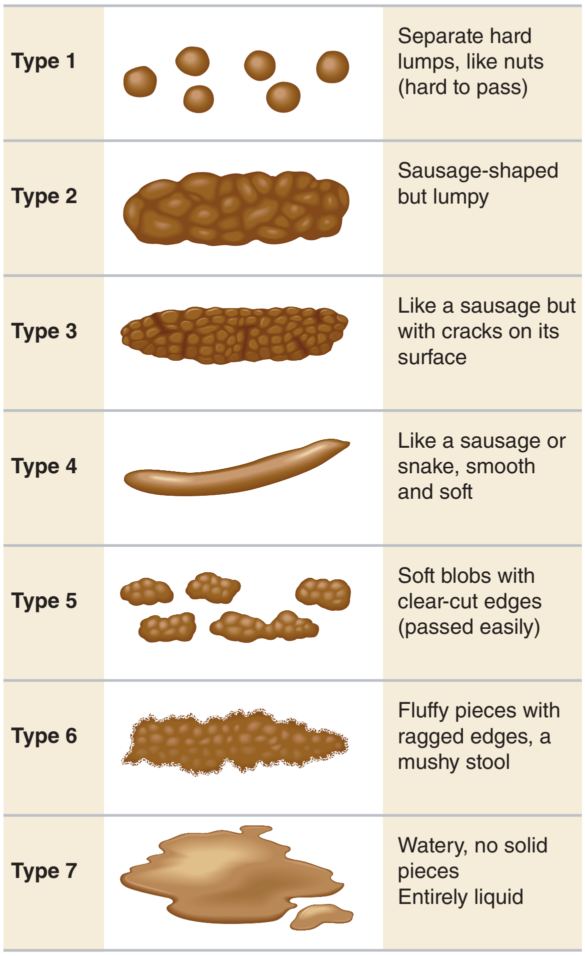
Diarrhoea is defined as the passage of 3 or more loose or liquid stools per day or more frequent passage than is normal for the individual. The history should address foods ingested (Box 14.12), duration and frequency of diarrhoea, presence of blood or steatorrhoea, abdominal pain and tenesmus, and whether other people have been affected. Fever and bloody diarrhoea suggest an invasive, colitic, dysenteric process. An incubation period of less than 18 hours suggests toxin-mediated food poisoning, and longer than 5 days suggests diarrhoea caused by protozoa or helminths. Person-to-person spread suggests infections, such as shigellosis or cholera.

Examination including assessment of the degree of dehydration such as thirst, headache, altered skin turgor, dry mucous membranes and postural hypotension, is important, particularly in tropical regions, where dehydration progresses rapidly. Signs of more marked dehydration include postural and supine hypotension, tachycardia, decreased urinary output, delirium and sunken eyes. The blood pressure, pulse rate, urine output and ongoing stool losses should be monitored closely.

The severity of diarrhoea may be assessed by reference to the Bristol stool form scale (Bristol stool chart), which allows an objective assessment of stool consistency by providing a verbal and visual reference scale (Fig. 14.4). The Bristol stool form scale guides decisions on stool sampling and infection prevention precautions in UK hospital inpatients, especially in relation to *C. difficile*.

Investigations

These include stool inspection for blood and microscopy for leucocytes, and also an examination for ova, cysts and parasites if the history indicates residence or travel to areas where parasitic infections are prevalent. Stool culture should be performed and *C. difficile* toxin sought. FBC and serum electrolytes indicate the degree of inflammation and dehydration. Where cholera is prevalent, examination of a wet film with dark-field microscopy for darting motility aids diagnosis. In a malarious area, a blood test for malaria should be obtained. Blood and urine cultures and a CXR may identify alternative sites of infection, particularly if the clinical features suggest a syndrome other than gastroenteritis.



Type 1
Separate hard lumps, like nuts (hard to pass)
Type 2
Sausage-shaped but lumpy
Type 3
Like a sausage but with cracks on its surface
Type 4
Like a sausage or snake, smooth and soft
Type 5
Soft blobs with clear-cut edges (passed easily)
Type 6
Fluffy pieces with ragged edges, a mushy stool
Type 7
Watery, no solid pieces
Entirely liquid

Fig. 14.4 Bristol stool chart. The stool is given a 'score' of 1–7 by reference to the verbal and visual description. This is recorded on a chart (usually known as a 'Bristol stool chart') or in a patient monitoring database. *Adapted from Lewis SJ, Heaton KW. Stool form scale as a useful guide to intestinal transit time. Scand J Gastroenterol 1997;32:920–924.*

Management

All patients with acute, potentially infective diarrhoea should be appropriately isolated to minimise person-to-person spread of infection. If the history suggests a food-borne source, public health measures must be implemented to identify the source and to establish whether other linked cases exist.

Fluid replacement

Replacement of fluid losses in diarrhoeal illness is crucial and may be life-saving.

Normal daily fluid intake in an adult is around 1–2 litres, but there is considerable additional fluid movement in and out of the gut in secretions (see Fig. 22.7). Altered gut resorption with diarrhoea causes substantial isotonic fluid loss; up to 10–20 L per day in cholera. Water and electrolytes need to be replaced, but electrolyte absorption from the gut is an active energy-requiring process. Mucosa during infection is capable of very rapid fluid and electrolyte transport if carbohydrate is available as an

14.13 Composition of oral rehydration solution and other replacement fluids*

Fluid	Na	K	Cl	Energy
WHO	90	20	80	54
Dioralyte	60	20	60	71
Pepsi	6.5	0.8	–	400
7UP	7.5	0.2	–	320
Apple juice	0.4	26	–	480
Orange juice	0.2	49	–	400
Breast milk	22	36	28	670

*Values given in mmol/L for electrolyte and kcal/L for energy components.
(WHO = World Health Organization)

energy source. Oral rehydration solutions (ORS) therefore contain sugars, as well as water and electrolytes (Box 14.13). ORS are as effective as intravenous replacement fluid, even for cholera. In mild to moderate gastroenteritis, adults should be encouraged to drink fluids and continue normal dietary food intake. If this is impossible – due to vomiting, for example – intravenous fluid administration is required. In very sick patients or those with cardiac or renal disease, monitoring of urine output and central venous pressure may be necessary.

The volume of fluid replacement required should be estimated based on the following considerations:

- *Replacement of established deficit*. The average adult's diarrhoeal stool accounts for a loss of 200 mL of isotonic fluid. After 48 hours of moderate diarrhoea (6–10 stools per 24 hours), the average adult will be 2–4 L depleted. This requires rapid replacement of 1–1.5 L, either orally (ORS) or by intravenous infusion (normal saline), within the first 2–4 hours of presentation. Longer symptomatology, additional vomiting or more persistent/severe diarrhoea rapidly produces fluid losses comparable to diabetic ketoacidosis and is a metabolic emergency requiring active intervention. Serum potassium needs to be monitored closely.
- *Replacement of ongoing losses*. Stool losses should be accurately recorded and an estimate of ongoing losses calculated. Commercially available rehydration sachets provide 200 mL of ORS; one sachet per diarrhoea stool replaces losses.
- *Replacement of normal daily requirement*. The average adult has a daily requirement of 1–1.5 L of fluid in addition to the calculations above. This will be increased substantially in fever or a hot environment.

Antimicrobial agents

In non-specific gastroenteritis, routine use of antimicrobials does not improve outcome and may lead to prolonged illness, antimicrobial resistance or side-effects. They are usually used where there is systemic involvement, immunocompromise or significant comorbidity.

Evidence suggests that, in EHEC infections, antibiotics should not be used since they can enhance haemolytic uraemic syndrome (HUS; p. 623) due to increased toxin release.

Conversely, antibiotics are indicated in *Shigella dysenteriae* infection and in invasive salmonellosis – in particular, typhoid fever. Antibiotics may also be advantageous in cholera epidemics, reducing infectivity and controlling infection spread.

Antidiarrhoeal, antimotility and antisecretory agents

These agents are not recommended in acute infective diarrhoea. Loperamide, diphenoxylate and opiates are potentially dangerous in dysentery in childhood, causing intussusception. Antisecretory agents, such as bismuth and chlorpromazine, may make the stools appear bulkier but do not reduce stool fluid losses and may cause significant sedation. Adsorbents, such as kaolin or charcoal, have little effect.

Non-infectious causes of food poisoning

Although less common, non-infectious causes must also be considered in the differential diagnosis of gastroenteritis. These are discussed on page 273.

Antimicrobial-associated diarrhoea

Antimicrobial-associated diarrhoea (AAD) is a common complication of antimicrobial therapy, especially with broad-spectrum agents. It is most common in older people but can occur at all ages. Although the specific mechanism is unknown in most cases of AAD, *C. difficile* is implicated in 20%–25% of cases and is the most common cause among patients with evidence of colitis. *Clostridium perfringens* is a rarer cause that usually remains undiagnosed, and *Klebsiella oxytoca* may also cause antibiotic-associated haemorrhagic colitis.

Infection in particular settings

Infection in the injection drug-user

Intravenous injection of recreational drugs is a global problem. Infective organisms are introduced by non-sterile (often shared) injection equipment (Fig. 14.5). Approximately 50% of people who inject drugs (PWID) report a recent bacterial infection, especially with Group A streptococci and *Staphylococcus aureus*. Risk factors for these infections include increasing age, homelessness and injection in prison. The risks increase with prolonged drug use and injection into large veins of the groin and neck necessitated by progressive thrombosis of superficial peripheral veins. The most common causes of fever are soft tissue or respiratory infections.

Clinical assessment

The history should address the following risk factors:

- *Site of injection*. Femoral vein injection is associated with vascular complications such as deep venous thrombosis (DVT; 50% of which are septic) and accidental arterial injection with false aneurysm formation or a compartment syndrome due to swelling within the fascial sheath. Local complications include ilio-psoas abscess and septic arthritis of the hip joint or sacroiliac joint. Injection of the jugular vein can be associated with cerebrovascular complications. Subcutaneous and intramuscular injection has been related to infection by clostridial species, the spores of which contaminate heroin. *Clostridium novyi* causes a local lesion with significant toxin production, leading to shock and multi-organ failure. Tetanus, wound botulism, anthrax and gas gangrene also occur.
- *Technical details of injection*. Sharing of needles and other injecting paraphernalia (including spoons and filters) increases the risk of blood-borne virus infection (e.g. HIV-1, hepatitis B or C virus). Some users lubricate their needles by licking them prior to injection, thus introducing mouth organisms (e.g. anaerobic streptococci, *Fusobacterium* spp. and *Prevotella* spp.). Contamination of commercially available lemon juice, used to dissolve heroin before injection, has been associated with blood-stream infection with *Candida* spp. Excessive use of citric acid to dissolve heroin is associated with DVT and skin and soft tissue infection.
- *Substances injected*. Injection of cocaine is associated with a variety of vascular complications. Psychoactive drugs increase risk taking and bacterial infections. Certain formulations of heroin have been linked with particular infections, e.g. wound botulism with black tar heroin. Drugs are often mixed with other substances, e.g. talc.
- *Blood-borne virus status*. Results of previous HIV-1 and hepatitis virus tests or vaccinations for hepatitis viruses should be recorded.
- *Surreptitious use of antimicrobials*. PWIDs may use antimicrobials to self-treat infections, masking initial blood culture results.

Fig. 14.5 Fever in the injection drug-user: key features of clinical examination. Full examination is required but features most common amongst injection drug-users are shown here. (DVT = deep venous thrombosis; HIV = human immunodeficiency virus; JVP = jugular venous pulse)

Key findings on clinical examination are shown in Figure 14.5. It can be difficult to distinguish the effects of infection from the effects of drugs or drug withdrawal (excitement, tachycardia, sweating, marked myalgia, delirium). Stupor and delirium may result from drug administration but may also indicate meningitis or encephalitis. Non-infected venous thromboembolism is also common in this group.

Investigations

The initial investigations are as for any fever (see above), including a CXR and blood cultures. Since blood sampling may be difficult, contamination is often a problem. Echocardiography (transthoracic or transoesophageal) to detect infective endocarditis should be performed in all injection drug-users with bacteraemia due to *Staphylococcus aureus* or other organisms associated with endocarditis (Fig. 14.6A); thromboembolic phenomena; or a new or previously undocumented murmur. Endovascular infection should also be suspected if lung abscesses or pneumatoceles are detected radiologically. Infected thrombus at injection sites, such as the groin, is common and may lead to abscess formation. Additional imaging should be focused on sites of injection or of localising symptoms (Fig. 14.6B). Any pathological fluid collections should be sampled.

Urinary toxicology tests may suggest a non-infectious cause of the presenting complaint. While being investigated, all injection drug-users should be tested for infection with hepatitis B and C virus and HIV-1.

PWIDs may have more than one infection. Skin and soft tissue infections are most often due to *Staphylococcus aureus* or streptococci, and sometimes to *Clostridium* spp. or anaerobes. Pulmonary infections are most often due to the common pathogens causing community-acquired pneumonia, tuberculosis or septic emboli (Fig. 14.6C). Endocarditis with septic emboli commonly involves *Staphylococcus aureus* and viridans streptococci, but *Pseudomonas aeruginosa* and *Candida* spp. are also encountered.

Management

Empirical therapy of fever in the injection drug-user includes an antistaphylococcal penicillin (e.g. flucloxacillin) or, where meticillin-resistant *Staphylococcus aureus* (MRSA) is prevalent, a glycopeptide (e.g. vancomycin) or lipopeptide (e.g. daptomycin). Once microbiological

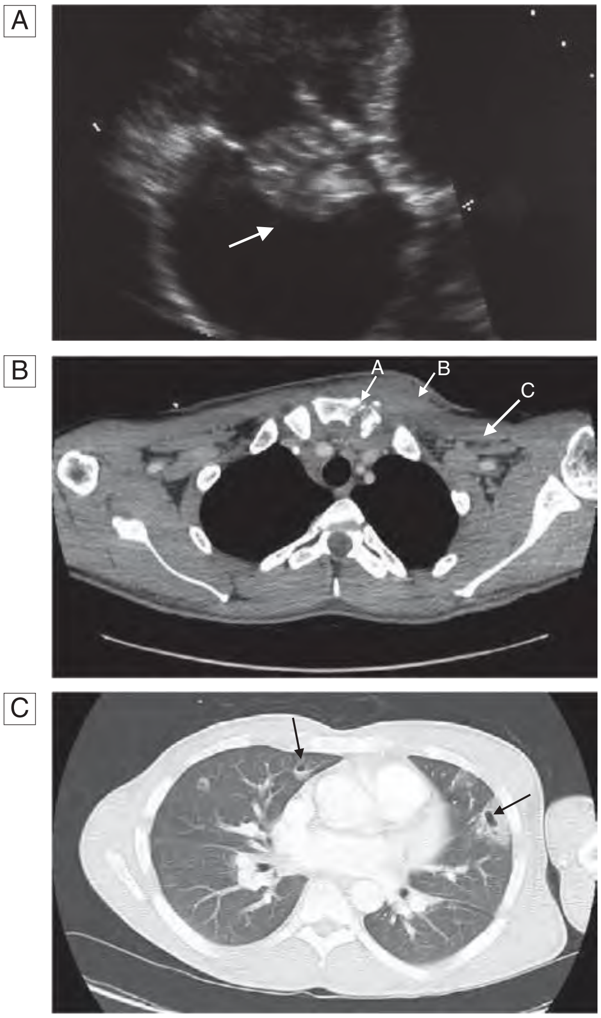

Fig. 14.6 Causes of fever in injection drug-users. **A** Endocarditis: large vegetation on the tricuspid valve (arrow). **B** Septic arthritis of the left sternoclavicular joint (arrow A) (note the erosion of the bony surfaces at the sternoclavicular joint) with overlying soft tissue collection and gas (arrow B/C). **C** Tricuspid valve endocarditis caused by *Staph. aureus*. Thoracic CT scan shows multiple embolic lesions with cavitation (arrows). The patient presented with haemoptysis. *(C) Courtesy of Dr Julia Greig, Royal Hallamshire Hospital, Sheffield.*

results are available, therapy can be narrowed to focus on the microorganism identified. In injection drug-users, meticillin-sensitive *Staphylococcus aureus* (MSSA) is customarily treated with high-dose intravenous flucloxacillin, with a 2-week duration for uncomplicated right-sided endocarditis. Right-sided endocarditis caused by MRSA is usually treated with 4 weeks of vancomycin. Venous access may be difficult and open to abuse so specialist advice should be sought. Dalbavancin, a once-a-week second-generation lipoglycopeptide antibiotic, may be useful.

For localised infections of the skin and soft tissues, oral therapy with agents active against staphylococci, streptococci and anaerobes is appropriate (e.g. flucloxacillin or clindamycin). Non-adherence to prescribed antimicrobial regimens leads to a high rate of complications.

Infections acquired in the tropics

Recent decades have seen unprecedented increases in long-distance travel, as well as extensive migration. Some infections maintain a fixed geographical distribution, being dependent on specific vectors or weather conditions, while others move with their human hosts and some may then be transmitted to other people. This means that the pattern of infectious diseases seen in each country changes constantly, and travel history and information on countries previously lived in, particularly during childhood, are crucial.

14.14 How to assess health needs in travellers before departure*

- Destination
- Personal details, including previous travel experience
- Dates of trip
- Itinerary and purpose of trip
- Personal medical history, including pregnancy, medication and allergies (e.g. to eggs, vaccines, antibiotics)
- Past vaccinations:
    - Childhood schedule followed? Diphtheria, tetanus, pertussis, polio, *Neisseria meningitidis* types A/B/C, *Haemophilus influenzae* B (HiB), pneumococcal
    - Travel-related? Typhoid, yellow fever, hepatitis A, hepatitis B, meningococcal ACW135Y, rabies, Japanese B encephalitis, tick-borne encephalitis
- Malaria prophylaxis: questions influencing the choice of antimalarial drugs are destination, past experience with antimalarials, history of epilepsy or psychiatric illness

*Further information is available at www.nhsinform.scot/healthy-living/travel-health/travel-health-and-vaccinations/.

In general, the diversity of infectious diseases is greater in tropical than in temperate countries, and people in temperate countries have immunity to a narrower range of infections, reflecting less exposure in childhood and less ongoing boosting of immunity later in life, so that the most common travel-associated infections are those that are acquired by residents of temperate countries during visits to the tropics. In addition, those who have lived in tropical areas may lose immunity when they move to temperate countries and become susceptible when visiting their homeland.

Most travel-associated infections are preventable. Pre-travel advice is tailored to the destination and the traveller (Box 14.14). It includes avoidance of insect bites (using at least 20% diethyltoluamide (DEET)), sun protection (sunscreen with a sun protection factor (SPF) of at least 15), food and water hygiene ('Boil it, cook it, peel it or forget it!'), how to respond to travellers' diarrhoea (seek medical advice if bloody or if it lasts more than 48 hours) and, if relevant, safe sex (condom use).

Fever acquired in tropical regions

Presentation with unexplained fever is common in travellers who are visiting or have recently travelled to tropical areas. Fever may also occur in those living in tropical regions if they lack immunity to endemic pathogens or if immunity is compromised by factors such as pregnancy. Common causes are malaria, enteric fever, viral hepatitis and dengue fever. Travellers or those resident in affected areas may have viral haemorrhagic fevers (VHFs) such as Ebola, Lassa, Crimean–Congo and Marburg (see Box 14.54), avian influenza (H5N1) or Middle East respiratory syndrome (MERS), which require special isolation precautions (high consequence infectious diseases; HCIDs).

Clinical assessment

The approach to unexplained fever is as described above and key questions relating to infections acquired in tropical regions are listed in Box 14.15. Medicines purchased in some countries may have reduced efficacy due to counterfeiting (fake or falsified) or poor storage, e.g. antimalarials. Consult reliable up-to-date sources, e.g. National Travel Health Network and Centre (NaTHNaC), about resistance to antimalarial drugs in the country visited. Vaccinations against yellow fever and hepatitis A and B are sufficiently effective to virtually exclude these infections. Oral and injectable typhoid vaccinations are 70%–90% effective.

The differential diagnosis is guided by the clinical scenario, presence of specific exposures (Box 14.16) and incubation period (Box 14.17).

14.15 How to obtain a history from travellers to the tropics with fever

Questions	Factors to ascertain
Countries visited and dates of travel	Relate travel to known outbreaks of infection or antimicrobial resistance
Determine the environment visited	Travel to rural environments, forests, rivers or lakes
Clarify where the person slept	Sleeping in huts, use of bed nets, sleeping on the ground
Establish what he/she was doing	Exposure to people with medical illness, animals, soil, lakes and rivers
History of insect bites	Type of insect responsible, circumstances (location, time of day etc.), preventative measures
Dietary history	Ingestion of uncooked foods, salads and vegetables, meats (especially if under-cooked), shellfish, molluscs, unpasteurised dairy products, unbottled water and sites at which food prepared
Sexual history	History of sexual intercourse with commercial sex workers, local population or travellers from other countries
Malaria prophylaxis	Type of prophylaxis
Vaccination history	Receipt of pre-travel vaccines and appropriateness to area visited
History of any treatments received while abroad	Receipt of medicines, local remedies, blood transfusions or surgical procedures

14.16 Specific exposures and causes of fever in the tropics

Exposure	Infection or disease
Mosquito bite	Malaria, dengue fever, chikungunya, filariasis, tularaemia
Tsetse fly bite	African trypanosomiasis
Tick bite	Rickettsial infections including typhus, Lyme disease, tularaemia, Crimean–Congo haemorrhagic fever, Kyasanur forest disease, babesiosis, tick-borne encephalitis
Louse bite	Typhus
Flea bite	Plague
Sandfly bite	Leishmaniasis, arbovirus infection
Reduviid bug	Chagas disease
Animal contact	Q fever, brucellosis, anthrax, plague, tularaemia, viral haemorrhagic fevers, rabies
Freshwater swimming	Schistosomiasis, leptospirosis, *Naegleria fowleri*
Exposure to soil	Inhalation: dimorphic fungi Inhalation or inoculation: *Burkholderia pseudomallei* Inoculation (most often when barefoot): hookworms, *Strongyloides stercoralis*
Exposure to caves	Ebola, Marburg, rabies, tick-borne relapsing fever, leptospirosis, histoplasmosis
Raw or under-cooked fruit and vegetables	Enteric bacterial infections, hepatitis A or E virus, *Fasciola hepatica*, *Toxocara* spp., *Echinococcus granulosus* (hydatid disease), *Entamoeba histolytica*
Under-cooked pork	*Taenia solium* (cysticercosis)
Crustaceans or molluscs	Paragonimiasis, gnathostomiasis, *Angiostrongylus cantonensis* infection, hepatitis A virus, cholera
Unpasteurised dairy products	Brucellosis, salmonellosis, abdominal tuberculosis, listeriosis
Untreated water	Enteric bacterial infections, giardiasis, *Cryptosporidium* spp. (chronic in immunocompromised), hepatitis A or E virus

Falciparum malaria typically presents 7–28 days after exposure. VHF, dengue and rickettsial infection can usually be excluded if more than 21 days have passed between leaving the area and onset of illness.

Clinical examination is summarised on page 300. Particular attention should be paid to the skin, throat, eyes, nail beds, lymph nodes, abdomen and heart. Patients may be unaware of tick bites or eschars. Body temperature should be measured at least twice daily.

Investigations and management

Initial investigations include blood films and a rapid diagnostic test (RDT; antigen detection) for malaria parasites, FBC, urinalysis and CXR if indicated. Box 14.18 lists diagnoses and investigations to consider in unexplained acute fever.

Management is directed at the underlying cause. In patients with suspected HCID, such as VHF, strict infection control measures with isolation and barrier nursing are immediately implemented to prevent contact with the patient's body fluids. The risk of VHF should be determined using epidemiological risk factors, exposure history and clinical signs (Fig. 14.7), and further management undertaken as described in this chapter.

Diarrhoea acquired in the tropics

Gastrointestinal illness is the most common infection amongst visitors to the tropics, with *Salmonella* spp., *Campylobacter* spp. and *Cryptosporidium* spp. infections prevalent worldwide (Box 14.19). *Shigella* spp. and *Entamoeba histolytica* (amoebiasis) are usually acquired in South Asia or sub-Saharan and southern Africa.

The approach to patients with acute diarrhoea is described on page 308. The benefits of treating travellers' diarrhoea with antimicrobials are marginal, with slight reductions in stool frequency and increased likelihood of cure at 72 hours offset by increased side-effects. The

14.18 Investigation of tropically acquired acute fever without localising signs

Features on full blood count	Further investigations
Neutrophil leucocytosis	
Bacterial sepsis	Blood culture
Leptospirosis	Culture of blood and urine, serology
Borreliosis (tick- or louse-borne relapsing fever)	Blood film
Amoebic liver abscess	Ultrasound
Normal white cell count and differential	
Malaria (may have low platelets or anaemia)	Blood film, antigen test
Typhoid fever	Blood and stool culture
Typhus	Serology
Lymphocytosis	
Viral fevers, including VHF	Serology, PCR
Infectious mononucleosis	Monospot test, serology
Malaria	Blood film, antigen test
Rickettsial fevers	Serology
Atypical lymphocytes	
Dengue and other VHF	Serology, antigen, PCR
Infectious mononucleosis-like syndromes	Serology, PCR
HIV (acute retroviral syndrome)	Serology, antigen
Hepatitis viruses	Serology, antigen, PCR
Parasitic, malaria, trypanosomiasis	Blood film, antigen test, PCR

(HIV = human immunodeficiency virus; PCR = polymerase chain reaction; VHF = viral haemorrhagic fever)

differential diagnosis of diarrhoea persisting for more than 14 days is wide (see Box 22.20). The differential diagnosis of chronic diarrhoea includes parasitic and bacterial causes, tropical malabsorption, inflammatory bowel disease and neoplasia. Causes particularly associated with the tropics include giardiasis, strongyloidiasis, chronic intestinal schistosomiasis, intestinal flukes, enteropathogenic *E. coli*, HIV enteropathy, hypolactasia (lactase deficiency) and chronic calcific pancreatitis. The workup should include tests for parasitic causes of chronic diarrhoea, such as examination of stool, faecal elastase and calprotectin, endoscopic duodenal aspirates for ova and parasites, and serological investigation.

Giardia lamblia infection (giardiasis) may progress to a malabsorption syndrome and chronic fatigue syndrome. If no cause is found, empirical treatment for giardiasis with metronidazole is often helpful.

HIV-1 may cause chronic diarrhoea due to medications or infection. Causes such as HIV enteropathy or infection with agents such as *Cryptosporidium* spp., *Cystoisospora belli* or microsporidia are uncommon once antiretroviral therapy is commenced, and AIDS-associated diarrhoea due to CMV or disseminated *Mycobacterium avium* complex infection is uncommon in tropical regions.

Eosinophilia acquired in the tropics

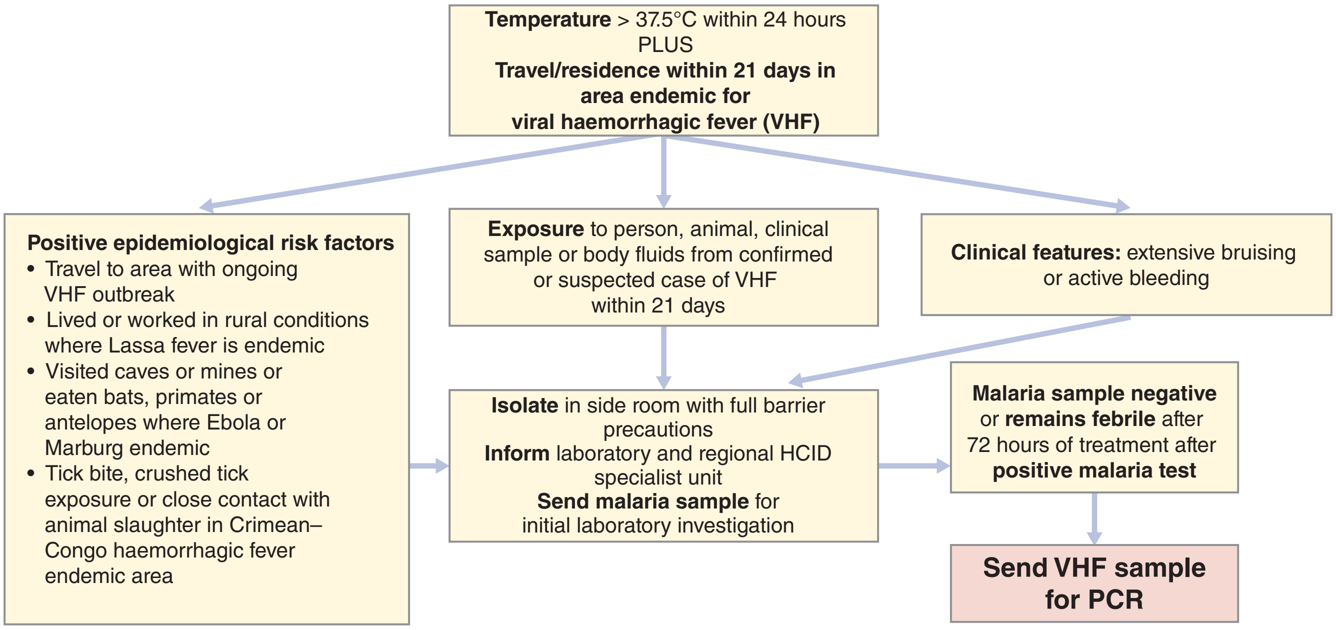
Eosinophilia occurs in a variety of haematological, allergic and inflammatory conditions discussed on page 955. It may also arise in HIV-1 and human T-cell lymphotropic virus (HTLV)-1 infection. However, eosinophils are important in the immune response to parasitic infections, especially those with a tissue migration phase. In the context of travel to or residence in the tropics, a patient with an eosinophil count of more than 0.4×10^9/L should be investigated for both non-parasitic (see Box 24.9) and parasitic causes (Box 14.20).

The response to parasite infections is often different when travellers to and residents of endemic areas are compared. Travellers often have recent and light infections associated with eosinophilia. Residents who have been infected for a long time often have chronic pathology without eosinophilia.

Clinical assessment

A history of travel to known endemic areas for schistosomiasis, onchocerciasis and the filariases will indicate possible causes. Assessment should establish duration of exposure and the history should address all the elements in Box 14.15.

Physical signs or symptoms that suggest a parasitic cause for eosinophilia include transient rashes (schistosomiasis or strongyloidiasis), fever (Katayama syndrome), pruritus (onchocerciasis) or migrating subcutaneous swellings (loiasis, gnathostomiasis) (see Box 14.21). Paragonimiasis can give rise to haemoptysis, and the migratory phase of intestinal nematodes or lymphatic filariasis may cause cough, wheezing and transient



Temperature > 37.5°C within 24 hours
PLUS
Travel/residence within 21 days in area endemic for viral haemorrhagic fever (VHF)
Positive epidemiological risk factors
• Travel to area with ongoing VHF outbreak
• Lived or worked in rural conditions where Lassa fever is endemic
• Visited caves or mines or eaten bats, primates or antelopes where Ebola or Marburg endemic
• Tick bite, crushed tick exposure or close contact with animal slaughter in Crimean–Congo haemorrhagic fever endemic area
Exposure to person, animal, clinical sample or body fluids from confirmed or suspected case of VHF within 21 days
Clinical features: extensive bruising or active bleeding
Isolate in side room with full barrier precautions
Inform laboratory and regional HCID specialist unit
Send malaria sample for initial laboratory investigation
Malaria sample negative or remains febrile after 72 hours of treatment after positive malaria test
Send VHF sample for PCR

Fig. 14.7 Approach to the patient with suspected viral haemorrhagic fever (VHF). See Box 14.54. Fever and recent time spent in a VHF endemic location trigger epidemiological, exposure and clinical questions which, if positive, result in appropriate steps and guide an algorithm for management including a polymerase chain reaction (PCR) test for VHF. (HCID = high consequence infectious disease) *Adapted from assets.publishing.service.gov.uk/media/5a807f14ed915d74e33fac3d/VHF_Algo.pdf.*

i 14.19 Most common causes of travellers' diarrhoea

- Enterotoxigenic *E. coli* (ETEC)
- *Shigella* spp.
- *Campylobacter jejuni*
- *Salmonella* serovars
- *Plesiomonas shigelloides*
- Non-cholera *Vibrio* spp.
- *Aeromonas* spp.

pulmonary infiltrates. Schistosomiasis, strongyloidiasis and gnathostomiasis induce transient respiratory symptoms with infiltrates in the acute stages and, when eggs reach the pulmonary vasculature in chronic schistosomiasis infection, can result in shortness of breath with features of right heart failure due to pulmonary hypertension. Fever and hepatosplenomegaly are seen in schistosomiasis, *Fasciola hepatica* infection and toxocariasis (visceral larva migrans). Intestinal worms, such as *Ascaris lumbricoides* and *Strongyloides stercoralis*, can cause abdominal symptoms, including intestinal obstruction and diarrhoea. In the case of heavy infestation with *Ascaris*, this may be due to fat malabsorption and there may be associated nutritional deficits. *Schistosoma haematobium* can cause haematuria or haematospermia. *Toxocara* spp. can give rise to choroidal lesions with visual field defects. *Angiostrongylus cantonensis* and gnathostomiasis induce eosinophilic meningitis, and the hyperinfection syndrome caused by *S. stercoralis* in immunocompromised hosts induces meningitis due to gram-negative bacteria. Myositis is a feature of trichinosis (trichinellosis) and cysticercosis. Periorbital oedema can occur with trichinosis.

Investigations

The diagnosis of a parasitic infestation requires direct visualisation of adult worms, larvae or ova. Serum antibody detection may not distinguish between active and past infection and is often unhelpful in those born in endemic areas. Radiological investigations may provide circumstantial evidence of parasite infestation. Box 14.21 describes initial investigations for eosinophilia.

Management

A specific diagnosis guides therapy. In the absence of a specific diagnosis, many clinicians will give an empirical course of praziquantel if the individual has potentially been exposed to schistosomiasis, or albendazole/ivermectin if strongyloidiasis or intestinal nematodes are likely causes.

Skin conditions acquired in the tropics

Community-based studies in the tropics consistently show that skin infections (bacterial and fungal), scabies and eczema are the most common skin problems (Box 14.22). Scabies and eczema are discussed on pages 1123 and 1125. Cutaneous leishmaniasis and onchocerciasis have defined geographical distributions. In travellers, secondarily infected insect bites, pyoderma, cutaneous larva migrans and non-specific dermatitis are common.

During the investigation of skin lesions, enquiry should be made about habitation, activities undertaken, and regions visited (see Box 14.15). Examples of skin lesions in tropical disease are shown in Figure 14.8.

Skin biopsies are helpful in diagnosing aetiology. Culture of biopsy material may be needed to diagnose bacterial, fungal, parasitic and mycobacterial infections.

Infections in adolescence

Particular issues of relevance in adolescent patients are shown in Box 14.23.

Infections in pregnancy

Box 14.24 shows some of the infections encountered in pregnancy.

Infections in the immunocompromised host

Immunocompromised hosts include those with congenital immunodeficiency, HIV infection and iatrogenic immunosuppression induced by chemotherapy, or immunosuppressant medicines, including high-dose

14.20 Parasite infections that cause eosinophilia

Infestation	Pathogen	Clinical syndrome with eosinophilia
Strongyloidiasis	*Strongyloides stercoralis*	Larva currens
Soil-transmitted helminthiases		
Hookworm	*Necator americanus*	Anaemia
	Ancylostoma duodenale	Anaemia
Ascariasis	*Ascaris lumbricoides*	Löffler syndrome
Toxocariasis	*Toxocara canis*	Visceral larva migrans
Schistosomiasis	*Schistosoma haematobium*	Katayama fever
	S. mansoni, S. japonicum	Chronic infection
Filariases		
Loiasis	*Loa loa*	Skin nodules
Wuchereria bancrofti	*W. bancrofti*	Lymphangitis, lymphadenopathy, orchitis, intermittent bouts of cellulitis, lymphoedema and elephantiasis
Brugia malayi	*B. malayi*	Brugian elephantiasis similar but typically less severe than that caused by *W. bancrofti*
Mansonella perstans	*M. perstans*	Asymptomatic infection, occasionally subconjunctival nodules
Onchocerciasis	*Onchocerca volvulus*	Visual disturbance, dermatitis
Other nematode infections	*Trichinella spiralis*	Myositis
	Gnathostoma spinigerum	Pruritus, migratory nodules, eosinophilic meningitis
Cestode infections	*Taenia saginata, T. solium*	Usually asymptomatic; eosinophilia associated with migratory phase
	Echinococcus granulosus	Lesions in liver or other organ; eosinophilia associated with leakage from cyst
Liver flukes	*Fasciola hepatica*	Hepatic symptoms; eosinophilia associated with migratory phase
	Clonorchis sinensis	As for fascioliasis
	Opisthorchis felineus	As for fascioliasis
Lung fluke	*Paragonimus westermani*	Lung lesions

14.21 Initial investigation of eosinophilia

Investigation	Pathogens sought
Stool microscopy	Ova, cysts and parasites
Terminal urine	Ova of *Schistosoma haematobium*
Duodenal aspirate	Filariform larvae of *Strongyloides*, liver fluke ova
Day bloods	Microfilariae *Brugia malayi, Loa loa*
Night bloods	Microfilariae *Wuchereria bancrofti*
Skin snips	*Onchocerca volvulus*
Slit-lamp examination	*Onchocerca volvulus*
Serology	Schistosomiasis, filariasis, strongyloidiasis, hydatid, trichinosis, gnathostomiasis etc.

glucocorticoids, monoclonal antibodies, tyrosine kinase inhibitors and cellular therapies. Metabolic abnormalities, such as under-nutrition or hyperglycaemia, may also contribute. Multiple elements of the immune system are potentially compromised. A patient may have impaired neutrophil function from chemotherapy, impaired T-cell and/or B-cell responses due to underlying malignancy, T-cell and phagocytosis defects due to glucocorticoids, mucositis from chemotherapy and an impaired skin barrier due to insertion of a central venous catheter. In contrast, monoclonal antibodies or small molecule inhibitors of specific signalling pathways may have more selective effect on the immune response. Fever may result from infectious or non-infectious causes, including drugs (either the immunomodulator or other agents used in combination with these), vasculitis, neoplasm, lymphoproliferative disease, graft-versus-host disease (in recipients of haematopoietic stem cell transplants (HSCT)), organising pneumonitis or Sweet syndrome (reddish nodules or plaques with fever and leucocytosis, in association with haematological malignancy).

Although many infections in immunocompromised patients are caused by common organisms, they may also be infected with organisms that rarely or never cause infection in the non-immunocompromised host (opportunistic pathogens/opportunistic infections). Inhibition of a particular signalling pathway or cytokine may result in quite selective susceptibility to infection, for example mucocutaneous candidiasis with monoclonal antibodies against IL-17 (secukinumab) and meningococcal disease with the complement inhibitor eculizumab. In contrast, some small molecule inhibitors can have broader impact on susceptibility to infection, for example there is increased susceptibility to pneumocystis pneumonia, invasive fungal infection and CMV with the phosphatidylinositol-3-kinase inhibitor idelalisib and to tuberculosis, pneumocystis pneumonia, shingles, CMV and progressive multifocal leukoencephalopathy and varicella with the Janus kinase inhibitors.

Clinical assessment

The following should be addressed in the history:

- identification of the immunosuppressant factors, nature of the immune defect and known susceptibility patterns for that agent or class of agents
- any past infections and their treatment, including antimicrobial-resistant or recurrent infections
- epidemiological risk factors increasing exposure to infections, including opportunistic infections that would not cause disease in an immunocompetent host
- prophylactic medicines and vaccinations administered.

Examination should include inspection of the skin, any central venous catheters, the mouth, sinuses, ears and perianal area (digital rectal examination should be avoided as it may induce bacteraemia). Disseminated infections can manifest as cutaneous lesions. The areas around fingernails and toenails should also be inspected closely.

Investigations

Initial screening tests are as described above. Immunocompromised hosts often have decreased inflammatory responses leading to attenuation of physical signs, such as neck stiffness with meningitis, radiological features and laboratory findings, such as leucocytosis. Chest CT scan

14.22 Rash in tropical travellers/residents

Maculopapular rash

- Dengue
- HIV-1
- Typhoid
- *Spirillum minus*
- Rickettsial infections
- Measles

Petechial or purpuric rash

- Viral haemorrhagic fevers
- Yellow fever
- Meningococcal sepsis
- Leptospirosis
- Rickettsial spotted fevers
- Malaria

Vesicular rash

- Monkeypox
- Insect bites
- Rickettsial pox

Urticarial rash

- Katayama fever (schistosomiasis)
- *Toxocara* spp.
- *Strongyloides stercoralis*
- Fascioliasis

Ulcers

- Leishmaniasis
- *Mycobacterium ulcerans* (Buruli ulcer)
- Dracunculosis
- Anthrax
- Rickettsial eschar
- Tropical ulcer (*Fusobacterium ulcerans* and *Treponema vincentii*)
- Ecthyma (staphylococci, streptococci)

Papules

- Scabies
- Insect bites
- Prickly heat
- Ringworm
- Onchocerciasis

Nodules or plaques

- Leprosy
- Chromoblastomycosis
- Dimorphic fungi
- Trypanosomiasis
- Onchocerciasis
- Myiasis (larvae of tumbu fly or botfly)
- Tungiasis (*Tunga penetrans*)

Migratory linear rash

- Cutaneous larva migrans (CLM; dog hookworms)
- *Strongyloides stercoralis* (larva currens, more rapid than CLM)

Migratory papules/nodules

- Loa loa
- Gnathostomiasis
- Schistosomiasis

Thickened skin

- Mycetoma (actinomycetoma/eumycetoma)
- Elephantiasis (filariasis)

(CLM = cutaneous larva migrans; HIV-1 = human immunodeficiency virus-1)

14.23 Key issues in infectious diseases in adolescence

- **Common infectious syndromes**: infectious mononucleosis, bacterial pharyngitis, whooping cough, pneumonia, staphylococcal skin/soft tissue infections, urinary tract infections, acute gastroenteritis.
- **Life-threatening infections**: meningococcal infection (sepsis and/or meningitis).
- **Sexually transmitted infections**: human papillomavirus (HPV), human immunodeficiency virus-1 (HIV-1), hepatitis B virus and chlamydia. These may reflect either voluntary sexual activity or sexual coercion/abuse.
- **Travel-related infections**: diarrhoea, malaria etc. are relatively common.
- **Infections in susceptible groups**: patients with cystic fibrosis, congenital immunodeficiency, acute leukaemia and other adolescent malignancies are vulnerable to specific groups of infections.
- **Infections requiring prolonged antimicrobial use**: adherence to chronic therapy is challenging, for both oral (antituberculous or antiretroviral) and systemic (osteomyelitis, septic arthritis or post-operative infections) treatments. Outpatient antimicrobial therapy is preferred to minimise hospitalisation.
- **Vaccination**: engagement with age-specific vaccine programmes should be ensured, e.g. HPV, childhood booster vaccines and meningococcal vaccine.
- **Risk reduction**: education relating to sexual health and alcohol and recreational drug usage is important.

should be considered in addition to CXR when respiratory symptoms occur. Abdominal imaging may also be warranted, particularly if there is right lower quadrant pain, which may indicate typhlitis (inflammation of the caecum) in neutropenic patients. Blood cultures from a central venous catheter, urine cultures and stool cultures if diarrhoea is present are also recommended.

Nasopharyngeal aspirates are sometimes diagnostic, as immunocompromised hosts may shed respiratory viruses for prolonged periods. Skin lesions should be biopsied if nodules are present, and investigation should include fungal stains. Useful molecular techniques include PCR for cytomegalovirus (CMV) and *Aspergillus* spp. DNA. Antigen assays that may be used include blood tests for cryptococcal antigen (CrAg), *Aspergillus* galactomannan, (1,3)-β-D-glucan (for *Pneumocystis jirovecii* and fungi other than *Cryptococcus* spp. and mucoraceous moulds) and a urine test for *Legionella pneumophila* type 1. Antibody detection is rarely useful in immunocompromised patients except for HIV-1. Patients with respiratory signs or symptoms should be considered for bronchoalveolar lavage (BAL) to detect *Pneumocystis jirovecii*, other fungi, bacteria and viruses.

Neutropenic fever

Patients with neutropenia are highly susceptible to bacterial and fungal infection, the risk of which increases progressively as the neutrophil count drops below 1.0 × 10^9/L. Gram-positive organisms are the most common pathogens, particularly in association with in-dwelling catheters. There is no universal definition of neutropenic fever, but most authorities define neutropenia as a neutrophil count of $<0.5 \times 10^9$/L (p. 955) and fever as a single measurement >38.5°C or sustained temperature >38°C.

Empirical broad-spectrum antimicrobial therapy is commenced when cultures have been obtained. The most common regimens for neutropenic fever are broad-spectrum anti-pseudomonal penicillins, e.g. piperacillin–tazobactam with vancomycin if MRSA positive. The routine addition of aminoglycosides to these agents is not supported by trial data. If fever has not resolved after 3–5 days, empirical antifungal therapy (e.g. caspofungin) is added (p. 151). An alternative antifungal strategy is to use azole prophylaxis in high-risk patients and markers of early fungal infection, such as galactomannan, (1,3)-β-D-glucan and/or fungal PCR, to guide initiation of antifungal treatment (a ‘pre-emptive approach’).

14.24 Infections of specific importance in pregnancy

Infection	Consequence	Prevention and management
Rubella	Congenital malformation	Childhood vaccination and vaccination of non-immune mothers post-delivery
Cytomegalovirus	Neonatal infection, congenital malformation	Limited prevention strategies
Zika virus	Congenital malformation	Avoidance of travel, delay in pregnancy if infected
Varicella zoster (VZ) virus	Neonatal infection, congenital malformation, severe infection in mother	VZ immunoglobulin, antiviral prophylaxis (see Box 14.48)
Herpes simplex virus (HSV)	Congenital or neonatal infection	Aciclovir and consideration of caesarean section for mothers who shed HSV from genital tract at time of delivery. Aciclovir for infected neonates
Hepatitis B virus	Chronic infection of neonate	Hepatitis B immunoglobulin and active vaccination of newborn
Hepatitis E virus	Fulminant hepatitis, pre-term delivery, fetal loss	Maintenance of standard food hygiene practices
Human immunodeficiency virus-1 (HIV-1)	Chronic infection of neonate	Antiretroviral drugs for mother and infant and consideration of caesarean section if HIV-1 viral load detectable. Avoidance of breastfeeding if viral load not suppressed.
Parvovirus B19	Congenital infection	Avoidance of individuals with acute infection if pregnant
Measles	More severe infection in mother and neonate, fetal loss	Childhood vaccination, human normal immunoglobulin in non-immune pregnant contacts and vaccination post-delivery
Dengue	Neonatal dengue if mother has infection < 5 weeks prior to delivery	Vector (mosquito) control
Syphilis	Congenital malformation	Serological testing in pregnancy with prompt treatment of infected mothers
Neisseria gonorrhoeae* and *Chlamydia trachomatis	Neonatal conjunctivitis (ophthalmia neonatorum, see Ch. 15)	Treatment of infection in mother and neonate
Listeriosis	Neonatal meningitis or bacteraemia, bacteraemia or pyrexia of unknown origin in mother	Avoidance of unpasteurised cheeses and other dietary sources
Brucellosis	Possibly increased incidence of fetal loss	Avoidance of unpasteurised dairy products
Group B streptococcal infection	Neonatal meningitis and sepsis. Sepsis in mother after delivery	Risk- or screening-based antimicrobial prophylaxis in labour (recommendations vary between countries)
Toxoplasmosis	Congenital malformation	Diagnosis and prompt treatment of cases, avoidance of under-cooked meat while pregnant
Malaria	Fetal loss, intrauterine growth retardation, severe malaria in mother	Avoidance of insect bites. Intermittent preventative treatment during pregnancy to decrease incidence in high-risk countries

Post-transplantation fever

Fever in transplant recipients may be due to infection, episodes of graft rejection in solid organ transplant recipients, or graft-versus-host disease following haematopoietic stem cell transplantation.

Infections in solid organ transplant recipients are grouped according to the time of onset (Box 14.25). Those in the first month are mostly related to the underlying condition or surgical complications. Those occurring 1–6 months after transplantation are characteristic of impaired T-cell function. Risk factors for CMV infection have been identified; patients commonly receive either prophylaxis or intensive monitoring involving regular testing for CMV DNA by PCR and early initiation of anti-CMV therapy using intravenous ganciclovir or oral valganciclovir if tests become positive. Greater use of prophylactic regimens, despite reducing infections overall, is extending the period of risk so that some opportunistic infections, e.g. CMV, may be seen after this initial 6-month period.

Following HSCT, infections in the first 4 weeks are more common in patients receiving a myeloablative-conditioning regimen (see Box 14.25). Later infections are more common if an allogeneic, as opposed to autologous, procedure is performed.

Post-transplant lymphoproliferative disorder (PTLD) is an Epstein–Barr virus (EBV)-associated lymphoma that can complicate transplantation, particularly when primary EBV infection occurs after transplantation.

14.25 Infections in transplant recipients

Time post-transplantation	Infections
Solid organ transplant recipients	
0–1 month	Bacterial or fungal infections related to the underlying condition or surgical complications
1–6 months	CMV, other opportunistic infections (e.g. *Pneumocystis jirovecii* pneumonia)
> 6 months	Bacterial pneumonia, other bacterial community-acquired infections, shingles, cryptococcal infection, PTLD
Myeloablative haematopoietic stem cell transplant recipients	
Pre-engraftment (typically 0–4 weeks)	Bacterial and fungal infections, respiratory viruses or HSV reactivation
Post-engraftment:	
Early (< 100 days)	CMV, *Pneumocystis jirovecii* pneumonia, moulds or other opportunistic infections
Late (> 100 days)	Community-acquired bacterial infections, shingles, CMV, PTLD

(CMV = cytomegalovirus; HSV = herpes simplex virus; PTLD = post-transplant lymphoproliferative disorder)

Epidemiology

The acquired immunodeficiency syndrome (AIDS) is caused by the human immunodeficiency virus (HIV), which progressively impairs cellular immunity. HIV is a zoonotic infection with simian immunodeficiency viruses (SIV) from African primates, probably first infecting local hunters. HIV-1 was transmitted from chimpanzees (and occasionally gorillas (*Troglodytes gorilla*)) and HIV-2 from sooty mangabey monkeys. HIV-1 is the cause of the global HIV pandemic. HIV-2, which causes a similar illness to HIV-1 but progresses more slowly and is less transmissible, is restricted mainly to western Africa.

Diagnosis, treatment and prevention strategies for HIV-2 are similar to those for HIV-1 although HIV-2 has intrinsic resistance to non-nucleoside reverse transcriptase inhibitor (NNRTI) drugs.

Global and regional epidemics

The global epidemiology of HIV has been dramatically changed by expanding access to antiretroviral therapy (ART), which reached 30.7 million people in 2023: the annual number of AIDS-related deaths has been reduced by 69% since the peak in 2004, the number of new infections has decreased by 60% since the peak in 1995, and the number of people with HIV (PWH) has increased as life expectancy improves on ART. Regions have marked differences in HIV prevalence, incidence trends for new infections and dominant modes of transmission (Box 14.26). HIV has had a devastating impact in sub-Saharan Africa, but this region has experienced the steepest decline in new HIV infections globally.

Modes of transmission

HIV is transmitted by sexual contact, by exposure to blood (e.g. injection drug use) and blood products, or to infants of HIV-positive mothers, who may be infected in utero, perinatally or via breastfeeding. The risk of contracting HIV after exposure to infected body fluid is dependent on the integrity of the exposed site, the type and volume of fluid, and the level of viraemia in the source person. The approximate transmission risk after exposure is given in Box 14.27. Factors that increase the risk of transmission are listed in Box 14.28. Routine screening of blood and blood products for HIV infection has virtually eliminated this mode of transmission.

Virology and transmission

HIV is an enveloped ribonucleic acid (RNA) retrovirus from the lentivirus family. After mucosal exposure, HIV is transported via dendritic cells to the lymph nodes, where infection becomes established. This is followed by viraemia and dissemination to lymphoid organs, which are the main sites of viral replication.

The HIV virion has a lipid membrane lined by a matrix protein studded with glycoprotein (gp) 120 and gp41 spikes. The inner cone-shaped protein core (p24) houses two copies of the single-stranded RNA genome and viral enzymes, which are targets of therapy.

HIV infects cells bearing the CD4 receptor: T-helper lymphocytes, monocyte–macrophages, dendritic cells and microglial cells in the central nervous system (CNS). Entry into the cell commences with binding of gp120 to the CD4 receptor (Fig. 14.9), which results in a conformational change in gp120 that permits binding to one of two chemokine co-receptors (CXCR4 or CCR5). The chemokine co-receptor CCR5 is utilised during initial infection, but subsequently the virus may adapt to use CXCR4. Individuals who are homozygous for the CCR5 delta 32 mutation do not express functional CCR5 on CD4 cells, thus preventing

14.27 Risk of HIV transmission after single exposure to an HIV-infected source*

HIV exposure	Approximate risk
Sexual	
Vaginal intercourse: female to male	0.05%
Vaginal intercourse: male to female	0.1%
Anal intercourse: insertive	0.1%
Anal intercourse: receptive	1.4%
Oral intercourse: insertive	< 0.01%
Oral intercourse: receptive	< 0.01%
Blood exposure	
Blood transfusion	90%
Intravenous drug-users sharing needles	0.67%
Percutaneous needlestick injury	0.3%
Mucous membrane splash	0.09%
Mother to child	
Vaginal delivery	15%
Breastfeeding (per month)	0.5%

*These are approximate estimates and assume that the source person is not being treated with ART.

14.28 Factors increasing the risk of transmission of HIV

Common to all transmission categories

- High viral load

Sexual transmission

- STIs, especially genital ulcers
- Cervical ectopy
- Rectal or vaginal lacerations
- Menstruation
- Uncircumcised male partner
- Receptive anal intercourse
- Sexual activity with recreational drug use ('chemsex')

Injection drug use transmission

- Sharing equipment
- Linked commercial sex
- Intravenous use
- Concomitant cocaine use
- Incarceration

Occupational transmission

- Deep injury
- Visible blood on device
- Needle was in a blood vessel

Vertical transmission

- Prolonged rupture of membranes
- Older gestational age

(STIs = sexually transmitted infections)

14.26 Regional HIV prevalence in 2022, new infection incidence trend and dominant mode of transmission

Region	People living with HIV (millions)	HIV new infection incidence trend	Dominant transmission
Sub-Saharan Africa	25.6	Decreasing	Heterosexual
Asia and Pacific	6.1	Decreasing	MSM, heterosexual
Americas	3.8	Decreasing	MSM, heterosexual
Europe	3.0	Increasing	MSM, IDU
Eastern mediterranean	0.49	Decreasing	IDU, MSM

(IDU = injection drug-users; MSM = men who have sex with men)

Transcription

Fig. 14.9 **Life cycle of HIV.** HIV engages CD4+ cells using gp120. Chemokine co-receptor binding is then achieved followed by membrane fusion and cellular entry involving gp41. After penetrating the cell and uncoating, a DNA copy is transcribed from the RNA genome by the reverse transcriptase enzyme, which is carried by the infecting virion. Reverse transcription is an error-prone process and multiple mutations arise with ongoing replication, which results in considerable viral genetic heterogeneity. Viral DNA is transported into the nucleus and integrated within the host cell genome by the integrase enzyme. Integrated virus is known as proviral DNA and persists for the life of the cell. Cells infected with proviral HIV DNA produce new virions if they undergo cellular activation, resulting in the transcription of viral messenger RNA (mRNA) copies, which are then translated into viral peptide chains. The precursor polyproteins are then cleaved by the viral protease enzyme to form new viral structural proteins and enzymes that migrate to the cell surface and are assembled using the host cellular apparatus to produce infectious viral particles, containing viral genomic RNA, which recruit gag proteins to enable viral assembly at the plasma membrane. These bud from the cell surface, incorporating the host cell membrane into the viral envelope. The virion then infects other CD4-expressing cells and the process is repeated. Red arrows indicate sites of action of antiretroviral drugs.

HIV infection. In asymptomatic PWH it has been estimated that more than 10^{10} virions are produced and 10^9 CD4 lymphocytes destroyed daily. CD4 lymphocytes are destroyed primarily by the host immune response rather than by cytopathic effects of HIV.

A small population of T-helper lymphocytes enter a post-integration latent phase. Latently infected cells are important as a viral reservoir forming sanctuary sites from antiretroviral drugs, which act only on replicating virus. Current ART is unable to eradicate HIV infection completely due to the persistence of proviral DNA in long-lived latently infected CD4 cells.

Following primary infection there is an initial peak of viraemia; this settles to a plateau phase of persistent chronic viraemia (Fig. 14.10). Over time there is gradual attrition of the CD4 T-cell population. As these cells are pivotal in orchestrating the immune response, PWH eventually become susceptible to opportunistic diseases.

The predominant opportunist infections in PWH are the consequences of impaired cell-mediated immunity (e.g. to mycobacteria, herpesviruses). However, there is also a B-lymphocyte defect with impaired antibody production to new antigens and dysregulated antibody production, with a polyclonal increase in gamma globulins, resulting in an increased risk of infection with encapsulated bacteria, notably *Streptococcus pneumoniae*.

The immune activation in response to HIV infection does not completely resolve on effective ART. This residual inflammatory state has been implicated in the pathogenesis of several non-communicable diseases that occur at a higher rate in PWH on ART than in the general population, notably vascular disease.

Diagnosis and investigations

Globally, the trend is towards universal HIV testing, rather than testing only people at high risk or those with manifestations of HIV infection. In the UK testing also targets high-risk groups (Box 14.29), particularly in hard to reach settings where the group may not often engage with health services. HIV is diagnosed by detecting host antibodies either with rapid point-of-care tests or in the laboratory. Most tests detect antibodies to both HIV-1 and HIV-2 and often include an assay for p24 antigen to detect patients with primary infection before the antibody response occurs. Two positive antibody tests from two different immunoassays are sufficient to confirm infection. Nucleic acid amplification tests to detect HIV RNA are used to diagnose infections in infants of HIV-positive mothers, who carry maternal antibodies to HIV for up to 15 months, and to diagnose primary infection before antibodies have developed. PCR is more sensitive than p24 antigen detection for diagnosing primary infection.

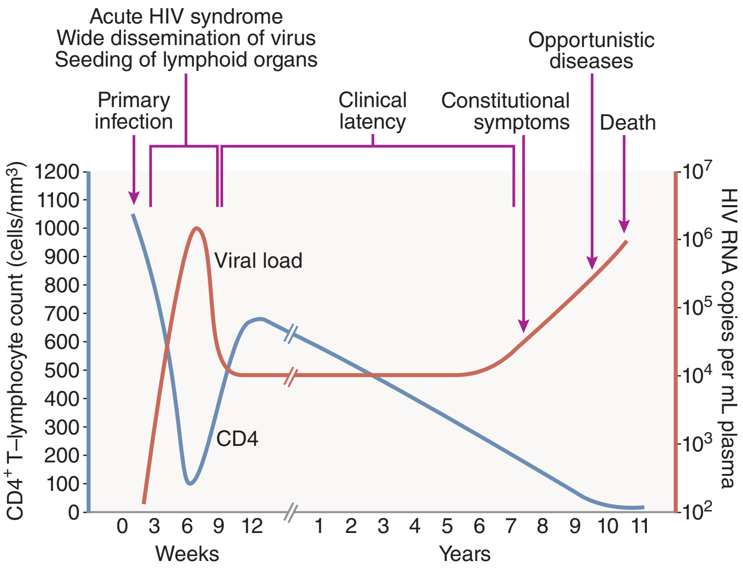

Fig. 14.10 Virological and immunological progression of untreated HIV infection. The host immune response to HIV infection is both humoral, with the development of antibodies to a wide range of antigens, and cellular, with a dramatic expansion of HIV-specific CD8 cytotoxic T lymphocytes, resulting in a CD8 lymphocytosis and reversal of the usual CD4:CD8 ratio. CD8 cytotoxic T lymphocytes kill activated CD4 cells with replicating HIV, but not latently infected CD4 cells. Uninfected bystander CD4 cells die by a range of mechanisms. HIV evades elimination despite this vigorous immune response, in part because the conserved regions of gp120 and gp41 that are necessary for viral attachment and entry are covered by highly variable glycoprotein loops.

14.29 Patients who should be offered and recommended HIV testing in the UK

Patients accessing specialist sexual health services (including genitourinary medicine)

- All patients who attend for testing or treatment

Patients accessing primary care (including emergency care) and secondary care

- All patients attending their first appointment at:
  - Drug dependency programmes
  - Pregnancy termination services
  - Services treating hepatitis B or C, lymphoma or tuberculosis
- All patients who:
  - Have symptoms that may indicate HIV or for which HIV is part of the differential diagnosis
  - Are from a country or group with high rate of HIV infection
  - Are male, or trans women, who have sex with men
  - Report sexual contact with someone from a country with a high rate of HIV infection
  - Disclose high-risk sexual practices, e.g. ‘chemsex’
  - Are diagnosed with, or request testing for, a sexually transmitted infection
  - Report a history of injecting drug use
  - Are the sexual partners of people known to be HIV-positive or at high risk of HIV
- In areas of high[1] and extremely high prevalence[2]:
  - All patients not previously diagnosed with HIV who register with a general practice or undergo blood testing for any reason
- In areas of extremely high prevalence[2]:
  - All emergency care and secondary care patients not previously diagnosed with HIV
  - At each general practice consultation consider offering opportunistic HIV testing

Prison inmates

- All new inmates not previously diagnosed with HIV

[1] Prevalence of diagnosed HIV is 2–5 per 1000 people aged 15–59.

[2] Prevalence of diagnosed HIV is ≥ 5 per 1000 people aged 15–59.

Adapted from National Institute for Health and Care Excellence. HIV testing: increasing uptake among people who may have undiagnosed HIV. NICE guideline NG60; 2016.

14.30 Baseline investigations

- CD4 count
- Viral load
- Hepatitis B surface antigen
- Hepatitis C antibody
- Liver function tests
- Full blood count
- Urinalysis, serum creatinine
- Syphilis serology
- Cervical smear in women
- Serum cryptococcal antigen (if CD4 < 100)
- Tuberculin skin test or interferon gamma release assay
- Sexually transmitted infection screen

The purpose of HIV testing is not only to identify PWH, but also to educate people about HIV prevention and transmission. Counselling in the client’s home language is essential both before testing and after the result is obtained. There are major advantages to using rapid point-of-care HIV tests, as ART can be initiated if HIV infection is diagnosed.

A number of baseline investigations should be done at the initial medical evaluation (Box 14.30). The extent of these investigations will depend on the resources available.

Monitoring

CD4 lymphocyte counts indicate the degree of immune suppression, and are used, together with clinical staging, in decisions to start prophylaxis against opportunistic infections. CD4 counts are of critical importance in the differential diagnosis of clinical problems.

The normal CD4 count is over 500 cells/mm^3. The rate of decline in CD4 count in PWH is highly variable. People with CD4 counts between 200 and 500 cells/mm^3 have a low risk of developing major opportunistic infections. Morbidity due to inflammatory dermatoses, herpes zoster, oral candidiasis, tuberculosis, bacterial pneumonia and HIV-related immune disorders (e.g. immune thrombocytopenia) becomes increasingly common as CD4 counts decline. Once the count is below 200 cells/mm^3, there is severe immune suppression and a high risk of AIDS-defining conditions. It is important to note that patients can be asymptomatic despite low CD4 counts and that major opportunistic diseases occasionally present with high CD4 counts.

The level of viraemia is measured by quantitative PCR of HIV RNA, known as the viral load. Determining the viral load is crucial for monitoring responses to ART (p. 333).

Clinical staging

Clinical staging should be done at the initial medical examination – it provides prognostic information and is a key criterion for initiating prophylaxis against opportunistic infections. Two clinical staging systems are used internationally (Box 14.31 and p. 319) – PWH are staged according to the most severe manifestation and do not improve their classification. People do not always progress steadily through all stages and may present with AIDS-defining illness having been asymptomatic. Advanced HIV disease is defined by WHO as stage 3 or 4 disease, or CD4 count <200 cells/mm^3.

Primary HIV infection

Primary infection is symptomatic in the majority of cases but the diagnosis is usually missed. The incubation period is 2–4 weeks. Symptoms typically resolve in 2 weeks. The clinical manifestations (Box 14.32) resemble those of infectious mononucleosis/glandular fever (p. 340) – the presence of maculopapular rash or mucosal ulceration strongly suggests primary HIV infection. Atypical lymphocytosis occurs less frequently than

- Progressive multifocal leukoencephalopathy

in EBV infection. Transient lymphopenia, including CD4 lymphocytes, is found in most cases (see Fig. 14.10), which may result in opportunistic infections, notably oropharyngeal candidiasis. Thrombocytopenia and moderate elevation of liver enzymes are commonly present.

Early diagnosis is made by detecting HIV RNA by PCR or p24 antigenaemia. The appearance of specific anti-HIV antibodies in serum (seroconversion) occurs 2–12 weeks after the development of symptoms. The window period during which antibody tests may be false negative is prolonged when post-exposure prophylaxis has been used.

Asymptomatic infection

A prolonged period of clinical latency follows primary infection, during which infected individuals are asymptomatic. Persistent generalised lymphadenopathy with nodes typically <2 cm diameter is a common finding. Eventually, the lymph nodes regress, with destruction of node architecture as disease advances.

Viraemia peaks during primary infection and then drops as the immune response develops, to reach a plateau after about 3 months. The level of viraemia at the plateau is a predictor of the rate of decline in CD4 counts. The median time from infection to the development of AIDS in adults is about 9 years, but is highly variable (see Fig. 14.10). A small proportion of untreated PWH are long-term non-progressors, with CD4 counts remaining normal for 10 years or more. Some long-term non-progressors have undetectable viral loads and are known as ‘elite controllers’.

Minor HIV associated disorders

A wide range of disorders indicating some impairment of cellular immunity occur in most PWH before they develop AIDS (CDC category B or WHO stages 2 and 3).

Acquired immunodeficiency syndrome

AIDS is defined by the development of specified opportunistic infections, cancers and severe manifestations of HIV itself (CDC category C or WHO stage 4).

Presenting problems in HIV infection

HIV itself is associated with a wide variety of clinical manifestations and opportunistic diseases. The CD4 count is of great value in differential diagnosis (Box 14.33). For example, pulmonary tuberculosis is a likely diagnosis and *Pneumocystis jirovecii* pneumonia (PCP) is very unlikely in a patient with a pulmonary infiltrate and a CD4 count of 350 cells/mm^3, but if the CD4 count is 50 cells/mm^3, both PCP and tuberculosis are likely.

Globally, tuberculosis is the most common cause of morbidity and mortality in PWH patients and should be considered in the differential diagnosis of most presenting problems in PWH from communities where tuberculosis is common.

Lymphadenopathy

Persistent generalised lymphadenopathy due to HIV is described above under asymptomatic infection. Rapid enlargement, asymmetric enlargement or lymphadenopathy associated with constitutional symptoms (even if the nodes are symmetrical) warrants further investigation. Asymmetric lymphadenopathy may be due to malignancy (Kaposi sarcoma or lymphoma) or tuberculosis. Tuberculous lymph nodes are often matted and may become fluctuant due to extensive caseous necrosis. Symmetrical generalised lymphadenopathy may occur in disseminated tuberculosis. Lymph node needle aspiration should be performed. One portion of the sample should be sent for *Mycobacterium tuberculosis* PCR, which has about a 70% yield in tuberculosis (or acid-fast bacilli (AAFB) microscopy if PCR is unavailable). The other portion should be fixed on a slide and sent for cytology. If caseous liquid is aspirated, this should be sent for mycobacterial culture or PCR. If needle aspiration is unhelpful, or if lymphoma or Kaposi sarcoma is suspected, excision or core needle biopsy should be performed.

Weight loss

Weight loss is common in advanced HIV disease. HIV wasting syndrome is an AIDS-defining condition, defined as weight loss of $>10\%$ of body weight, plus either unexplained chronic diarrhoea (lasting >1 month) or chronic weakness and unexplained prolonged fever (lasting >1 month). HIV wasting syndrome is a diagnosis of exclusion. If the weight loss is rapid (more than 1 kg a month), then major opportunistic infections or cancers become more likely (Fig. 14.11).

Fever

Common causes of prolonged fever with weight loss are listed in Figure 14.11. Non-typhoid *Salmonella* bacteraemia, which commonly presents with fever in low-income countries, is accompanied by diarrhoea in only about half of patients. HIV itself can present with prolonged fever but a treatable cause will be found in most patients. Abdominal imaging, preferably by computed tomography (CT) or magnetic resonance imaging (MRI), should be requested. Abdominal nodes (especially if they are hypodense in the centre) or splenic microabscesses suggest tuberculosis. Mycobacterial blood cultures, which can also detect some fungi, should be performed. Bone marrow aspirate and trephine biopsy are helpful if the full blood count shows cytopenias. Liver biopsy may be helpful if the liver enzymes are elevated but is invasive and seldom necessary. Mycobacterial and fungal stains and cultures should be done on all biopsies. Chest X-rays should be repeated after about a week, as micronodular or interstitial infiltrates may have become apparent (see p. 328).

Tuberculosis is by far the most common cause of PUO in PWH from communities with high tuberculosis prevalence – in this setting a trial of empirical therapy is warranted after cultures have been sent. Disseminated *Mycobacterium avium* complex (MAC) infection is an important cause of PUO, often presenting with diarrhoea and splenomegaly in high income settings. Disseminated endemic mycoses (e.g.

Post-inflammatory (especially pruritic papular eruption) Zidovudine	Emtricitabine (palms and soles)

*See Chapter 26 for more information.

Mucocutaneous disease

The skin and mouth should be carefully examined as mucocutaneous manifestations are extremely common in advanced HIV infection and many prognostically important conditions can be diagnosed by simple inspection. The differential diagnosis of dermatological conditions is simplified by categorising disorders according to the lesion type (Box 14.34). Some common dermatological diseases, notably psoriasis, are exacerbated by HIV. The risk of many drug rashes is increased in PWH. Skin biopsy should be sent for histology and culture for mycobacteria and fungi in patients with papular rashes if there are constitutional symptoms coinciding with the development of the rash.

Seborrhoeic dermatosis

Seborrhoeic dermatitis is common in HIV. The severity increases as the CD4 count falls. It presents as scaly red patches, typically in the nasolabial folds and in hairy areas. It responds well to a combined topical antifungal and glucocorticoid.

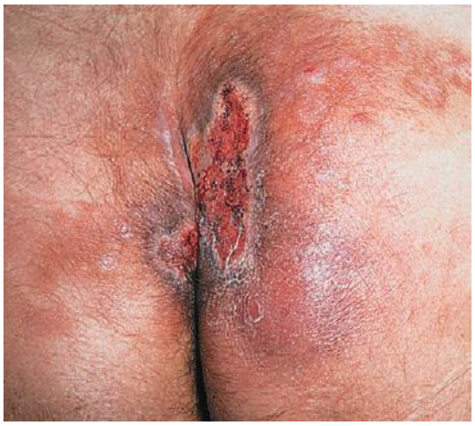

Fig. 14.13 **Severe mucocutaneous herpes simplex.** Chronic anogenital or perioral ulcers are very common in advanced HIV infection.

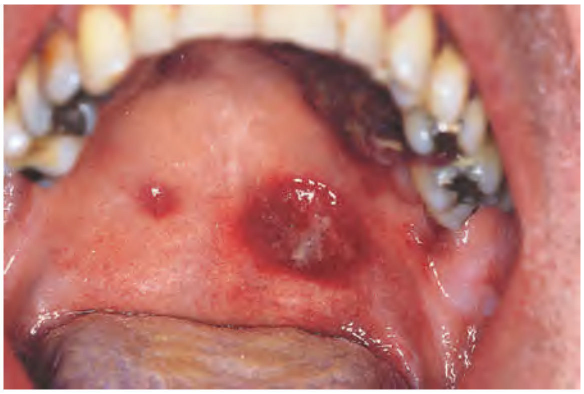

Fig. 14.14 **Oral Kaposi sarcoma.** A full examination is important to detect disease that may affect the palate, gums, fauces or tongue.

Herpes simplex infections

Recurrences of herpes simplex infection are common and primarily affect the nasolabial and anogenital areas (Fig. 14.13). As immune suppression worsens, the ulcers take longer to heal and become more extensive. Ulcers that persist for more than 4 weeks are AIDS-defining. The diagnosis is based on clinical appearance supported by PCR of vesicle fluid or from ulcer swabs. Response to a course of antiviral drug such as aciclovir is good but relapses are common.

Herpes zoster

Herpes zoster typically presents with a pathognomonic vesicular rash on an erythematous base in a dermatomal distribution (p. 338). In PWH, zoster is generally more extensive and has a longer duration and an increased risk of developing post-herpetic neuralgia. In people with advanced HIV disease, the rash may be multidermatomal and recurrent episodes may occur. Disseminated zoster is rare. Appropriate doses of aciclovir or its congeners should be given for all cases with active disease, irrespective of the time since the onset of the rash. Post-herpetic neuralgia is difficult to manage – analgesic adjuvants (e.g. amitriptyline, pregabalin) and topical capsaicin have modest efficacy.

Kaposi sarcoma

Kaposi sarcoma (KS) is a spindle-cell tumour of lympho-endothelial origin and is due to sexually transmitted human herpesvirus 8, also known as KS-associated herpesvirus (see p. 347).

In Africa, the male-to-female ratio of AIDS-associated KS is much lower than is seen with endemic KS, but men are still more affected than women, despite the fact that the seroprevalence of human herpesvirus 8 is the same in both sexes.

AIDS-associated KS is always a multicentric disease. Early mucocutaneous lesions are macular and may be difficult to diagnose. Subsequently, lesions become papular or nodular, and may ulcerate. KS lesions typically have a red–purple colour (Fig. 14.14 and p. 319) but may become hyperpigmented, especially in dark-skinned people. Lymphoedema is common as lymphatic vessels are infiltrated. KS commonly spreads to lymph nodes and viscerally, especially to the lungs and gastrointestinal tract. Visceral disease occasionally occurs in the absence of mucocutaneous involvement. B symptoms of fever, night sweats and weight loss may occur.

KS often responds to ART. Chemotherapy is reserved for people who fail to respond to ART, or is given together with ART if there are poor prognostic features (visceral involvement, oedema, ulcerated lesions and B symptoms).

Bacillary angiomatosis

Bacillary angiomatosis is a bacterial infection caused by *Bartonella henselae* or *B. quintana*. Skin lesions range from solitary superficial red–purple lesions resembling KS or pyogenic granuloma, to multiple subcutaneous nodules or plaques. Lesions are painful and may bleed or ulcerate. The infection may become disseminated with fevers, lymphadenopathy and hepatosplenomegaly. Diagnosis is made by biopsy and Warthin–Starry silver staining, which reveals aggregates of bacilli. Treatment with doxycycline or azithromycin is effective.

Papular pruritic eruption

Papular pruritic eruption (‘itchy red bump disease’) is an intensely itchy, symmetrical rash affecting the trunk and extremities. It is thought to be due to an allergic reaction to insect bites. Post-inflammatory hyperpigmentation is common. Topical glucocorticoids, emollients and antihistamines may be helpful. Measures to reduce insect bites are logical but difficult to implement in low-income settings.

Drug rashes

Cutaneous hypersensitivity to drugs occurs much more frequently in PWH. The most common presentation is an erythematous maculopapular rash. The drugs most commonly associated are sulphonamides and first-generation non-nucleoside reverse transcriptase inhibitors (NNRTIs). Severe, life-threatening features of drug rashes include blistering (when this affects more than 30% of surface area, it is known as toxic epidermal necrolysis), involvement of mucous membranes (Stevens–Johnson syndrome; p. 1134), or systemic involvement with fever or organ dysfunction (especially hepatitis, which is often delayed for a week or two after the rash develops). Because sulphonamides are important in the treatment and prophylaxis of opportunistic infections, rechallenge or desensitisation is often attempted in patients who have previously experienced rashes.

Oral conditions

Oropharyngeal candidiasis is nearly always caused by *C. albicans* (p. 398), but azole-resistant *Candida* species may be selected for if there have been repeated courses of azole drugs. Pseudomembranous candidiasis is the most common manifestation, with white patches on the buccal mucosa (p. 319) that can be scraped off to reveal a red raw surface. Angular cheilitis due to *Candida* is a common manifestation. Topical antifungals are usually effective. Systemic azole therapy, usually fluconazole, should be given if topical therapy fails or if there are oesophageal symptoms.

Oral hairy leucoplakia (p. 319) appears as corrugated white plaques running vertically on the side of the tongue – it is usually asymptomatic and is due to EBV.

Herpetiform oral ulcers occur in primary infection. Herpes simplex typically affects the nasolabial area but may cause oral ulcers. In early disease, minor aphthous ulcers are common. In advanced disease, giant aphthous ulcers occur, which need to be differentiated from herpes simplex and CMV ulcers by biopsy. They respond to systemic glucocorticoids and ART. Some disseminated endemic mycoses, notably histoplasmosis (p. 398), may cause oral ulcers, usually associated with constitutional symptoms.

KS often involves the mouth, especially the hard palate (see above and Fig. 14.14).

Gingivitis is common in advanced HIV disease. Acute necrotising ulcerative gingivitis and periostitis (p. 319) can result in loss of teeth.

Nail disorders

Fungal infections (onychomycosis, p. 1122) are common and often involve multiple nails.

Gastrointestinal disease

Oesophageal diseases

Oesophageal candidiasis (Fig. 14.15) is a common cause of odynophagia, dysphagia and regurgitation in advanced HIV infection. Concomitant oral candidiasis is present in most patients. Patients whose oesophageal symptoms fail to respond to azoles should be investigated with oesophagoscopy – major aphthous ulceration and CMV ulcers are the most likely causes.

Diarrhoea

Diarrhoea is common in advanced HIV disease, especially in areas where there is limited access to safe water. The differential diagnosis of diarrhoea depends on whether the presentation is with large or small bowel symptoms (see Fig. 14.11).

Large bowel diarrhoea Acute diarrhoea caused by the bacterial enteric pathogens *Campylobacter*, *Shigella* and *Salmonella* occurs more frequently than in HIV-negative people and the illness is more severe. Bacteraemia is more common, notably due to non-typhoid *Salmonella* (p. 364). Diarrhoea caused by *Clostridioides difficile* should be considered with exposure to antibiotics.

CMV colitis presents with chronic large bowel symptoms and fever in people with CD4 counts below 100 cells/mm^3. On colonoscopy, ulcers typically involve the left side of the colon with typical ‘owl’s-eye’ inclusion bodies on histology.

Small bowel diarrhoea Chronic small bowel diarrhoea, often causing wasting and without fever, may be due to HIV enteropathy, or infection with one of three intracellular parasites: cryptosporidiosis, microsporidiosis and cystoisosporiasis (Box 14.35). If the diagnosis is not made by stool microscopy on at least two specimens, a duodenal biopsy should be performed (Fig. 14.16).

About 40% of patients with disseminated MAC infections have watery diarrhoea. Fever is a prominent feature of MAC infection, which helps differentiate it from cryptosporidiosis, microsporidiosis and cystoisosporiasis. Intestinal tuberculosis typically involves the ileocaecal area and may present with fever, weight loss and diarrhoea, but the diarrhoea is seldom profuse.

Hepatobiliary disease

Chronic viral hepatitis

Hepatitis B and/or C (HBV and HCV) co-infection is common in PWH due to shared risk factors for transmission. The natural history of both HBV and HCV is altered by HIV co-infection. In the ART era, chronic liver disease from viral hepatitis has emerged as a major cause of morbidity and mortality. HBV and HCV are further described on pp. 904 and 908, respectively.

HIV co-infection increases HBV viraemia, is associated with less elevation of transaminases, and increases the risk of liver fibrosis and hepatocellular carcinoma. All patients with HBV infection should be treated with ART including the nucleotide reverse transcriptase inhibitor (NRTI) tenofovir, which is also effective against HBV. A flare of hepatitis may be associated with improved immune function after starting ART or discontinuing antiretrovirals that have anti-HBV activity. HBV co-infection increases the risk of antiretroviral hepatotoxicity.

HIV co-infection also increases HCV viraemia and increases the risk of liver fibrosis and hepatocellular carcinoma. Treatment for HCV should be commenced together with ART. A flare of hepatitis may be associated with improved immune function after starting ART, and there is an increased risk of antiretroviral hepatotoxicity. Response to anti-HCV therapy is similar to that seen in HIV-negative people.

HIV cholangiopathy

HIV cholangiopathy, a form of secondary sclerosing cholangitis (p. 919), may occur in patients with severe immune suppression (often associated with cryptosporidiosis or CMV infection). Papillary stenosis and acalculous cholecystitis may occur. ART may improve the condition.

14.35 Common causes of chronic watery diarrhoea

	Cryptosporidiosis	Microsporidiosis	Cystoisosporiasis
Organism	Protozoan	Fungus	Protozoan
Species	*Cryptosporidium parvum* *C. hominis*	*Enterozoon bieneusi* *Encephalitozoon intestinalis* etc.	*Cystoisospora belli*

Specific treatment	No established therapy	Albendazole (some species)	Co-trimoxazole

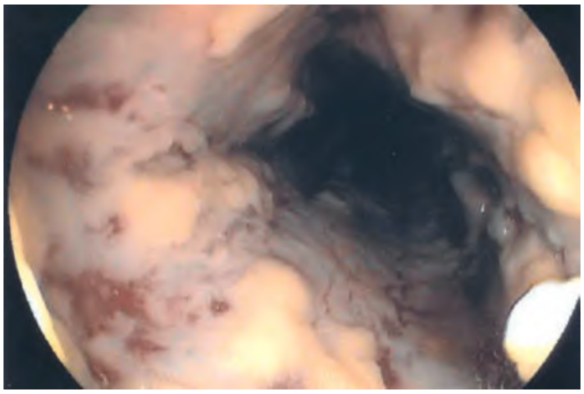

Fig. 14.15 Oesophageal candidiasis. Endoscopy showing typical pseudomembranous candidiasis.

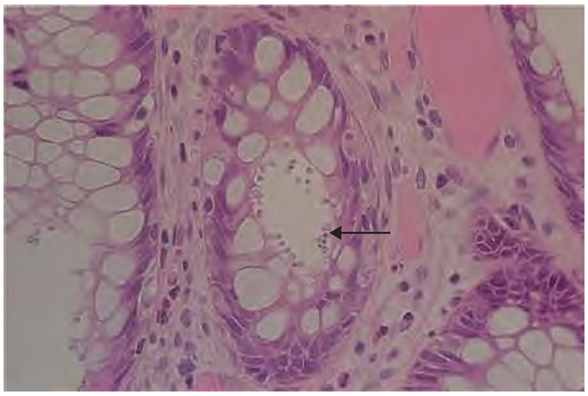

Fig. 14.16 Cryptosporidiosis. Duodenal biopsy may be necessary to confirm cryptosporidiosis or microsporidiosis. The arrow indicates an oöcyst.

Metabolic dysfunction-associated steatotic liver disease (MASLD)

MASLD is abnormal liver fat accumulation together with one or more cardiometabolic risk factors (p. 915) and can result in hepatic fibrosis and cirrhosis. MASLD has a higher prevalence in PWH due to the systemic inflammation in HIV, which occurs despite effective ART, and the use of NRTIs.

Respiratory disease

Pulmonary disease is the major reason for hospital admission in advanced HIV disease. Influenza and COVID-19 are more severe in PWH. Most patients who are admitted for respiratory diseases will have either bacterial pneumonia, pulmonary tuberculosis or PCP. PCP is more common in high-income countries, while tuberculosis is more common in low- and middle-income countries. An approach to the differential diagnosis of all three conditions is given in Box 14.36.

Pneumocystis jiroveci pneumonia

The key presenting feature of PCP is progressive dyspnoea with a duration of less than 12 weeks. Dry cough and fever are common. The chest X-ray typically shows bilateral interstitial infiltrates spreading out from the hilar regions (Fig. 14.17). High-resolution CT scan is more sensitive than chest X-ray, usually showing typical ‘ground-glass’ interstitial infiltrates. Pneumatoceles may occur and may rupture, resulting in a pneumothorax. The diagnosis is made with silver stains, PCR or immunofluorescence of broncho-alveolar lavage or induced sputum. Treatment is with high-dose co-trimoxazole, together with adjunctive systemic glucocorticoids if hypoxia is present (Box 14.37).

14.36 Comparative features of bacterial pneumonia, *Pneumocystis jirovecii* pneumonia and pulmonary tuberculosis

	Bacterial pneumonia	*Pneumocystis jirovecii* pneumonia (PCP)	Pulmonary tuberculosis
Duration	Acute	Subacute	Variable
Dyspnoea	Common	Prominent	Occasional
White cell count	Increased	Normal	Normal/low
Chest X-ray			
Infiltrate	Consolidation	Interstitial	Nodular
Bilateral infiltrate	Occasional	Usual	Common
Effusion	Occasional	No	Common
Nodes	Rare	No	Common

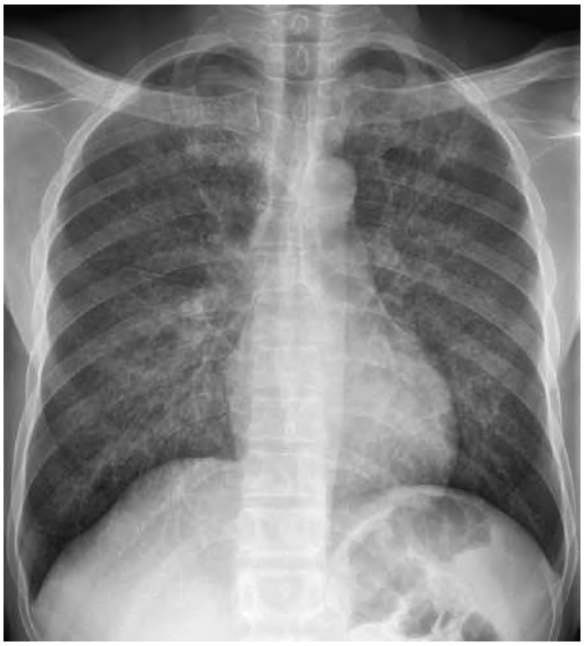

Fig. 14.17 ***Pneumocystis* pneumonia in an HIV patient showing the typical perihilar interstitial infiltrates.**

Pulmonary tuberculosis

Pulmonary tuberculosis in PWH with mild immune suppression typically presents as in HIV-negative patients, with a chronic illness and apical pulmonary cavities (p. 556). However, in advanced HIV disease, there are important differences in the clinical presentation of pulmonary tuberculosis:

- Tuberculosis progresses more rapidly, with a subacute or even acute presentation.
- The chest X-ray appearance alters: cavities are rarely seen, pulmonary infiltrates are no longer predominantly in apical areas, and pleural effusions and hilar or mediastinal lymphadenopathy are common (Fig. 14.18). A normal chest X-ray is not unusual in symptomatic patients with tuberculosis confirmed on sputum culture.
- Sputum smears, which are positive in most HIV-uninfected adults with pulmonary tuberculosis, are negative in more than half of patients because pulmonary cavities are less common.
- Disseminated tuberculosis may present with a classic miliary pattern on chest X-ray, but more commonly presents with atypical pulmonary infiltrates together with extrapulmonary tuberculosis. The most common sites of concomitant extrapulmonary tuberculosis are the pleura and lymph nodes. A rapid diagnosis can be made with the urine lipoarabinomannan lateral flow assay.

Tuberculosis in PWH responds well to standard short-course therapy (p. 561).

Bacterial pneumonia

The incidence of bacterial pneumonia is increased about 100-fold by HIV infection. The severity, likelihood of bacteraemia, risk of recurrent pneumonia and mortality are all increased compared with HIV-negative patients. The aetiology is similar to that of community-acquired pneumonia in HIV-negative patients with comorbidity: *S. pneumoniae* is the most common cause, followed by *Haemophilus influenzae*, Enterobacteriales (e.g. *Klebsiella pneumoniae*) and *Staphylococcus aureus*. The prevalence of atypical bacteria is generally similar to that in the general population.

Miscellaneous causes of pulmonary infiltrates

Pulmonary cryptococcosis may present as a component of disseminated disease or be limited to the lungs. The disseminated endemic mycoses (histoplasmosis, coccidioidomycosis, emergomycosis and talaromycosis) often cause diffuse pulmonary infiltrates, mimicking miliary tuberculosis.

Lymphoid interstitial pneumonitis is a slowly progressive disorder causing a diffuse reticulonodular infiltrate. It is caused by a benign polyclonal lymphocytic interstitial infiltrate and is part of the diffuse infiltrative lymphocytosis syndrome (DILS; see p. 331).

KS may spread to the lungs with irregular nodules, linear reticular patterns and pleural effusions on imaging.

Nervous system and eye disease

The central and peripheral nervous systems are commonly involved in HIV, either as a direct consequence of HIV infection or due to opportunistic diseases. An approach to common presentations is outlined in Figure 14.19.

Cognitive impairment

HIV-associated neurocognitive disorders HIV is a neurotropic virus and invades the CNS early during infection. Meningo-encephalitis may occur at seroconversion. HIV-associated neurocognitive disorder

14.37 Treatment of common opportunistic infections in adults with AIDS

Opportunistic infection	Treatment	Alternative treatment	Secondary prophylaxis[1]
***Pneumocystis jirovecii* pneumonia**	Co-trimoxazole 20/100 mg/kg/day IV/PO (in 4 divided doses; dose can be reduced to 15/75 mg/kg/day after 3 days and switched to PO when clinically improving) for 21 days; maximum per dose 320/1600 mg Early adjunctive prednisone 40 mg twice daily, if hypoxic	Clindamycin 900 mg 3 times daily IV (switch to 600 mg 3 times daily PO once improving) plus primaquine 30 mg PO daily for 21 days	Co-trimoxazole 160/800 mg daily PO
Cerebral toxoplasmosis	Sulfadiazine 15 mg/kg 4 times daily PO plus pyrimethamine 200 mg stat PO, then 75 mg daily plus folinic acid 15–25 mg daily for 6 weeks followed by maintenance therapy, Sulphadiazine (500 mg or 1 g 4 times daily PO) with pyrimethamine (25 mg daily PO) and folinic acid (10 mg daily PO).	Clindamycin (600 mg 4 times daily IV/PO) plus pyrimethamine (200 mg stat PO then 50–75 mg daily depending on weight) plus folinic acid (15–25 mg daily). Followed after 6 weeks by maintenance therapy: Clindamycin (300 mg 4 times daily or 600 mg 3 times daily PO) with pyrimethamine (25 mg daily PO) and folinic acid (10 mg daily). Co-trimoxazole 320/1600 mg twice daily IV/PO for 4 weeks, then 160/800 mg twice daily for 3 months	Co-trimoxazole 160/800 mg daily PO
Cryptococcosis	Liposomal amphotericin B 4 mg/kg/day IV plus flucytosine 25 mg/kg 4 times daily PO for 14 days, followed by fluconazole 400 mg daily PO for 8 weeks. (The above regimen is preferred in high-income settings with easy access to daily blood monitoring and IV fluids.) In resource-limited settings, WHO recommends: Liposomal amphotericin B 10 mg/kg IV as a single dose on day 1, followed by flucytosine 25 mg/kg PO 4 times a day plus fluconazole 1200 mg PO daily for 2 weeks followed by fluconazole 800 mg daily PO for 8 weeks.	Amphotericin B 1 mg/kg/day IV plus fluconazole[2] 800 mg daily IV/PO for 14 days, followed by fluconazole 400 mg daily PO for 8 weeks	Fluconazole 200 mg daily PO (for minimum of 1 year)
Oesophageal candidiasis	Fluconazole 200 mg daily IV/PO for 14 days	Itraconazole 200 mg daily PO for 14–21 days	Not usually recommended
Disseminated *Mycobacterium avium* complex	Clarithromycin 500 mg twice daily PO plus ethambutol 15 mg/kg daily PO	Azithromycin 500 mg daily PO plus ethambutol 15 mg/kg daily PO	Continue treatment for minimum of 1 year
Herpes simplex ulcers	Aciclovir 400 mg 3 times daily PO for 5–10 days	Valaciclovir 500 mg or famciclovir 125 mg twice daily PO for 5–10 days	Aciclovir 400 mg twice daily PO if recurrences are frequent/severe
***Cystoisospora belli* diarrhoea**	Co-trimoxazole 160/800 mg 4 times daily PO for 10 days	Ciprofloxacin 500 mg twice daily PO for 10 days	Co-trimoxazole 160/800 mg daily PO

[1] Secondary prophylaxis may be discontinued once CD4 counts have increased to > 200 cells/mm^3 on antiretroviral therapy for at least 3 months.
[2] Only if flucytosine is unavailable.
(IV = intravenous; PO = orally)

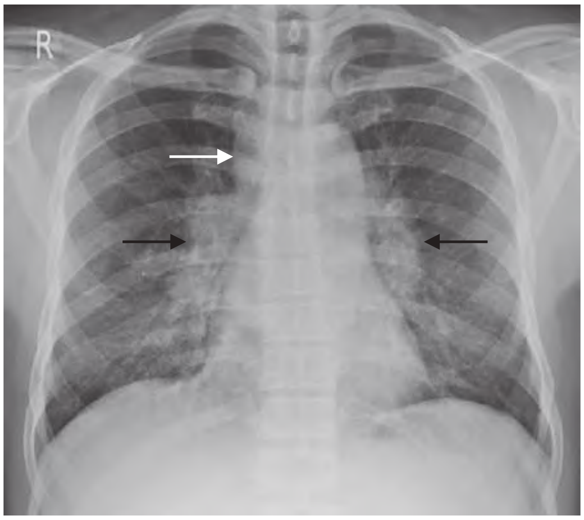

Fig. 14.18 **Chest X-ray of pulmonary TB in a patient with advanced HIV infection showing mid and lower zone patchy infiltrates and mediastinal (white arrow) and bilateral hilar nodal (black arrows) enlargement.**

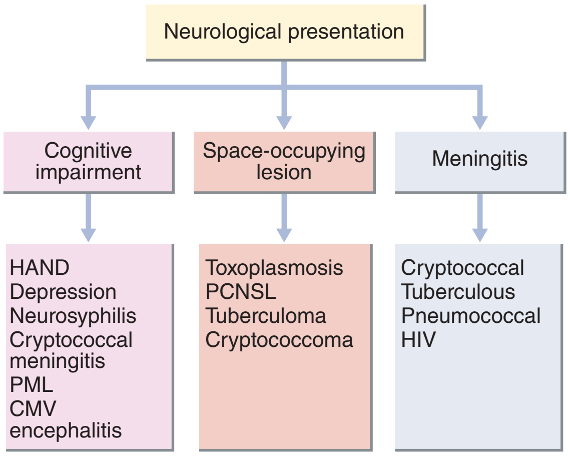

Fig. 14.19 **Presentation and differential diagnosis of HIV-related neurological disorders.** (CMV = cytomegalovirus; HAND = HIV-associated neurocognitive disorder; PCNSL = primary CNS lymphoma; PML = progressive multifocal leukoencephalopathy)

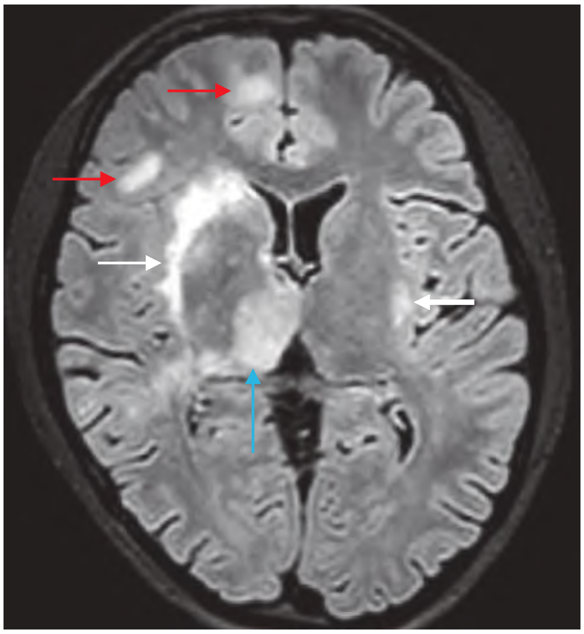

Fig. 14.20 Axial FLAIR scan demonstrating high signal changes in the external capsules bilaterally (white arrows), right subcortical white matter (red arrows) and right thalamus (blue arrow) typical of those seen with PML in a patient with HIV.

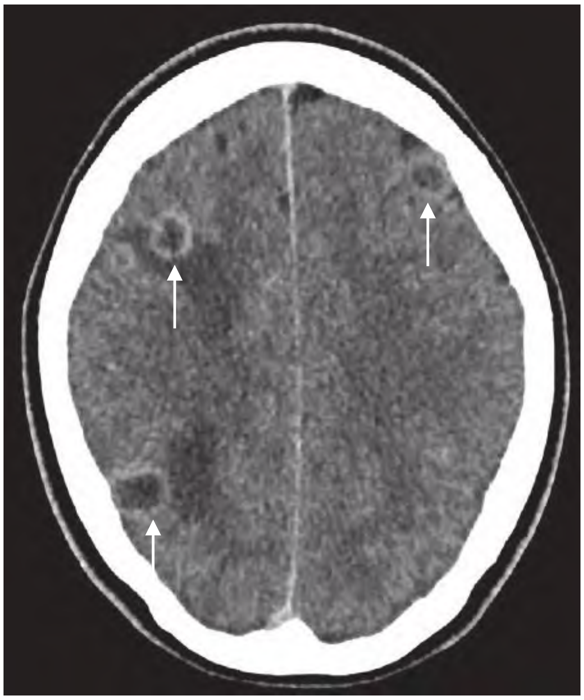

Fig. 14.21 Cerebral toxoplasmosis. Post-contrast CT demonstrating the typical findings of ring enhancing lesions (white arrows) with perilesional oedema.

(HAND) describes a spectrum of disorders: asymptomatic neurocognitive impairment, minor neurocognitive disorder and HIV-associated dementia (also called HIV encephalopathy). The risk of symptomatic HAND increases with declining CD4 counts. ART usually improves symptomatic HAND.

HIV-associated dementia is a subcortical dementia characterised by impairment of executive function, psychomotor retardation and impaired memory. CT or MRI shows diffuse cerebral atrophy out of keeping with age. It is important to exclude depression, cryptococcal meningitis and neurosyphilis. ART usually improves HIV-associated dementia.

Progressive multifocal leukoencephalopathy Progressive multifocal leukoencephalopathy (PML) is caused by the JC virus, and presents with stroke-like episodes and cognitive impairment. Vision is often impaired due to involvement of the occipital cortex. A combination of characteristic appearances on MRI (Fig. 14.20) and detection of JC in the cerebrospinal fluid (CSF) by PCR is diagnostic. There is no specific treatment and prognosis is poor despite ART.

CMV encephalitis CMV encephalitis typically presents with behavioural disturbance, cognitive impairment and a reduced level of consciousness. Detection of CMV DNA in the CSF supports the diagnosis. Response to anti-CMV therapy is usually poor.

Space-occupying lesions

Space-occupying lesions typically occur in advanced HIV disease.

Cerebral toxoplasmosis Cerebral toxoplasmosis is the commonest cause of space-occupying lesions and is caused by reactivation of residual *Toxoplasma gondii* cysts from past infection. Characteristic findings on imaging are multiple space-occupying lesions with ring enhancement on contrast and surrounding oedema (Fig. 14.21). *Toxoplasma* serology shows evidence of previous exposure (positive IgG antibodies); a negative serological test effectively rules out toxoplasmosis but a positive test is not specific. The standard therapy for toxoplasmosis is sulfadiazine with pyrimethamine, together with folinic acid, to reduce the risk of bone marrow suppression (see Box 14.37). However, co-trimoxazole has similar effectiveness, is less toxic and is much more widely available. Response to a trial of therapy is usually diagnostic, with clinical improvement in 1–2 weeks and shrinkage of lesions on imaging in 2–4 weeks. Definitive diagnosis is by brain biopsy, but this is seldom necessary.

Primary CNS lymphoma Primary CNS lymphoma (PCNSL) is a high-grade B-cell lymphoma associated with EBV infection. A single homogeneously enhancing, periventricular lesion with surrounding oedema is characteristic (Fig. 14.22). PCR for EBV DNA in the CSF has a high sensitivity and specificity for PCNSL. The prognosis is poor.

Tuberculoma Lesions resemble toxoplasmosis on imaging, but oedema tends to be less marked and single lesions occur more commonly. There may be evidence of tuberculosis elsewhere. The CSF may show features consistent with tuberculous meningitis. Response to antituberculosis therapy is slow and paradoxical expansion of lesions despite therapy is not uncommon.

Stroke

There is a higher incidence of stroke in patients with HIV disease. Atherosclerosis is accelerated by systemic inflammation due to the immune response to HIV. HIV vasculopathy, which is thought to be a vasculitis, can also cause a stroke. It is important to exclude tuberculous meningitis and meningovascular syphilis.

Meningitis

Cryptococcal meningitis *Cryptococcus neoformans* is the most common cause of meningitis in advanced HIV disease. Patients usually present subacutely with headache, vomiting and decreased level of consciousness. Neck stiffness is present in less than half. CSF pleocytosis is often mild or absent, and protein and glucose concentrations are variable. CSF cryptococcal antigen test has a high sensitivity and specificity. Treatment is with amphotericin B (liposomal amphotericin B if this is available) plus flucytosine for 2 weeks, followed by fluconazole

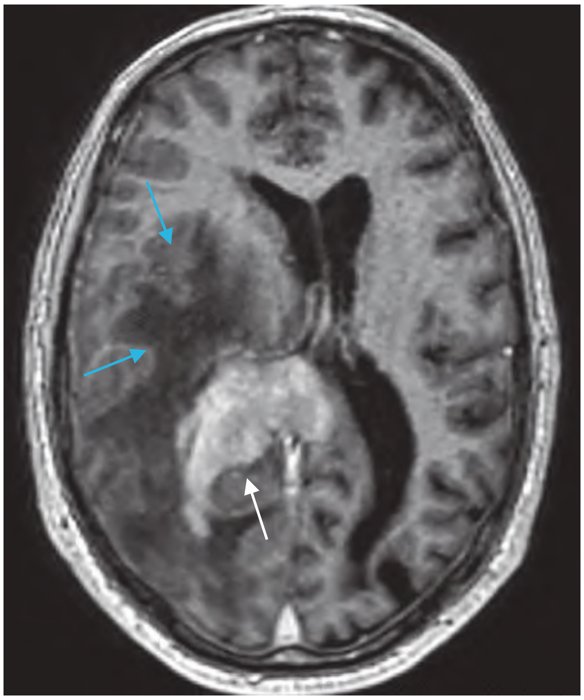

Fig. 14.22 **Primary lymphoma post-contrast T1 axial scan showing typical features of a periventricular enhancing mass (white arrow) with surrounding oedema (blue arrows).**

or with alternative regimens in resource limited settings (see Box 14.37). Raised intracranial pressure is common and should be treated with repeated therapeutic lumbar punctures, as this is a communicating hydrocephalus.

Tuberculous meningitis The presentation and CSF findings of tuberculous meningitis are similar to those in HIV-negative patients (p. 1219), except that concomitant tuberculosis at other sites is more common in PWH.

Peripheral nerve disease

HIV causes axonal degeneration, resulting in a sensorimotor peripheral neuropathy. The incidence increases with lower CD4 counts, older age and increased height. Sensory symptoms predominate. Treatment involves foot care, analgesia and analgesic adjuvants. ART has minimal effect on halting or reversing the process.

Acute inflammatory demyelinating polyneuropathy is uncommon, usually occurring in primary infection. Mononeuritis may occur, commonly involving the facial nerve.

Myelopathy and radiculopathy

The most common cause of myelopathy in HIV infection is cord compression from tuberculous spondylitis. Vacuolar myelopathy is due to HIV and typically presents with a slowly progressive paraparesis with no sensory level. MRI of the spine is important to exclude other causes. Most patients have concomitant HIV-associated dementia.

CMV polyradiculitis presents with painful legs, progressive flaccid paraparesis, saddle anaesthesia, absent reflexes and sphincter dysfunction. CSF shows increased neutrophil numbers, and the detection of CMV DNA by PCR confirms the diagnosis. Functional recovery is poor despite anti-CMV treatment.

Psychiatric disease

Psychiatric morbidity is more common in PWH than in the general population and is a major risk factor for poor adherence. Reactive depression is the most common disorder. Substance misuse is common in many groups of people at risk of HIV.

Retinopathy

CMV retinitis presents with painless, progressive visual loss in people with CD4 counts below 100 cells/mm^3. Haemorrhages and exudates are seen in the retina (p. 319). The disease usually starts unilaterally but progressive bilateral involvement occurs in untreated patients. Diagnosis is usually clinical. Demonstrating CMV DNA by PCR of vitreous fluid is diagnostic. Anti-CMV treatment stops progression of the disease but lost vision does not recover.

Three other conditions may mimic CMV retinitis: ocular toxoplasmosis (see Fig. 14.54), which typically presents with a vitritis and retinitis without retinal haemorrhages; HIV retinopathy, a microangiopathy that causes cotton wool spots, which are not sight-threatening; and varicella zoster virus, which can cause rapidly progressive outer retinal necrosis.

Rheumatological disease

The immune dysregulation associated with HIV infection may result in autoantibody formation, usually in low titres. Mild arthralgias and a fibromyalgia-like syndrome are common in PWH.

Arthritis

HIV can cause a seronegative arthritis, which resembles rheumatoid arthritis. A more benign oligoarthritis may also occur. Reactive arthritis is more severe in HIV infection (p. 1062).

Diffuse infiltrative lymphocytosis syndrome

Diffuse infiltrative lymphocytosis syndrome (DILS) is a benign disorder involving polyclonal CD8 lymphocytic infiltration of tissues, which has some features in common with Sjögren syndrome (p. 1173). DILS usually presents in patients with mild immune suppression. The most common manifestation is bilateral parotid gland enlargement with lymphoepithelial cysts. Sicca symptoms are common but usually mild. Other DILS manifestations include lymphocytic interstitial pneumonitis, mononeuritis, polyarthritis, polymyositis, interstitial nephritis and hepatiitis. The manifestations outside the salivary glands may respond to glucocorticoids. Parotid gland enlargement may be treated by aspiration of parotid cysts and instillation of a sclerosant. DILS may regress on ART but response is variable.

Haematological abnormalities

In advanced disease, haematopoiesis is impaired due to the direct effect of HIV and by cytokines. Pancytopenia may occur as a consequence of HIV, but it is important to exclude disorders infiltrating the bone marrow, such as mycobacterial infections or lymphoma.

Anaemia

Normochromic, normocytic anaemia is very common in advanced HIV disease. Opportunistic diseases may cause anaemia of chronic disease (e.g. tuberculosis) or marrow infiltration (e.g. MAC, tuberculosis, lymphoma, fungi). Red cell aplasia is rare and may be caused either by parvovirus B19 infection or by the NRTIs lamivudine and emtricitabine.

Neutropenia

Isolated neutropenia is occasionally due to HIV but is usually caused by drug toxicity (e.g. co-trimoxazole).

Thrombocytopenia

Transient thrombocytopenia is frequently seen in primary infection. Severe thrombocytopenia is usually due to immune-mediated platelet destruction resembling idiopathic thrombocytopenic purpura (p. 1006), which responds to glucocorticoids or intravenous immunoglobulin, together with ART. Severe thrombocytopenia with a microangiopathic anaemia is a thrombotic thrombocytopenic purpura-like illness (p. 1013), which has a better prognosis than the classical disease.

14.38 Approximate incidence ratio of virus-related cancers compared to the general population

Viral cancers	Incidence ratio
Human herpesvirus 8-related	
Kaposi sarcoma	3600
Epstein–Barr virus-related	
Non-Hodgkin lymphoma	80
Hodgkin lymphoma	10
Human papillomavirus-related	
Cervical cancer	6
Vulval cancer	6
Anal cancer	30
Penile cancer	4
Hepatitis B/C virus-related	
Hepatocellular carcinoma	5

Renal disease

Acute kidney injury is common, usually due to acute infection or nephrotoxicity of drugs (p. 625). HIV-associated nephropathy (HIVAN) is the most common cause of chronic kidney disease (CKD) in PWH, which is seen more frequently with low CD4 counts. Progression to end-stage disease is more rapid than with most other causes of CKD, and renal size is usually preserved. HIVAN presents with nephrotic syndrome, CKD, or a combination of both. ART slows the progression of HIVAN. With the improvement in life expectancy from ART, conditions such as diabetes mellitus, hypertension and vascular disease add to the burden of CKD. Outcomes of renal transplantation are good in patients on ART.

Cardiac disease

HIV-associated cardiomyopathy resembles idiopathic dilated cardiomyopathy (p. 510) but progresses more rapidly. ART may improve cardiac failure but does not reverse established cardiomyopathy. Pericardial disease due to opportunistic diseases is not uncommon; globally, the most common cause is tuberculosis. KS and lymphoma may cause pericardial effusions.

HIV is associated with an increased risk of myocardial infarction due to accelerated atherogenesis caused by the inflammatory state, which is not completely suppressed by ART.

HIV-related cancers

The AIDS-defining cancers are KS (see above), cervical cancer and non-Hodgkin lymphoma (NHL; p. 998). NHL may occur at any CD4 count but is more commonly seen with counts below 200 cells/mm^3. Almost all NHLs are B-cell tumours. Long-term remission rates similar to those in patients without HIV can be achieved with NHL using ART and chemotherapy (including the anti-B-cell monoclonal antibody rituximab if it is a B-cell tumour).

The incidence of several other cancers induced by viruses is also increased in PWH (Box 14.38). Regular cytological examination of the cervix should be performed to detect pre-malignant lesions, which are easier to treat. The risk of anal cancer is increased in people who practise receptive anal sex.

Prevention of opportunistic infections

The best way to prevent opportunistic infections is to improve the CD4 count with ART. However, infections continue to occur in the ART era as CD4 counts take time to improve if ART is initiated in patients with profound immune suppression, immune reconstitution on ART may be suboptimal, and CD4 counts may decline if antiretroviral resistance develops.

14.39 Opportunistic infections reduced by co-trimoxazole

- *Pneumocystis jirovecii* pneumonia
- Cerebral toxoplasmosis
- Bacterial pneumonia
- Bacteraemia
- Cystoisosporiasis
- Malaria

14.40 Symptom screen for tuberculosis before isoniazid preventive therapy

All of the following must be absent:

- Active cough
- Weight loss
- Night sweats
- Fever

Preventing exposure

Preventing exposure has a limited role in reducing the risk of infections in PWH. Consuming safe water and food may reduce the incidence of common diarrhoea pathogens. Safer sex will lower the risk of acquiring herpes simplex virus and human herpesvirus 8. PWH living in malarious areas should use insecticide-impregnated bed nets as malaria occurs more frequently and is more severe in PWH. PWH should avoid handling kittens or cat litter to reduce the risk of *Toxoplasma gondii* infection.

Chemoprophylaxis

Primary prophylaxis reduces the risk of opportunistic infections that have not yet occurred, while secondary prophylaxis reduces the risk of recurrence of incident opportunistic infections (see Box 14.37). Prophylaxis can be discontinued when CD4 counts increase to above 200 cells/mm^3 on ART. CMV and MAC prophylaxis can be stopped if CD4 counts increase to above 100 cells/mm^3.

Co-trimoxazole primary prophylaxis

Co-trimoxazole reduces the incidence of several opportunistic infections (Box 14.39). The main indication for initiating co-trimoxazole is advanced HIV disease (WHO clinical stages 3 or 4; or CD4 count <200 cells/mm^3). The recommended dose of co-trimoxazole is 960 mg daily. Co-trimoxazole prophylaxis can be stopped when CD4 counts increase to more than 200 cells/mm^3 on ART. However, in regions where malaria and/or severe bacterial infections are highly prevalent, WHO recommends initiating co-trimoxazole regardless of CD4 counts or clinical stage, and continuing it life-long.

If co-trimoxazole is not tolerated, then dapsone 100 mg daily should be substituted.

Tuberculosis preventive therapy

Trials in PWH not on ART showed that preventive therapy reduces the risk of tuberculosis primarily in those with a positive tuberculin skin test. However, recent evidence indicates that tuberculin skin tests or the interferon-gamma release assays do not predict benefit in patients starting ART or established on ART in high tuberculosis prevalence settings.

There is no CD4 count or clinical threshold for starting tuberculosis preventative therapy. It is important to rule out active tuberculosis before starting preventative therapy (Box 14.40). The usual duration of isoniazid preventative therapy is 6–9 months, but long-term use should be considered in settings with high tuberculosis transmission. A 12-week course of isoniazid combined with either rifampicin (dosed daily) or rifapentine (dosed weekly) is as effective as isoniazid monotherapy with higher completion rates.

Mycobacterium avium complex prophylaxis

In high-income countries, a macrolide (azithromycin or clarithromycin) is recommended to prevent MAC in patients with a CD4 count below 50 cells/mm^3, which can be discontinued once the CD4 count has risen to over 100 cells/mm^3 on ART. MAC is uncommon in low- and middle-income countries and primary prophylaxis is thus not warranted.

Preventing cryptococcosis

Serum cryptococcal antigen test should be performed in patients with a CD4 count below 100 cells/mm^3. If this is positive, pre-emptive therapy with fluconazole should be commenced.

Immunisation

Vaccination with live organisms is contraindicated in patients with severe immune suppression, as this may result in disease from the attenuated organisms. Immune responses to vaccination are impaired in PWH, especially with CD4 counts below 200 cells/mm^3. Therefore, it is preferable to wait until the CD4 count has increased to more than 200 cells/mm^3 on ART before immunisation. PWH should be given a conjugate pneumococcal vaccine and annual influenza vaccination. Hepatitis B vaccination should be given to those who are not immune. In the UK, the following additional vaccines are also recommended:

- *hepatitis A*: in those at risk
- *human papillomavirus*: below 40 years of age
- *measles, mumps and rubella (MMR)*: in those with negative measles serology
- *meningococcus*: below 25 years old, in those with asplenia or complement deficiency, or during outbreaks
- *diphtheria/tetanus/acellular pertussis* (*dTaP)/inactivated poliovirus vaccine (IPV)*: meeting general indications
- *chickenpox*: if seronegative; those who are seropositive should receive the shingles vaccine.

Bacille Calmette–Guérin (BCG) is contraindicated in PWH.

Antiretroviral therapy

Antiretroviral therapy (ART) has transformed HIV from a progressive illness with a fatal outcome into a chronic manageable disease with a near-normal life expectancy.

The goals of ART are to:

- reduce the viral load to an undetectable level for as long as possible
- improve the CD4 count to over 200 cells/mm^3 so that severe HIV-related disease is unlikely
- improve the quantity and quality of life without unacceptable drug toxicity
- reduce HIV transmission.

Many of the antiretroviral drugs that were initially used have largely been replaced because of toxicity or poor efficacy. The pill burden of currently recommended ART is low; the currently recommended first-line regimens are often available as a single pill. More recent developments include developments of long-acting injectable formulations. The drugs that are currently recommended are shown in Box 14.41, and their targets in the HIV life cycle (see Fig. 14.9).

i 14.41 Currently preferred antiretroviral drugs

Classes	Drugs
Nucleoside reverse transcriptase inhibitors (NRTIs)	Abacavir, emtricitabine, lamivudine, tenofovir, tenofovir alafenamide
Non-nucleoside reverse transcriptase inhibitors (NNRTIs)	Efavirenz*, doravirine, rilpivirine (only if viral load < 100 000)
Protease inhibitors (PIs)	Atazanavir*, darunavir
Integrase inhibitors	Dolutegravir, bictegravir, raltegravir, cabotegravir (injectable available in combination with rilpivirine)

*These drugs are no longer recommended as first-line options due to their toxicity.

Selecting antiretroviral regimens

The most frequently prescribed regimens are two nucleoside (or nucleoside and nucleotide) reverse transcriptase inhibitors (NRTI) combined with an integrase strand transfer inhibitor (INSTI) or occasionally a non-nucleoside reverse transcriptase inhibitor (NNRTI). Several effective two-drug regimens have been developed, including one NNRTI and one INST or notably rilpivirine and cabotegravir combined as long-acting injectable therapy dosed monthly. Protease inhibitors (PI) are reserved for viral resistance or intolerance of multiple other agents. PIs are always administered with the pharmacoenhancers ('boosters') ritonavir or cobicistat, which dramatically increase the concentrations of PIs by inhibiting their metabolism by the cytochrome P450 isoenzyme CYP3A.

In high-income countries most ART switches are now for drug intolerance. ART regimen switches for virological failure are now less common, particularly for INSTI-containing regimens, and are guided by the results of resistance testing (see below). In low- and middle-income countries, where resources for resistance testing are limited or absent, a standardised second-line regimen is usually recommended.

Starting ART

ART can be initiated as soon as the diagnosis of HIV has been made. Disclosure of HIV status, joining support groups and using patient-nominated treatment supporters should be encouraged, as these have been shown to improve adherence. Recognition and management of depression and substance abuse is important.

In patients with major opportunistic infections, ART should generally be started within 2 weeks, with two important exceptions: in cryptococcal meningitis (p. 330), ART should be deferred for 5 weeks, as earlier initiation increases the risk of death; and in tuberculosis, ART should be deferred until 8 weeks (except if the CD4 count is $<$50 cells/mm^3), as earlier initiation increases the risk of the immune reconstitution inflammatory syndrome (see below).

Monitoring efficacy

The most important measure of ART efficacy is the viral load. A baseline viral load should be measured prior to initiating treatment. The viral load should be suppressed after 3 months, but with INSTI-containing regimens is usually suppressed much sooner. Once the viral load is suppressed, measurement should be repeated 6 to 12 monthly. Failure of ART is defined by the viral load becoming detectable after suppression. In most guidelines, a viral load threshold is used to define virological failure, e.g. more than 200 (UK) or more than 1000 (WHO) copies/mL. Adherence support should be enhanced if virological failure is detected.

CD4 counts can be monitored together with the viral load, but there is little point in repeating the CD4 count in patients who maintain virological suppression and whose CD4 count is $>$350 cells/mm^3. The CD4 count increases rapidly in the first month, followed by a more gradual increase. In the first year, the CD4 count typically increases by 100–150 cells/mm^3, and about 80 cells/mm^3 per annum thereafter until the normal range is reached, provided the viral load is suppressed. However, CD4 responses are highly variable: in 15%–30% of patients, the CD4 count does not increase despite virological suppression, and in a similar proportion of patients the CD4 response is good despite the presence of virological failure. If ART is stopped, the CD4 count rapidly falls to the baseline value before ART was commenced.

Antiretroviral resistance

Reverse transcription is error-prone, generating many mutations. If the viral load is suppressed on ART, viral replication is prevented and resistance mutations will not be selected. If there is ongoing viral replication on ART, mutations conferring resistance to antiretroviral drugs will be selected. Antiretroviral drugs differ in their ability to select for HIV resistance mutations. Some drugs (e.g. emtricitabine, lamivudine) have a low genetic barrier to resistance, rapidly selecting for a single mutation conferring high-level resistance. PIs and the second-generation integrase inhibitors (bictegravir and dolutegravir) select for resistance mutations slowly, and multiple mutations generally need to accumulate before the drug's efficacy is impaired. Many resistance mutations, particularly those selected for by NRTIs, reduce viral fitness and in their presence antiretrovirals may retain some antiviral activity, which is why NRTIs are recycled despite the presence of resistance when combined with PIs or the integrase inhibitors dolutegravir and bictegravir. Patients who develop antiretroviral resistance will eventually develop clinical failure if the regimen is not changed, and may transmit resistant virus to others.

Antiretroviral resistance is assessed by sequencing the relevant viral genes to detect mutations that are known to confer resistance. The patient must be taking ART when the test is performed, as otherwise the wild-type virus will predominate due to the lack of selective pressure and resistant mutations will not be detected. However, the resistant proviral DNA archived in latent CD4 cells will re-emerge rapidly on re-exposure to the antiretroviral. In high-income countries, resistance testing is recommended at baseline (to detect primary resistance) and at every confirmed virological failure, in order to select the most appropriate antiretrovirals in a new regimen.

ART complications

Immune reconstitution inflammatory syndrome

Immune reconstitution inflammatory syndrome (IRIS) is a common early complication of ART, especially in patients who start ART with CD4 counts below 50 cells/mm^3. IRIS presents with paradoxical deterioration of an existing opportunistic disease (including infections that are responding to appropriate therapy) or with the unmasking of a new infection, or with worsening of inflammatory skin lesions, e.g. acne. The clinical presentation of IRIS events is characterised by an exaggerated immune response, with pronounced inflammatory features. For example, patients with CMV retinitis developing IRIS on ART develop a uveitis, and inflammatory haloes occur around KS lesions. Paradoxical tuberculosis IRIS events are common, but it is important to exclude multidrug resistance, which could be responsible for the deterioration. IRIS is associated with a mortality of around 5% but this is higher when it complicates CNS infections.

The management of IRIS is to continue ART and to ensure that the opportunistic disease is adequately treated. Symptomatic treatments are helpful. Glucocorticoids are sometimes used for more severe IRIS manifestations, but they should not be given to patients with KS, as this can result in rapid progression of KS lesions.

Antiretroviral adverse drug reactions

Currently recommended antiretrovirals are generally well tolerated. INSTIs may cause insomnia. NNRTIs commonly cause hypersensitivity rashes; efavirenz commonly causes mild neuropsychiatric effects, but tolerance develops in a few weeks in most patients. The NRTI tenofovir occasionally causes nephrotoxicity and loss of bone mineral density, but the newer prodrug tenofovir alafenamide (TAF) has fewer associated complications. PIs may cause gastrointestinal symptoms (nausea, vomiting and diarrhoea), and some are associated with dyslipidaemia.

ART in special situations

Pregnancy

All pregnant women should have HIV testing at an early stage in pregnancy. The CD4 count falls by about 25% during pregnancy due to haemodilution. The course of HIV disease progression is not altered by pregnancy. In the pre-ART era, the rate of mother-to-child transmission was 15%–40%, with rates being influenced by several factors (see Box 14.28).

ART has dramatically reduced the risk of mother-to-child transmission of HIV to less than 1%. All pregnant women who are ART-naïve should start ART as soon as possible. Pregnant women on ART may need to have their regimens modified as only a limited number of antiretrovirals are recommended in pregnancy. Close viral load monitoring is essential during pregnancy.

Caesarean section is associated with a lower risk of mother-to-child transmission than vaginal delivery, but the mode of delivery does not affect transmission risk if the viral load is suppressed on ART.

HIV is also transmitted by breastfeeding. In high-income countries, exclusive formula feeding is generally recommended; however, if women who are virologically suppressed choose to breastfeed, they should be supported to do so. In resource-poor settings, formula feeding is associated with a risk of infant morbidity and mortality due to gastrointestinal infections, which may negate the benefit of not transmitting HIV to the infant. There is minimal risk of transmitting HIV by breastfeeding in women with a suppressed viral load on ART. Furthermore, providing antiretrovirals to infants while they are breastfeeding reduces the risk of transmission. Infants should be exclusively breastfed for the first 6 months, as mixed feeding (with formula or solids) is associated with a higher risk of transmission.

Old age

The specific manifestations of HIV infection in older people are shown in Box 14.42.

Prevention of HIV

An effective HIV vaccine remains elusive due to the extensive genetic diversity of HIV. Measures for the prevention of HIV transmission are shown in Box 14.43.

14.42 HIV infection in old age

- **Epidemiology**: the HIV-positive population is ageing due to the life-prolonging effects of ART.
- **Immunity**: age-related decline increases the risk of infections. CD4 counts decline more rapidly as age extends beyond 40 years, resulting in faster disease progression. CD4 responses to ART decrease with increasing age.
- **Dementia**: HIV causes cerebral atrophy and neurocognitive disorders; dementia is therefore more common and more severe than in HIV-uninfected older adults.
- **Vascular disease**: HIV is associated with an increased risk, exacerbated by some antiretrovirals that cause dyslipidaemia or insulin resistance.
- **Fragility fractures**: bone mineral density is lower in PWH, which can be exacerbated by the NRTI tenofovir.
- **Polypharmacy**: treatment of comorbidities is complex due to drug–drug interactions with antiretrovirals.

14.43 Prevention measures for HIV transmission

Sexual

- Sex education programmes in schools
- Easily accessible voluntary counselling and testing centres
- Promotion of safer sex practices (delaying sexual debut, condom use, fewer sexual partners)
- Effective ART for HIV-infected individuals
- Pre-exposure prophylaxis (PrEP) for high-risk groups
- Male circumcision
- Post-exposure prophylaxis

Parenteral

- Blood product transmission: donor questionnaire, routine screening of donated blood
- Injection drug use: education, needle/syringe exchange, avoidance of 'shooting galleries', methadone maintenance programmes

Perinatal

- Routine 'opt-out' antenatal HIV antibody testing
- Measures to reduce vertical transmission (see text)

Occupational

- Education/training: universal precautions, needlestick injury avoidance
- Post-exposure prophylaxis

Pre-exposure prophylaxis

Pre-exposure prophylaxis (PrEP) with daily tenofovir plus emtricitabine reduces the risk of HIV acquisition in people at high risk and is well tolerated. Regular HIV testing should be done while on PrEP (p. 412).

Post-exposure prophylaxis

Post-exposure prophylaxis (PEP) is recommended after a careful risk assessment, in both occupational and non-occupational settings. The first dose should be given as soon as possible. The effectiveness of PEP diminishes with time and it is probably ineffective if given more than 72 hours after exposure. The most widely used PEP regimen is tenofovir plus emtricitabine or lamivudine together with either a PI or an INSTI depending on ART exposure in the source patient. PEP should not be given if the exposed person is HIV-infected. HIV antibody testing should be performed at baseline and 3 months after exposure.

Systemic viral infections with exanthem

Childhood exanthems are characterised by fever and widespread rash. Maternal antibody usually gives protection for the first 6–12 months of life. Comprehensive immunisation programmes have dramatically reduced the number of paediatric infections but incomplete uptake results in infections in later life.

Measles

The World Health Organization (WHO) has set the objective of eradicating measles globally using the current live attenuated vaccine. However, vaccination of more than 95% of the population is required to prevent outbreaks due to the high basic reproduction number (R_0 value; see p. 137). Breakdown of vaccination programmes or reluctance to accept childhood vaccination is associated with increasing cases. Clusters of infection in young adults are associated with mass gatherings, e.g. music festivals and sub-populations with lower vaccination coverage. Natural illness produces life-long immunity.

Clinical features

Infection is by respiratory droplets with an incubation period of 6–19 days. The infectivity period is typically from 4 days before to 4 days after rash onset. A prodromal illness occurs, 1–3 days before the rash, with upper respiratory symptoms, conjunctivitis and the presence of the pathognomonic Koplik spots: small white spots surrounded by erythema on the buccal mucosa (Fig. 14.23A). As natural antibody develops, the maculopapular rash appears, spreading from the face to the extremities (Fig. 14.23B). Generalised lymphadenopathy and diarrhoea are common. Complications are more common in older children and adults, and include otitis media, bacterial pneumonia, transient hepatitis, pancreatitis and clinical encephalitis (approximately 0.1% of cases). A rare late complication is subacute sclerosing panencephalitis (SSPE), which occurs up to 7 years after infection (see Ch. 27).

Measles is a serious disease in the malnourished, vitamin-deficient or immunocompromised. Persistent infection with a giant cell pneumonitis or encephalitis may occur but rash may be absent. In tuberculosis infection, measles suppresses cell-mediated immunity and may exacerbate disease; for this reason, measles vaccination should be deferred until after commencing antituberculous treatment. Measles does not cause congenital malformation but may be more severe in pregnant women.

Mortality clusters at the extremes of age and is highly dependent on health economic status. In 2022 there were approximately 136 000 deaths, primarily in Africa and the eastern Mediterranean regions, an increase of 43% versus 2021, related to COVID-19 enforced interruptions to vaccination programmes (WHO data). Death usually results from a bacterial superinfection, occurring as a complication of measles: most often pneumonia, diarrhoeal disease or noma/cancrum oris, a gangrenous stomatitis. Death may also result from complications of measles encephalitis.

Diagnosis

Measles is diagnosed by detection of RNA by reverse transcriptase (RT)-PCR. Nasopharyngeal or throat specimens are preferred over urine. Detection of antibodies (immunoglobulin (Ig) M and fourfold rises in IgG) can confirm diagnosis. It is a notifiable disease in the UK.

Management and prevention

Immunoglobulin therapy attenuates the disease in the immunocompromised (regardless of vaccination status) and in non-immune pregnant women but must be given within 6 days of exposure. Vaccination can be used in outbreaks and vitamin A may improve the outcome in uncomplicated disease. Antibiotic therapy is reserved for bacterial complications. In the UK children are offered vaccination with a combined measles, mumps and rubella vaccine (MMR; a live attenuated vaccine) at 1 year of age, with a pre-school booster at 3 years 4 months.

Rubella (German measles)

Rubella causes exanthem in the non-immunised.

Clinical features

Rubella is spread by respiratory droplet, with infectivity from up to 10 days before to 2 weeks after the onset of the rash. The incubation period is 15–20 days. In childhood, most cases are subclinical, although clinical features may include fever, maculopapular rash spreading from the face and lymphadenopathy. Complications are rare but include thrombocytopenia and hepatitis. Encephalitis and haemorrhage are occasionally reported. In adults, arthritis involving hands or knees is relatively common, especially in women.

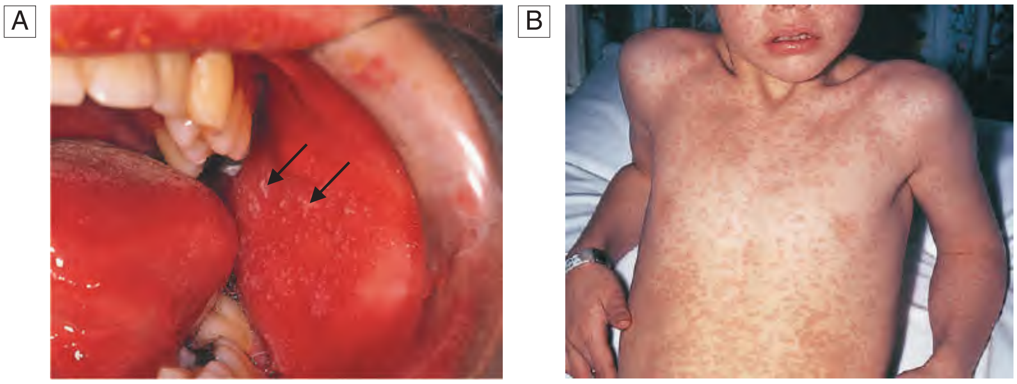

Fig. 14.23 **Measles.** **A** Koplik spots (arrows) seen on buccal mucosa in the early stages of clinical measles. **B** Typical measles rash.

14.44 Rubella infection: risk of congenital malformation

Stage of gestation	Likelihood of malformations
1–2 months	65%–85% chance of illness, multiple defects/ spontaneous abortion
3 months	30%–35% chance of illness, usually a single congenital defect (most frequently deafness, cataract, glaucoma, mental retardation or congenital heart disease, especially pulmonary stenosis or patent ductus arteriosus)
4 months	10% risk of congenital defects, most commonly deafness
> 20 weeks	Occasional deafness

If transplacental infection takes place in the first trimester or later, persistence of the virus is likely and severe congenital disease may result (Box 14.44). Even if normal at birth, there is an increased incidence of other diseases, e.g. diabetes, later in life.

Diagnosis

Laboratory confirmation of rubella is required if there has been contact with a pregnant woman. Rubella RNA is detected by RT-PCR and nasopharyngeal swabs are the preferred specimen. Detection of rubella IgM in serum or by IgG seroconversion also confirms diagnosis. In the exposed pregnant woman, absence of rubella-specific IgG confirms the potential for congenital infection.

Prevention

All children should be immunised with MMR vaccine. Congenital rubella syndrome may be controlled by testing women of child-bearing age for rubella antibodies and offering vaccination if seronegative. Antenatal rubella screening for pregnant mothers in the UK ceased in 2016 because of the rarity of rubella in the target population.

Parvovirus B19

Parvovirus B19 causes exanthem and other clinical syndromes. Some 50% of children and 60%–90% of adults are seropositive. Most infections are spread by the respiratory route, although spread via contaminated blood is also possible. The virus has particular tropism for red cell precursors.

Clinical features

Many infections are subclinical. Clinical manifestations result after an incubation period of 14–21 days (Box 14.45). The classic exanthem (erythema infectiosum) is preceded by a prodromal fever and coryzal symptoms. A 'slapped cheek' rash is characteristic (Fig. 14.24) but the rash is very variable, including 'glove and stocking'. In adults, polyarthropathy is common. Infected individuals have a transient block in erythropoiesis for a few days. This is of no clinical consequence except in individuals with increased red cell turnover due to haemoglobinopathy or haemolytic anaemia, who develop an acute anaemia that may be severe (transient aplastic crisis). People with sickle-cell disorder are at particular risk. Erythropoiesis usually recovers spontaneously after 10–14 days. Immunocompromised individuals can develop a more sustained block in erythropoiesis in response to the chronic viraemia that results from their inability to clear the infection. Infection during the first two trimesters of pregnancy can result in intrauterine infection and impact on fetal bone marrow; it causes 10%–15% of non-immune (non-Rhesus-related) hydrops fetalis, a rare complication of pregnancy.

Diagnosis

IgM to parvovirus B19 suggests recent infection but may persist for months, and false positives occur. Seroconversion to IgG positivity confirms infection, but in isolation a positive IgG is of little diagnostic utility. Detection of parvovirus B19 DNA in blood is particularly useful in immunocompromised patients. Detection of DNA in blood can be combined with serological testing in acute infections. Giant pronormoblasts or haemophagocytosis may be demonstrable in the bone marrow.

14.45 Clinical features of parvovirus B19 infection

Affected age group	Clinical manifestations
Fifth disease (erythema infectiosum)	
Small children	Three clinical stages: a 'slapped cheek' appearance, followed by a maculopapular rash progressing to a reticulate eruption on the body and limbs, then a final stage of resolution. Often the child is quite well throughout
Gloves and socks syndrome	
Young adults	Fever and an acral purpuric eruption with a clear margin at the wrists and ankles. Mucosal involvement also occurs
Arthropathies	
Adults and occasionally children	Symmetrical small-joint polyarthropathy. In children it tends to involve the larger joints in an asymmetrical distribution
Impaired erythropoiesis	
Adults, those with haematological disease, the immunosuppressed	Mild anaemia; in an individual with an underlying haematological abnormality it can precipitate transient aplastic crisis, or in the immunocompromised a more sustained but often milder pure red cell aplasia
Hydrops fetalis	
Transplacental fetal infection	Asymptomatic or symptomatic maternal infection that can cause fetal anaemia with an aplastic crisis, leading to non-immune hydrops fetalis and spontaneous abortion

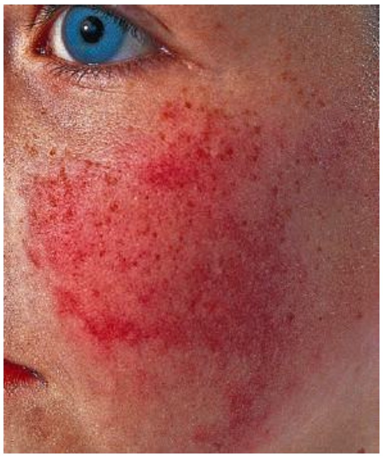

Fig. 14.24 Slapped cheek syndrome. The typical facial rash of parvovirus B19 infection.

Management

Infection is usually self-limiting. Symptomatic relief for arthritic symptoms may be required. Severe anaemia requires transfusion. Persistent viraemia in immunocompromised hosts may require immunoglobulin therapy to clear the virus.

Pregnant women should avoid contact with parvovirus B19 infection; if they are exposed, serology should be performed to establish whether they are immune (IgG-positive).

Passive prophylaxis with immunoglobulin therapy has been suggested for non-immune pregnant women exposed to infection, but there are limited data to support this recommendation. Pregnancy should be closely monitored by ultrasound scanning, so that hydrops fetalis can be treated by fetal transfusion.

Human herpesvirus 6 and 7

Human herpesvirus 6 (HHV-6) is a lymphotropic virus that causes a childhood viral exanthem (exanthem subitum), rare cases of an infectious mononucleosis-like syndrome and infection in the immunocompromised host. Infection is almost universal, with approximately 95% of children acquiring this virus by 2 years of age. Transmission is via saliva.

HHV-7 is very closely related to HHV-6 and is believed to be responsible for a proportion of cases of exanthem subitum. Like HHV-6, HHV-7 causes an almost universal infection in childhood, with subsequent latent infection and occasional infection in the immunocompromised host.

Clinical features

Exanthem subitum is also known as roseola infantum or sixth disease (Box 14.46). A high fever is followed by a maculopapular rash as the fever resolves. Fever and/or febrile convulsions may also occur without a rash. Rarely, older children or adults may develop an infectious mononucleosis-like illness, hepatitis or rash. In the immunocompromised, infection is rare but can cause fever, rash, hepatitis, pneumonitis, cytopenia or encephalitis.

14.46 Herpesvirus infections

Virus	Infection
Herpes simplex virus (HSV)	
HSV-1	Herpes labialis ('cold sores') Stomatitis, pharyngitis Corneal ulceration Finger infections ('whitlows') Eczema herpeticum Encephalitis
HSV-2	Genital ulceration and neonatal infection (acquired during vaginal delivery) Acute meningitis or transverse myelitis; rarely, encephalitis
Varicella zoster virus (VZV)	Chickenpox (varicella) Shingles (herpes zoster)
Cytomegalovirus (CMV)	Congenital infection Infectious mononucleosis (heterophile antibody-negative) Hepatitis Disease in immunocompromised patients: retinitis, encephalitis, pneumonitis, hepatitis, enteritis Fever with abnormalities in haematological parameters
Epstein–Barr virus (EBV)	Infectious mononucleosis Burkitt and other lymphomas Nasopharyngeal carcinoma Oral hairy leucoplakia (AIDS patients) Other lymphomas, post-transplant lymphoproliferative disorder
Human herpesvirus 6 and 7 (HHV-6, HHV-7)	Exanthem subitum Disease in immunocompromised patients
Human herpesvirus 8 (HHV-8)	Kaposi sarcoma Primary effusion lymphoma Multicentric Castleman disease

Diagnosis and management

Exanthem subitum is usually a clinical diagnosis but can be confirmed by DNA detection. The disease is self-limiting. Treatment with ganciclovir or foscarnet is used in immunocompromised hosts infected with HHV-6.

Chickenpox (varicella)

Varicella zoster virus (VZV) is a dermotropic and neurotropic virus that produces primary infection, usually in childhood, which may reactivate in later life. VZV is spread by aerosol and direct contact. It is highly infectious to non-immune individuals. Disease in children is usually well tolerated. Manifestations are more severe in adults, pregnant women and the immunocompromised.

Clinical features

The incubation period is 11–20 days, after which a vesicular eruption begins (Fig. 14.25), often on mucosal surfaces first, followed by rapid dissemination in a centripetal distribution (most dense on trunk and sparse on limbs). New lesions occur every 2–4 days and each crop is associated with fever. The rash progresses from small pink macules to vesicles and pustules within 24 hours. Infectivity lasts from up to 4 days (but usually 48 hours) before the lesions appear until the last vesicles crust over. Due to intense itching, secondary bacterial infection from scratching is the most common complication of primary chickenpox. Self-limiting cerebellar ataxia and encephalitis are rare complications.

Adults, pregnant women and the immunocompromised are at increased risk of visceral involvement, which presents as pneumonitis, hepatitis or encephalitis. Pneumonitis can be fatal and is more likely to occur in smokers. Maternal infection in early pregnancy carries up to 2% risk of neonatal damage with developmental abnormalities of eyes, CNS and limbs. Chickenpox within 5 days of delivery leads to severe neonatal varicella with visceral involvement and haemorrhage.

Diagnosis

Diagnosis is primarily by recognition of the rash. If necessary, this can be confirmed by detection of DNA in aspirated vesicular fluid or scabs. Antigen detection by direct immunofluorescence is an alternative method of detection but less commonly used now. Serology is used to identify seronegative individuals at risk of infection.

Management and prevention

The benefit of antivirals for uncomplicated primary VZV infection in children is marginal, shortening the duration of rash by only 1 day, and is not normally required. Antivirals are, however, used for uncomplicated

14

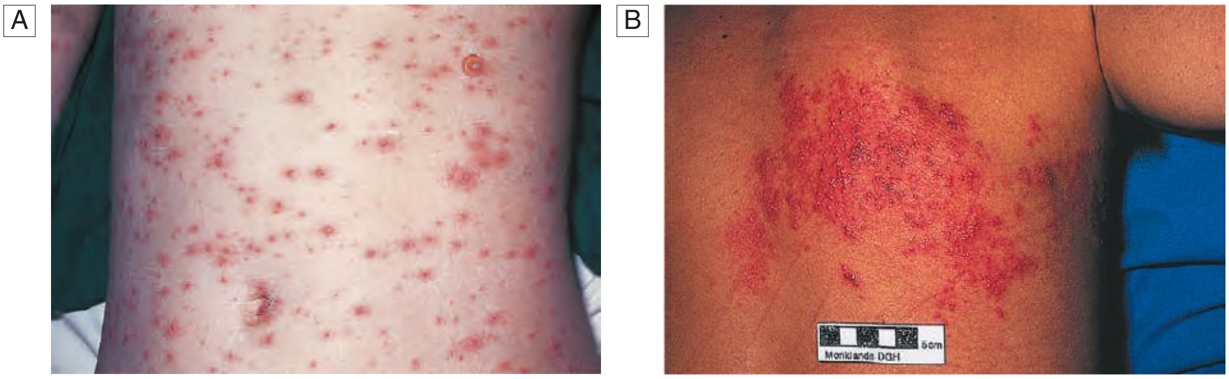

Fig. 14.25 **Varicella zoster virus infection.** A Chickenpox. B Shingles in a thoracic dermatome.

14.47 Therapy for herpes simplex and varicella zoster virus infection

Disease state	Treatment options
Primary genital HSV	Famciclovir 250 mg 3 times daily for 7–10 days Valaciclovir 1 g twice daily for 7–10 days Oral aciclovir 200 mg 5 times daily or 400 mg 3 times daily for 7–10 days
Severe and preventing oral intake	Aciclovir 5 mg/kg 3 times daily IV until patient can tolerate oral therapy
Recurrent genital HSV-1 or 2	Oral aciclovir 200 mg 5 times daily or 400 mg 3 times daily for 5 days Famciclovir 125 mg twice daily for 5 days Valaciclovir 500 mg twice daily for 3–5 days or 2 g twice daily for 1 day. Shorter durations increasingly favoured
Primary or recurrent oral HSV	Usually no treatment If required, usually short duration, e.g. valaciclovir 2 g twice daily for 1 day
Mucocutaneous HSV infection in immunocompromised host	Aciclovir 5 mg/kg 3 times daily IV for 7–10 days Oral aciclovir 400 mg 4 times daily for 7–10 days Famciclovir 500 mg 3 times daily for 7–10 days Valaciclovir 1 g twice daily for 7–10 days
Chickenpox in adult or child	Oral aciclovir 800 mg 5 times daily for 5 days Famciclovir 500 mg 3 times daily for 5 days Valaciclovir 1 g 3 times daily for 5 days
Immunocompromised host/pregnant woman	Aciclovir 5 mg/kg 3 times daily IV until patient is improving, then complete therapy with oral therapy until all lesions are crusting over
Shingles	Treatment and doses as for chickenpox but duration typically 7–10 days
Visceral involvement (non-CNS) in HSV	Aciclovir IV 5 mg/kg 3 times daily for 14 days
Visceral involvement (non-CNS) in VZV	Aciclovir IV 5 mg/kg 3 times daily for 7 days
Severe complications (encephalitis, disseminated infection)	Aciclovir IV 10 mg/kg 3 times daily (up to 20 mg/kg in neonates) for 14–21 days
HSV disease suppression	Aciclovir 400 mg twice daily Famciclovir 250 mg twice daily Valaciclovir 500 mg daily

(CNS = central nervous system; HSV = herpes simplex virus; IV = intravenous; VZV = varicella zoster virus)

chickenpox in adults when the patient presents within 24–48 hours of onset of vesicles, in all patients with complications, and in those who are immunocompromised, including pregnant women, regardless of duration of vesicles (Box 14.47). More severe disease, particularly in immunocompromised hosts, requires initial parenteral therapy. Immunocompromised patients may have prolonged viral shedding and may require prolonged treatment until all lesions crust over.

Post-exposure prophylaxis is used to attenuate infection in people who have had significant contact with VZV, are susceptible to infection (i.e. have no history of chickenpox or shingles and are seronegative for VZV IgG) and are at risk of severe disease (e.g. immunocompromised or pregnant) (Box 14.48). Shortages and now discontinuation of human VZ immunoglobulin (VZIG) have resulted in greater use of antiviral prophylaxis. Antivirals are now recommended for pregnant women and in most cases of exposure in early life. Varicella zoster immunoglobulin given IV is combined with aciclovir for newborns whose mothers developed chickenpox from 7 days before delivery up to 7 days after. If varicella zoster immunoglobulin is not available, normal immunoglobulin is used instead.

A live, attenuated VZV vaccine is available and in routine use in the USA and other countries, but in the UK its use was formerly restricted to non-immune health-care workers and household contacts of immunocompromised individuals. In 2026 it entered the vaccination programme in the United Kindgom combined with MMR. Children receive one dose at 12 months of age and a second dose at 18 months of age; seronegative adults receive two doses at least 1 month apart. The vaccine may also be used prior to planned iatrogenic immunosuppression, e.g. before transplant and for people aged over 70 to prevent shingles.

Shingles (herpes zoster)

After initial infection, VZV persists in latent form in the dorsal root ganglion of sensory nerves and can reactivate in later life.

Clinical features

Burning discomfort occurs in the affected dermatome following reactivation, and discrete vesicles appear 3–4 days later. Brief viraemia can produce distant satellite 'chickenpox' lesions. Occasionally, paraesthesia occurs without rash ('zoster sine herpete'). Severe disease, a prolonged duration of rash, multiple dermatomal involvement or recurrence suggests underlying immune deficiency. Chickenpox may be contracted from a case of shingles but not vice versa.

Although thoracic dermatomes are most commonly involved (see Fig. 14.25B), the ophthalmic division of the trigeminal nerve is also frequently affected; vesicles may appear on the cornea and lead to ulceration. This condition can lead to blindness and urgent ophthalmology review is required. Geniculate ganglion involvement causes the Ramsay Hunt syndrome of facial palsy, ipsilateral loss of taste and buccal ulceration, plus a rash in the external auditory canal. This may be mistaken for Bell palsy, which is discussed on page 1170. Bowel and bladder dysfunction occur with sacral nerve root involvement. The virus occasionally causes cranial nerve palsy, myelitis or encephalitis. Granulomatous cerebral angiitis is a cerebrovascular complication that leads to a stroke-like syndrome in association with shingles, especially in an ophthalmic distribution.

In post-herpetic neuralgia, pain from shingles persists for 3 months or longer following healing of the rash. It is more common with advanced age and in PWH.

Management

Early therapy with aciclovir or related antivirals has been shown to reduce both early- and late-onset pain, especially in patients over 65 years. Post-herpetic neuralgia requires aggressive analgesia, along with agents such as amitriptyline 25–100 mg daily, gabapentin (commencing at 300 mg daily and building slowly to 300 mg twice daily or more) or pregabalin (commencing at 75 mg twice daily and building up to 100 mg or 200 mg 3 times daily if tolerated). Capsaicin cream (0.075%) may be

14.48 Indications for varicella zoster post-exposure prophylaxis (UK guidance)

An adult should satisfy all three of the following conditions:

1. Significant contact

Contact with chickenpox (any time from 24 hrs before the rash until crusting of lesions) or zoster (exposed, disseminated or, with immunocompromised contacts, localised zoster; between development of the rash until crusting) defined as:

- Prolonged household contact, sharing a room for ≥ 15 mins or face-to-face contact (includes direct contact with zoster lesions)
- Hospital contact with chickenpox in another patient, health-care worker or visitor
- Intimate contact (e.g. touching) with person with shingles lesions
- Newborn whose mother develops chickenpox no more than 5 days before delivery or 2 days after delivery

2. Susceptible contact

- Individual with no history of chickenpox or vaccination, ideally confirmed by negative test for VZV IgG

3. Predisposition to severe chickenpox

- Immunocompromised due to disease (e.g. acute leukaemia, human immunodeficiency virus, other primary or secondary immunodeficiency)
- Medically immunosuppressed (e.g. following solid organ transplant; current or recent (< 6 months) cytotoxic chemotherapy or radiotherapy; current or recent (< 3 months) high-dose glucocorticoids; haematopoietic stem cell transplant)
- Pregnant (any stage)
- Infants: newborn whose mother has had chickenpox as above; premature infants < 28 weeks

Choice of prophylaxis*

- Immunocompromised adults: acyclovir 800 mg 4 times daily orally or valaciclovir 1 g 3 times daily orally, started 7 days after exposure or 7 days after first day of rash in person exposed to. Consider varicella zoster immune globulin (VZIG) only if renal impairment or malabsorption.
- Pregnant women: aciclovir as in immunocompromised. Valaciclovir as alternative, all antiviral doses as above.
- Neonate: aciclovir 20 mg/kg (3 times daily IV and convert to orally after 48 hours if able, 4 times daily at same dose) if mother develops chickenpox in the window from 7 days before delivery to 7 days after delivery. In this case, start antivirals as soon as possible after baby is born. In addition, give varicella zoster immunoglobulin IV 25–50 IU/kg or, if not available, normal IV immunoglobulin. All other exposures in early life can be treated with antivirals alone. When antivirals cannot be used, normal IV immunoglobulin at 0.2 g/kg can be used.

*https://www.gov.uk/government/publications/post-exposure-prophylaxis-for-chickenpox-and-shingles/guidelines-on-post-exposure-prophylaxis-pep-for-varicella-or-shingles-january-2023.

helpful but has modest efficacy especially in PWH. Glucocorticoids have not been demonstrated to reduce post-herpetic neuralgia.

Two zoster vaccines are available in the United Kingdom: a live attenuated vaccine (Zostavax) with a higher dose of VZV than the chickenpox vaccine; and a recombinant subunit vaccine (Shingrix). These reduce the incidence of shingles and of post-herpetic neuralgia. In the UK, shingles vaccines are recommended for people who turned 65 on or after September 1st, 2023, those aged 70–79 years and those aged over 50 with severe immunocompromise. The attenuated vaccine, however, should not be given to patients with a severe degree of immunocompromise. The recombinant vaccine is given as two doses 2–6 months apart and is the preferred vaccine because of greater efficacy in preventing shingles. In the United States it is given to patients over 50 years of age and over 19 years of age with immunocompromise.

Enteroviral exanthems

Coxsackievirus or echovirus infections can lead to a maculopapular eruption or roseola-like rash that occurs after fever falls. Enteroviral infections are discussed further under viral infections of the skin (see below).

Systemic viral infections without exanthem

Other systemic viral infections present with features other than a rash suggestive of exanthem. Rashes may occur in these conditions but differ from those seen in exanthems or are not the primary presenting feature.

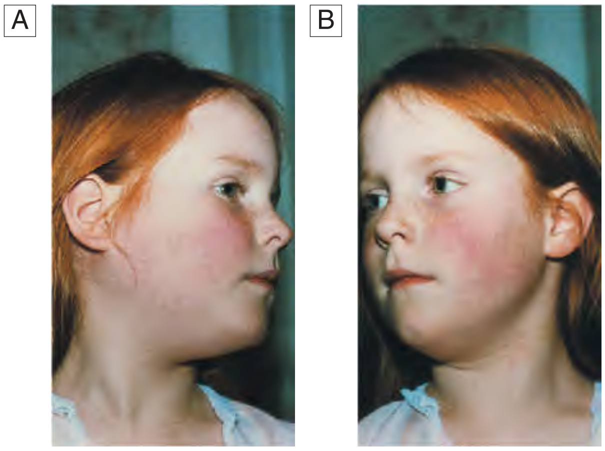

Fig. 14.26 Typical unilateral mumps. A Note the loss of angle of the jaw on the affected (right) side. B Comparison showing normal (left) side.

Mumps

Mumps is a systemic viral infection characterised by swelling of the parotid glands. Infection is endemic worldwide and peaks at 5–9 years of age. Vaccination has reduced the incidence in children but incomplete coverage and waning immunity with time have led to outbreaks in young adults. Infection is spread by respiratory droplets.

Clinical features

The median incubation period is 19 days, with a range of 15–24 days. Classical tender parotid enlargement, which is bilateral in 75%, follows a prodrome of pyrexia and headache (Fig. 14.26). Meningitis complicates up to 10% of cases. The cerebrospinal fluid (CSF) reveals a lymphocytic pleocytosis or, less commonly, neutrophils. Rare complications include encephalitis, transient hearing loss, labyrinthitis, electrocardiographic abnormalities, pancreatitis and arthritis.

Approximately 25% of post-pubertal males with mumps develop epididymo-orchitis but, although testicular atrophy occurs, sterility is unlikely. Oophoritis is less common. Abortion may occur if infection takes place in the first trimester of pregnancy. Complications may occur in the absence of parotitis.

Diagnosis

The diagnosis is usually clinical. In atypical presentations without parotitis, detection of viral RNA by RT-PCR of saliva, buccal swab (after massaging the parotid gland), urine or CSF is the preferred diagnostic method. Serology for mumps-specific IgM or IgG seroconversion (four-fold rise in IgG convalescent titre) also confirms the diagnosis. Virus can also be cultured from urine in the first week of infection.

Management and prevention

Treatment is with analgesia. There is no evidence that glucocorticoids are of value for orchitis. Mumps vaccine is one of the components of the combined MMR or the MMRV vaccine incorporating the varicella-zoster virus vaccine.

Influenza

Influenza is an acute systemic viral infection that primarily affects the respiratory tract and carries a significant mortality. It is caused by influenza A virus or, in milder form, influenza B virus. Infection is seasonal, and variation in the haemagglutinin (H) and neuraminidase (N) glycoproteins on the surface of the virus leads to disease of variable intensity each year. Minor changes in haemagglutinin are known as ‘genetic drift’, whereas a switch in the haemagglutinin or neuraminidase antigen is termed ‘genetic shift’. Nomenclature of influenza strains is based on these glycoproteins, e.g. H1N1, H3N2 etc. Genetic shift results in the circulation of a new influenza strain within a community to which few people are immune, potentially initiating an influenza epidemic or pandemic in which there is a high attack rate and there may be increased disease severity. Re-assortment of swine, avian and human influenza strains can occur in pigs and lead to outbreaks of swine 'flu' in humans, as occurred in 2009, with the outbreak of H1N1pdm2009 influenza.

Clinical features

After an incubation period of 1–3 days, uncomplicated disease leads to fever, malaise and cough. Viral pneumonia may occur, although pulmonary complications are most often due to superinfection with *Streptococcus pneumoniae*, *Staphylococcus aureus* or other bacteria. Rare extrapulmonary manifestations include myositis, myocarditis, pericarditis and neurological complications (Reye syndrome in children, encephalitis or transverse myelitis). Mortality is greatest in older people, those with medical comorbidities and pregnant women. Polymorphisms in the gene encoding an antiviral protein, interferon-induced transmembrane protein 3 (IFITM3), are associated with more severe influenza.

Diagnosis

Acute infection is diagnosed by RNA detection (or antigen) in a nasopharyngeal sample. Point-of-care tests aid rapid diagnosis and can be combined with detection of other respiratory viruses e.g. SARS-CoV-2 and RSV. Rapid molecular tests that detect RNA are more accurate than rapid influenza diagnostic tests that detect antigen. The disease may also be diagnosed retrospectively by serology.

Management and prevention

Management involves early microbiological identification of cases and good infection control, with an emphasis on hand hygiene and preventing dissemination of infection by coughing and sneezing. Administration of a neuraminidase inhibitor, e.g. oral oseltamivir, inhaled zanamivir, intravenous peramivir or the oral cap-dependent endonuclease inhibitor baloxavir, can reduce the severity of symptoms if started within 48 hours of symptom onset (or possibly later in immunocompromised individuals). Baloxavir is currently not recommended for hospitalised or pregnant patients. Antiviral drugs can also be used as prophylaxis in high-risk individuals during the 'flu' season. Resistance can emerge to neuraminidase inhibitors and so updated local advice should be followed with regard to the sensitivity to antivirals of the circulating strain.

Prevention relies on seasonal vaccination of older age groups, children 2–7 years of age and individuals with chronic medical illnesses that place them at increased risk of the complications of influenza, such as chronic cardiopulmonary diseases or immune compromise, as well as their health-care workers. The vaccine composition changes each year to cover the 'predicted' seasonal strains but vaccination may fail when a new pandemic strain emerges.

Avian influenza

Avian influenza is caused by transmission of avian influenza A viruses to humans. Avian viruses, such as H5N1, possess alternative haemagglutinin antigens to seasonal influenza strains. Most cases have had contact with sick poultry, predominantly in South-east Asia, and person-to-person spread has been limited to date. Infections with H5N1 viruses have been severe, with enteric features and respiratory failure. Treatment depends on the resistance pattern but often involves oseltamivir. Vaccination against seasonal 'flu' does not adequately protect against avian influenza. There is a concern that adaptation of an avian strain to allow effective person-to-person transmission is likely to lead to a global pandemic of life-threatening influenza. Since 2020 a variant of H5N1 has been causing an unprecedented global outbreak spreading through Asia, Africa, Europe and the Americas. In 2024 this ongoing outbreak of H5N1 avian influenza spread to dairy herds in the United States with reported sporadic cases of transmission to humans in farm workers.

Infectious mononucleosis and Epstein–Barr virus

Infectious mononucleosis (IM) is a clinical syndrome characterised by pharyngitis, cervical lymphadenopathy, fever and lymphocytosis (known colloquially as glandular fever). It is most often caused by Epstein–Barr virus (EBV), but other infections can produce a similar clinical syndrome (Box 14.49).

EBV is a gamma herpesvirus. In lower- or middle-income countries (LMIC), subclinical infection in childhood is virtually universal. In high-income countries, primary infection may be delayed until adolescence or early adult life. Under these circumstances, about 50% of infections result in typical IM. The virus is usually acquired from asymptomatic excreters via saliva, either by droplet infection or environmental contamination in childhood, or by kissing among adolescents and adults. EBV is not highly contagious and isolation of cases is unnecessary.

Clinical features

EBV infection has a prolonged but undetermined incubation period, followed in some cases by a prodrome of fever, headache and malaise. This is followed by IM with severe pharyngitis, which may include tonsillar exudates and non-tender anterior and posterior cervical lymphadenopathy. Palatal petechiae, periorbital oedema, splenomegaly, inguinal or axillary lymphadenopathy and macular, petechial or erythema multiforme rashes may occur. In most cases, fever resolves over 2 weeks, and fatigue and other abnormalities settle over a further few weeks. Complications are listed in Box 14.50. Death is rare but can occur due to respiratory obstruction, haemorrhage from splenic rupture, thrombocytopenia or encephalitis.

The diagnosis of EBV infection outside the usual age in adolescence and young adulthood is more challenging. In children under 10 years the illness is mild and short-lived, but in adults over 30 years of age it can be

14.49 Causes of infectious mononucleosis syndrome

- Epstein–Barr virus infection
- Cytomegalovirus
- HHV-6 or 7
- HIV-1 primary infection
- Toxoplasmosis

(HHV = human herpesvirus; HIV = human immunodeficiency virus)

14.50 Complications of Epstein–Barr virus infection

Common

- Severe pharyngeal oedema
- Antibiotic-induced rash (80%–90% with ampicillin)
- Hepatitis (80%)
- Prolonged post-viral fatigue (10%)
- Jaundice (< 10%)

Uncommon

Neurological

- Cranial nerve palsies
- Polyneuritis
- Transverse myelitis
- Meningoencephalitis

Haematological

- Haemolytic anaemia
- Thrombocytopenia

Renal

- Abnormalities on urinalysis
- Interstitial nephritis

Cardiac

- Myocarditis
- ECG abnormalities
- Pericarditis

Rare

- Ruptured spleen
- Respiratory obstruction
- Agranulocytosis
- X-linked lymphoproliferative syndrome

EBV-associated malignancy

- Nasopharyngeal carcinoma
- Burkitt lymphoma
- Hodgkin lymphoma (certain subtypes only)
- Primary CNS lymphoma
- Lymphoproliferative disease in immunocompromised

(CNS = central nervous system; EBV = Epstein–Barr virus; ECG = electrocardiogram) severe and prolonged. In both groups, pharyngeal symptoms are often absent. EBV may present with jaundice, as a PUO or with a complication.

EBV can be one cause of a post-viral fatigue syndrome where fatigue persists after other symptoms of viral infection have gone. Post-viral fatigue can be characterised by complete physical and mental exhaustion. Fatigue interferes with normal activities, is worsened by activity and is associated with sleep problems. Associated symptoms include poor memory, headaches and muscle or joint pains. These features give rise to myalgic encephalomyelitis/chronic fatigue syndrome, although there is no evidence of encephalitis or myelitis. Other potential infection associations with this syndrome include SARS-CoV-2, giardiasis, dengue, Ross Valley fever and *Coxiella* infection. There is no specific diagnostic test and management involves addressing individual symptoms, including managing any associated symptoms of anxiety or depression that may arise as a complication.

Long-term complications of EBV infection

Lymphoma complicates EBV infection in immunocompromised hosts (e.g. post-transplant lymphoproliferative disorder), and some forms of Hodgkin lymphoma are EBV-associated. The endemic form of Burkitt lymphoma complicates EBV infection in areas of sub-Saharan Africa where *falciparum* malaria is endemic. Nasopharyngeal carcinoma is a geographically restricted tumour seen in China and Alaska that is associated with EBV infection. X-linked lymphoproliferative (Duncan) syndrome is a familial lymphoproliferative disorder that follows primary EBV infection in boys without any other history of immunodeficiency; it is due to mutation of the *SAP* gene, causing failure of T-cell and NK-cell activation and inability to contain EBV infection. Intriguingly, infection with Epstein–Barr virus dramatically increases the odds of developing multiple sclerosis later in life.

Investigations

Atypical lymphocytes are common in EBV infection but also occur in other causes of IM, acute retroviral syndrome with HIV, viral hepatitis, mumps and rubella (Fig. 14.27A). They are also a feature of dengue, malaria and other geographically restricted infections (see Box 14.18). A 'heterophile' antibody is present during the acute illness and convalescence, which is detected by the Paul–Bunnell or 'Monospot' test. A heterophile antibody is an antibody that has affinity for antigens other than the specific one, in this case animal immunoglobulins; the Paul–Bunnell and Monospot tests exploit this feature by detecting the ability of test serum to agglutinate sheep and horse red blood cells, respectively. Sometimes antibody production is delayed, so an initially negative test should be repeated. However, many children and 10% of adolescents with IM do not produce heterophile antibody at any stage.

Specific EBV serology confirms the diagnosis. Acute infection is characterised by IgM antibodies against the viral capsid, antibodies to EBV early antigen and the initial absence of antibodies to EBV nuclear antigen (anti-EBNA). Seroconversion of anti-EBNA at approximately 1 month after the initial illness may confirm the diagnosis in retrospect. CNS infections may be diagnosed by detection of viral DNA in CSF.

Management

Treatment is symptomatic. If a throat culture yields a β-haemolytic streptococcus, penicillin should be given. Administration of ampicillin or amoxicillin in this condition commonly causes an itchy macular rash and should be avoided (Fig. 14.27B). When pharyngeal oedema is severe, a short course of glucocorticoids, e.g. prednisolone 30 mg daily for 5 days, may help. Current antiviral drugs are not active against EBV.

Return to work or school is governed by physical fitness rather than laboratory tests; contact sports should be avoided until splenomegaly has resolved because of the danger of splenic rupture. Unfortunately, about 10% of patients with IM suffer a chronic relapsing syndrome.

For patients at risk of post-transplant lymphoproliferative disease with high EBV viral load, rituximab can be used as a pre-emptive strategy along with reduction of immunosuppression, while treatment of established post-transplant lymphoproliferative disease can include rituximab and may also include chemotherapy or adoptive immunotherapy with infusion of donor-derived cytotoxic lymphocytes targeting EBV.

Cytomegalovirus

Cytomegalovirus (CMV), like EBV, circulates readily among children. A second period of virus acquisition occurs among adolescents and young adults, peaking between the ages of 25 and 35 years, rather later than with EBV infection. CMV infection is persistent and is characterised by subclinical cycles of active virus replication and by persistent low-level virus shedding. Most post-childhood infections are therefore acquired from asymptomatic excreters who shed virus in saliva, urine, semen and genital secretions. Sexual transmission and oral spread are common among adults but infection may also be acquired through caring for children with asymptomatic infections.

Clinical features

Most post-childhood CMV infections are subclinical, although some young adults develop an IM-like syndrome, and some have a prolonged influenza-like illness lasting 2 weeks or more. Physical signs resemble IM, but in CMV infections hepatomegaly is more common, while lymphadenopathy, splenomegaly, pharyngitis and tonsillitis occur less often. Jaundice is uncommon and usually mild. Complications include meningoencephalitis, Guillain–Barré syndrome, autoimmune haemolytic anaemia, thrombocytopenia, myocarditis and skin eruptions, such as ampicillin-induced rash. Immunocompromised patients can develop hepatitis, oesophagitis, colitis, pneumonitis, retinitis, encephalitis and polyradiculitis.

Women who develop a primary CMV infection during pregnancy have about a 40% chance of passing CMV to the fetus, causing congenital infection and disease at any stage of gestation. Features include petechial rashes, hepatosplenomegaly and jaundice; 10% of infected infants

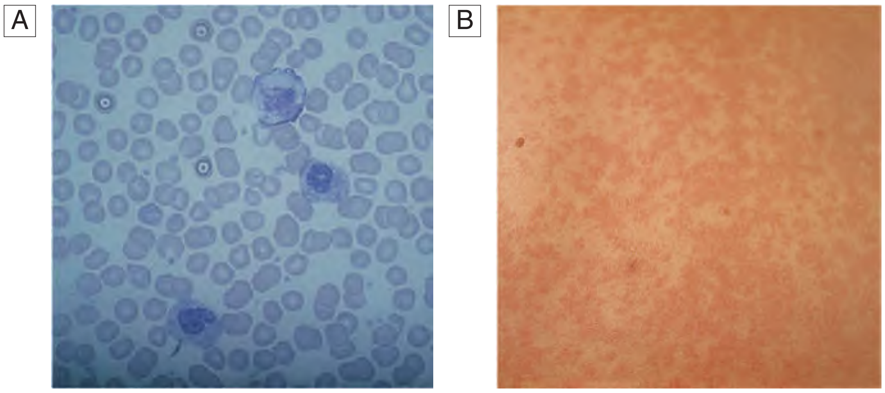

Fig. 14.27 Features of infectious mononucleosis. **A** Atypical lymphocytes in peripheral blood. **B** Skin reaction to ampicillin.

will have long-term CNS sequelae, such as microcephaly, cerebral calcifications, chorioretinitis and deafness. Infections in the newborn usually are asymptomatic or have features of an IM-like illness, although subtle sequelae affecting hearing or mental development may occur.

Investigations

Atypical lymphocytosis is not as prominent as in EBV infection and heterophile antibody tests are usually negative. LFTs are often abnormal, with an alkaline phosphatase level raised out of proportion to transaminases. Serological diagnosis depends on the detection of CMV-specific IgM antibody plus a fourfold rise or seroconversion of IgG. In the immunocompromised, antibody detection is unreliable and detection of CMV in an involved organ by PCR, antigen detection, culture or histopathology establishes the diagnosis. Detection of CMV in the blood may be useful in transplant populations but not in HIV-positive individuals, since in HIV infection CMV reactivates at regular intervals, but these episodes do not correlate well with episodes of clinical disease. Detection of CMV in urine is not helpful in diagnosing infection, except in neonates, since CMV is intermittently shed in the urine throughout life following infection.

Management

Only symptomatic treatment is required in the immunocompetent patient. Immunocompromised individuals are treated with intravenous ganciclovir 5 mg/kg twice daily or with oral valganciclovir 900 mg twice daily for at least 14 days. Foscarnet or cidofovir is also used in CMV treatment of immunocompromised patients who are resistant to or intolerant of ganciclovir-based therapy. They can be given intravitreally if required. Maribavir is licensed for use in transplant recipients with CMV refractory to treatment with ganciclovir, valganciclovir, foscarnet or cidofovir. It acts on the UL97 kinase and may be used with or without documented mutations that cause resistance to other antivirals that are dependent on UL97 kinase activity. Letermovir is used in the prevention of CMV in high-risk transplant patients, e.g. some haematopoietic stem cell transplant recipients.

Dengue

Dengue is a febrile illness caused by a flavivirus transmitted by mosquitoes. It is endemic in Asia, the Pacific, Africa and the Americas (Fig. 14.28). Approximately 400 million infections and 100 million clinically apparent infections occur annually, and dengue is the most rapidly spreading mosquito-borne viral illness. In 2023 the highest number of reported cases ever occurred, and the ongoing increase in cases involved more than 90 countries, reflecting the impact of climate change. The 2023 dengue outbreak in many countries was associated with higher mortality and hospitalisation rates. Locally acquired dengue was reported in France, Italy and Spain, but despite the presence of appropriate vectors (*Aedes albopictus*), the ongoing risk of local transmission in areas where the vectors were present was still assessed as low due to reported vector activity patterns and levels of ongoing virus replication in vectors. However, there is significant potential for spread of infection if these parameters change. The principal vector globally is the mosquito *Aedes aegypti*, which breeds in standing water; collections of water in containers, water-based air coolers and tyre dumps are a good environment for the vector in large cities. *Aedes albopictus* is a vector in some South-east Asian countries. There are four serotypes of dengue virus, all producing a similar clinical syndrome; type-specific immunity is life-long but immunity against the other serotypes lasts only a few months. Dengue haemorrhagic fever (DHF) and dengue shock syndrome (DSS) occur in individuals immune to one dengue virus serotype who are subsequently infected with a different serotype. Prior immunity results in production of non-neutralizing antibody, resulting in increased uptake of virus by cells expressing the antibody Fc receptor and increased T-cell activation with resultant cytokine release. This process is called antibody-dependent enhancement, which leads to capillary leak and disseminated intravascular coagulation (DIC; Ch. 24). Previously, dengue was seen in small children and DHF/DSS in children 2–15 years old, but these conditions are now being seen in children less than 2 years old, and most frequently in those 16–45 years of age or older, in whom severe organ dysfunction is more common. Other epidemiological changes include the spread of dengue into rural communities and high-resource countries and greater case fatality in women.

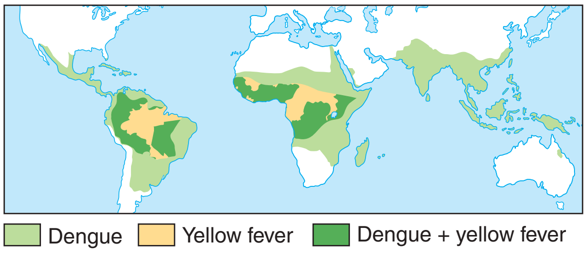

Fig. 14.28 Endemic zones of yellow fever and dengue. Map lines delineate study areas and do not necessarily depict accepted national boundaries.

Clinical features

Many cases of dengue infection are asymptomatic in children. Clinical disease presents with undifferentiated fever, termed 'dengue-like illness'. When dengue infection occurs with characteristic symptoms or signs, it is termed 'dengue' (Box 14.51). A rash frequently follows the initial febrile phase as the fever settles. Laboratory features include leucopenia, neutropenia, thrombocytopenia and elevated alanine aminotransferase (ALT) or aspartate aminotransferase (AST). The differential diagnosis of thrombocytopenia with fever in dengue endemic areas is shown in Box 14.52. Many symptomatic infections run an uncomplicated course, but complications or a protracted convalescence may ensue. Warning signs justify intense medical management and monitoring for progression to severe dengue. Atypical clinical features of dengue as the presenting features are increasingly common (see Box 14.51), especially in infants or older patients, and in rural locations. These, along with DHF or DSS, are recognised as features of severe dengue in the 2015 case definition and contribute to mortality, mandating urgent medical management (Box 14.53).

The period 3–7 days after onset of fever is termed the 'critical' phase, during which signs of DHF or DSS may develop. In mild forms, petechiae occur in the arm when a blood pressure cuff is inflated to a point between systolic and diastolic blood pressure and left for 5 minutes (the positive 'tourniquet test') – a non-specific test of capillary fragility and thrombocytopenia. As the extent of capillary leak increases, DSS develops, with a raised haematocrit, tachycardia and hypotension, pleural effusions and ascites. This may progress to metabolic acidosis and multi-organ failure, including acute respiratory distress syndrome (ARDS). Minor (petechiae, ecchymoses, epistaxis) or major (gastrointestinal or vaginal) haemorrhage, a feature of DHF, may occur. Cerebrovascular bleeding may be a complication of severe dengue.

Diagnosis

In endemic areas, mild dengue must be distinguished from other viral infections. The diagnosis can be confirmed by seroconversion of IgM or a fourfold rise in IgG antibody titres. Serological tests may detect cross-reacting antibodies from infection or vaccination against other flaviviruses, including yellow fever virus, Japanese encephalitis virus and West Nile virus. Isolation of dengue virus or detection of dengue virus RNA by PCR in blood or CSF is available in specialist laboratories and PCR is now the preferred diagnostic method in most centres. Commercial enzyme-linked immunosorbent assay (ELISA) kits to detect the NS1 viral antigen, although less sensitive than PCR, are available in many endemic areas.

Management and prevention

Treatment is supportive, emphasising fluid replacement and appropriate management of shock and organ dysfunction, which is a major determinant of morbidity and mortality. With intensive care support, mortality rates are 1% or less. Aspirin should be avoided due to bleeding risk. Glucocorticoids have not been shown to help. No existing antivirals are effective.

Breeding places of *Aedes* mosquitoes should be eliminated and the adults destroyed by insecticides.

14.51 Clinical features of dengue fever

Incubation period

- 2–7 days

Prodrome

- 2 days of malaise and headache

Acute onset

- Fever, backache, arthralgias, headache, generalised pains ('break-bone fever'), pain on eye movement, lacrimation, scleral injection, anorexia, nausea, vomiting, pharyngitis, upper respiratory tract symptoms, relative bradycardia, prostration, depression, hyperaesthesia, dysgeusia, lymphadenopathy

Fever

- Continuous or 'saddle-back', with break on 4th or 5th day and then recrudescence; usually lasts 7–8 days

Rash

- Initial flushing faint macular rash in first 1–2 days. Maculopapular, scarlet morbilliform blanching rash from days 3–5 on trunk, spreading centrifugally and sparing palms and soles; onset often with fever defervescence. May desquamate on resolution or give rise to petechiae on extensor surfaces

Convalescence

- Slow and may be associated with prolonged fatigue syndrome, arthralgia or depression

Complications

- Dengue haemorrhagic fever and disseminated intravascular coagulation
- Dengue shock syndrome
- Severe organ involvement
- Vertical transmission if infection within 5 weeks of delivery

Atypical presentations*

- Cardiovascular: myocarditis, pericarditis, arrythmias
- Respiratory: acute lung injury, pulmonary haemorrhage, acute respiratory distress syndrome (ARDS)
- Hepatobiliary: hepatitis, fulminant hepatic failure, acalculous cholecystitis, pancreatitis
- Gastrointestinal: diarrhoea, gastrointestinal haemorrhage, acute parotitis
- Renal: acute kidney injury, haemolytic uremic syndrome (HUS)
- Haematological and lymphoreticular: disseminated intravascular coagulopathy (DIC), splenomegaly, splenic rupture, lymphadenopathy
- Neurological: encephalitis, encephalopathy, aseptic meningitis, intracranial haemorrhage or thrombosis, seizures, mononeuritis, polyneuropathy, transverse myelitis, Guillain–Barré syndrome, myositis, rhabdomyolysis

*The list contains a range of atypical presentations but is not exhaustive.

14.52 Differential diagnosis of thrombocytopenia with fever in dengue endemic areas

Common	Less frequent
Malaria Sepsis Typhoid	Rickettsial infection Leptospirosis Other viruses, e.g. chikungunya, viral haemorrhagic fevers, yellow fever

The first licensed dengue vaccine was Dengvaxia. It was a tetravalent live recombinant vaccine recommended for individuals aged 9–45/9–60 (depending on country-specific recommendations), who lived in a dengue endemic area and had pre-vaccination positive dengue serology, but the marketing authorization was withdrawn in 2025 in Europe and the company stated it was not continuing marketing for commercial reasons. As of 2025, Q-denga (TAK-003) was the only licensed vaccine. It is a live attenuated vaccine incorporating a DENV2 backbone and includes recombinant DENV2 strains incorporating the other three serotypes. It can be given to dengue-naïve children and is recommended for use in children 6–16 years of age in high transmission settings. The vaccine has been approved in UK, Europe and many other countries for all individuals over four. Other vaccines are also in development.

14.53 WHO case definitions of dengue, 2015

Probable dengue fever

- Exposure in an endemic area
- Fever
- Two of:
    - Nausea/vomiting
    - Rash
    - Aches/pains
    - Positive tourniquet test
    - Leucopenia
    - Any warning sign

Laboratory confirmation important

Needs regular medical observation and instruction in observing for the 'warning signs'

If there are no 'warning signs', need for hospitalisation is influenced by age, comorbidities, pregnancy and social factors

Dengue with warning signs

- Probable dengue plus one of:
    - Abdominal pain or tenderness
    - Persistent vomiting
    - Signs of fluid accumulation, e.g. pleural effusion or ascites
    - Mucosal bleed
    - Hepatomegaly > 2 cm
    - Rapid increase in haematocrit with fall in platelet count

Needs medical intervention, e.g. intravenous fluid

Severe dengue

- Severe plasma leakage leading to:
    - Shock (dengue shock syndrome)
    - Fluid accumulation with respiratory distress
- Severe haemorrhagic manifestations, e.g. gastrointestinal haemorrhage
- Severe organ involvement (atypical features):
    - Liver AST or ALT ≥ 1000 U/L
    - CNS: impaired consciousness, meningoencephalitis, seizures
    - Cardiomyopathy, conduction defects, arrhythmias
    - Other severe organ involvement, e.g. acute kidney injury, pancreatitis, acute lung injury, disseminated intravascular coagulopathy, rhabdomyolysis

Needs emergency medical treatment and specialist care with intensive care input

(ALT = alanine aminotransferase; AST = aspartate aminotransferase; CNS = central nervous system; WHO = World Health Organization)
Adapted from https://www.who.int/docs/default-source/outbreak-toolkit/updates-documents_july-5/dengue-outbreak-data-collection-toolbox---inis-3-july-1.pdf?sfvrsn=ec3ffcf3_2.

Yellow fever

Yellow fever is a haemorrhagic fever of the tropics, caused by a flavivirus. It is a zoonosis of monkeys in West and Central African, and South and Central American tropical rainforests, and may cause epidemics (see Fig. 14.28). Transmission is by tree-top mosquitoes, *Aedes africanus* (Africa) and *Haemagogus* spp. (America). The infection is introduced to humans either by infected mosquitoes when trees are felled, or by monkeys raiding human settlements. In towns, yellow fever may be transmitted between humans by *Aedes aegypti*, which breeds efficiently in small collections of water. The distribution of this mosquito is far wider than that of yellow fever, threatening geographical spread.

Yellow fever causes up to 170 000 infections each year, mainly in sub-Saharan Africa. In 2023, 34 African and 13 Central or South American counties were endemic, or contained endemic foci, for yellow fever. Mortality varies but is approximately 15%. Humans are infectious during the viraemic phase, which starts 3–6 days after the bite of the infected mosquito and lasts for 4–5 days.

Clinical features

After an incubation period of 3–6 days, yellow fever is often a mild febrile illness lasting less than 1 week, with headache, myalgia, conjunctival erythema and bradycardia. This is followed by fever resolution (defervescence) but, in some cases, fever recurs after a few hours to days. In more severe disease, fever recrudescence is associated with lower back pain, abdominal pain and somnolence, prominent nausea and vomiting, bradycardia and jaundice. Liver damage and DIC lead to bleeding with petechiae, mucosal haemorrhages and gastrointestinal bleeding. Shock, hepatic failure, renal failure, seizures and coma may ensue.

Diagnosis

The differential diagnosis includes malaria, typhoid, viral hepatitis, leptospirosis, haemorrhagic fevers and aflatoxin poisoning. Diagnosis of yellow fever can be confirmed by detection of virus in the blood in the first 3–4 days of illness by culture or RT-PCR, by the presence of IgM or by a fourfold rise in IgG antibody titre. Leucopenia is characteristic. Liver biopsy should be avoided due to the risk of fatal bleeding. Postmortem features, such as acute mid-zonal necrosis and Councilman bodies with minimal inflammation in the liver, are suggestive but not specific. Immunohistochemistry for viral antigens improves specificity.

Management and prevention

Treatment is supportive, with meticulous attention to fluid and electrolyte balance, urine output and blood pressure. Blood transfusions, plasma expanders and peritoneal dialysis may be necessary. Patients should be isolated, as their blood and body products may contain virus particles.

A single vaccination with a live attenuated vaccine gives full protection and travellers do not require a booster unless specified by individual countries' travel requirements. Potential side-effects include hypersensitivity, acute neurotropic disease (encephalitis) (YEL-NVD) and systemic features of yellow fever with acute viscerotropic disease (YEL-AVD) caused by the attenuated virus. Vaccination is not recommended in people who are significantly immunosuppressed or aged over 60 years. The risk of vaccine side-effects must be balanced against the risk of infection for less immunocompromised hosts, pregnant women and older patients. An internationally recognised certificate of vaccination is sometimes necessary when crossing borders. The Eliminate Yellow Fever Epidemics (EYE) strategy was launched in 2017 in response to urban outbreaks in Luanda (Angola) and Kinshasa (Democratic Republic of the Congo) and aims to protect a billion people living in at-risk countries in Africa and the Americas by 2026.

Viral haemorrhagic fevers

Viral haemorrhagic fevers (VHFs) are zoonoses caused by several different viruses (Box 14.54). They are geographically restricted and previously occurred in rural settings or in health-care facilities. The largest outbreak of VHF to date started in 2014, with Ebola circulating in Guinea, Liberia and Sierra Leone. The outbreak resulted in more than 28 000 cases by 2016. From 2018 to 2020 there was a further Ebola outbreak in the eastern part of the Democratic Republic of Congo (DRC).

Serological surveys have shown that Lassa fever is widespread in West Africa and may lead to up to 500 000 infections annually. In 2024 there have continued to be significant numbers of cases of Lassa fever reported from Nigeria. Mortality overall may be low, as 80% of cases are asymptomatic, but in hospitalised cases mortality averages 15%. Marburg has been documented less frequently, with outbreaks in the DRC and Uganda, but the largest outbreak to date involved 163 cases in Angola in 2005. Mortality rates of Ebola and Marburg vary but are high. Lujo haemorrhagic fever is caused by an arenavirus that causes a Lassa-like illness with high mortality. The only outbreak to date occurred in Zambia in 2008 and it is thought to be spread by contact with infected rodents.

VHFs have extended into Europe, with an outbreak of Congo–Crimean haemorrhagic fever (CCHF) in Turkey in 2006, and cases of haemorrhagic fever with renal syndrome in the Balkans and Russia. In 2024 Eastern Turkey, North Macedonia and Spain have reported CCHF cases. An outbreak of CCHF in 2011 in Gujarat, India, involved several health-care workers and emphasised the importance of maintaining a high index of suspicion for VHF and implementing appropriate infection control measures at the first opportunity. Kyasanur forest disease is a tick-borne VHF currently confined to a small focus in Karnataka, India; there are about 500 cases annually. Monkeys are the principal hosts but, with forest felling, there are fears that this disease will increase. Severe fever with thrombocytopenia syndrome (SFTS) is a tick-borne VHF that has emerged in rural China, South Korea and Japan since 2009.

New outbreaks and new agents are identified sporadically. Details on recent disease outbreaks can be found at the WHO website (see 'Further information').

Clinical features

VHFs present with non-specific fever, malaise, body pains, sore throat and headache. On examination, conjunctivitis, throat injection, an erythematous or petechial rash, haemorrhage, lymphadenopathy and bradycardia may be noted. Endothelial dysfunction causes capillary leak. Bleeding is due to endothelial damage and platelet dysfunction. Hypovolaemic shock and ARDS may develop.

Haemorrhage is a late feature of most VHFs and many patients present with earlier features. In Lassa fever, joint and abdominal pain is prominent. A macular blanching rash may be present but bleeding is unusual, occurring in only 20% of hospitalised patients. Encephalopathy may develop and deafness affects 30% of survivors. In CCHF, bleeding, manifest by haematemesis or bleeding per rectum, may be an early feature, accompanied by derangement of LFTs.

The clue to the viral aetiology comes from the travel and exposure history. Travel to an outbreak area, activity in a rural environment and contact with sick individuals or animals within 21 days all increase the risk of VHF. Enquiry should be made about insect bites, hospital visits and attendance at ritual funerals (Ebola virus infection). For Lassa fever, retrosternal pain, pharyngitis and proteinuria have a positive predictive value of 80% in West Africa.

Investigations and management

Non-specific findings include leucopenia, thrombocytopenia and proteinuria. In Lassa fever, an AST of > 150 U/L is associated with a 50% mortality. It is important to exclude other causes of fever, especially malaria, typhoid and respiratory tract infections. In the UK, most patients suspected of having a VHF turn out to have malaria.

A febrile patient from an endemic area within the 21-day incubation period, who has specific epidemiological risk factors (see Fig. 14.7), known contact with a VHF case or clinical samples from a person with VHF or with signs of organ failure or haemorrhage, should be treated as being at high risk of VHF; appropriate infection control measures must be implemented and the patient transferred to a centre with biosafety level (BSL) 4 facilities if they test positive. Individuals with a history of travel within 21 days and fever, but without the relevant high-risk epidemiological features or signs of VHF, are classified as medium-risk and should have an initial blood sample tested to exclude malaria. If this is negative, relevant specimens (blood, throat swab, urine and pleural fluid, if available) are collected and sent to an appropriate reference laboratory for nucleic acid detection (PCR), virus isolation and serology. If patients are still felt to be at significant risk of VHF or if infection is confirmed, they should be transferred to a specialised HCID unit. All further laboratory tests should be performed at BSL 4. Transport requires an ambulance with BSL 3 facilities.

In addition to general supportive measures, ribavirin is given intravenously (100 mg/kg, then 25 mg/kg daily for 3 days and 12.5 mg/kg daily for 4 days) when Lassa fever or South American haemorrhagic fevers are suspected.

Prevention

Ribavirin has been used as prophylaxis in close contacts in Lassa fever but there are no formal trials of its efficacy.

Ebola virus disease (EVD)

Ebola virus disease (EVD) is thought to spread to human populations from fruit bats, sometimes indirectly via contact with infected primates or other

14.54 Viral haemorrhagic fevers

Disease	Reservoir	Transmission	Incubation period	Geography	Mortality rate	Clinical features of severe disease[1]
Lassa fever	Multimammate rats (*Mastomys natalensis*)	Urine from rat Body fluids from patients	6–21 days	West Africa	15%	Haemorrhage, shock, encephalopathy, ARDS (responds to ribavirin), deafness in survivors
Ebola fever	Fruit bats (Pteropodidae family) and bush meat	Body fluids from patients Handling infected primates	2–21 days	Central Africa Outbreaks as far north as Sudan	25%–90%	Haemorrhage and/or diarrhoea, hepatic failure and acute kidney injury
Marburg fever	Undefined	Body fluids from patients Handling infected primates	3–9 days	Central Africa Outbreak in Angola	25%–90%	Haemorrhage, diarrhoea, encephalopathy, orchitis
Yellow fever	Monkeys	Mosquitoes	3–6 days	See Fig. 14.28	~15%	Hepatic failure, acute kidney injury, haemorrhage
Dengue	Humans	*Aedes aegypti*	2–7 days	See Fig. 14.28	$<10\%$[2]	Haemorrhage, shock
Crimean–Congo haemorrhagic fever	Small vertebrates	*Ixodes* tick	1–3 days up to 9 days	Africa, Asia, Eastern Europe	30%	Encephalopathy, early haemorrhage, hepatic failure, acute kidney injury, ARDS
	Domestic and wild animals	Body fluids	3–6 days up to 13 days			
Rift Valley fever	Domestic livestock	Contact with animals, mosquito or other insect bites	2–6 days	Africa, Arabian peninsula	1%	Haemorrhage, blindness, meningoencephalitis (complications only in a minority)
Kyasanur fever	Monkeys	Ticks	3–8 days	Karnataka State, India	5%–10%	Haemorrhage, pulmonary oedema, neurological features, iridokeratitis in survivors
Bolivian and Argentinian haemorrhagic fever (Junin and Machupo viruses)	Rodents (*Calomys* spp.)	Urine, aerosols Body fluids from case (rare)	5–19 days (3–6 days for parenteral)	South America	15%–30%	Haemorrhage, shock, cerebellar signs (may respond to ribavirin)
Haemorrhagic fever with renal syndrome (Hantaan fever)	Rodents	Aerosols from faeces	5–42 days (typically 14 days)	Northern Asia, northern Europe, Balkans	5%	Acute kidney injury, cerebrovascular accidents, pulmonary oedema, shock (hepatic failure and haemorrhagic features only in some variants)
Severe fever with thrombocytopenia syndrome (SFTS)	Domestic and wild animals	*Ixodes* ticks	5–14 days, average 9 days	China, South Korea, Japan	7%	Organ failure (liver, heart, kidney, lungs), haemorrhage and disseminated intravascular coagulopathy, neuropsychiatric, prominent thrombocytopenia

[1] All potentially have circulatory failure.
[2] Mortality of uncomplicated and haemorrhagic dengue fever, respectively.
(ARDS = acute respiratory distress syndrome)

animals. Person-to-person spread, via contact with blood, secretions or body parts, establishes EVD in populations. Family members, health-care workers and people performing traditional burials are at particular risk. The 2014 outbreak involved the Zaire strain of Ebola virus rather than the Sudan strain usually found in central and east African outbreaks.

Clinical features

The incubation period is 2–21 days but typically 8–10 days. Fever and non-specific signs are accompanied by abdominal pain, diarrhoea, vomiting and hiccups. A maculopapular rash occurs after 5–7 days in some. Although bleeding from the gums or venepuncture sites or in the stool occurs, haemorrhage may be less prominent than in other VHFs and is often a terminal event. In contrast, fluid losses from diarrhoea are more marked and reach 10 L per day. Complications include meningo-encephalitis, uveitis and miscarriages in pregnant women.

Investigations

Lymphopenia occurs, followed by neutrophilia, atypical lymphocytosis, thrombocytopenia and coagulation abnormalities. Elevations of AST/ALT, features of acute kidney injury, electrolyte disturbances and proteinuria are also observed. The virus is detected by a PCR in blood or body fluids, but may need retesting if the duration of symptoms is less than 3 days. Antigen detection has also been used in rural settings. Serology provides a retrospective diagnosis.

Management

Treatment is supportive and aimed at fluid replacement. Bacterial super-infections should be promptly treated. Mortality varies but is approximately 50% (range 25%–90%). Survivors recover from the second week of illness but experience late sequelae, including arthritis (76%), uveitis (60%) and deafness (24%), while skin sloughing is common. Relapse with meningitis is reported months after recovery. Monoclonal antibodies are a promising therapeutic approach.

Prevention

Ebola virus may be detected in the semen months after recovery. Male survivors are therefore encouraged to practise safe sex for 12 months after symptom onset or until two negative semen tests, but recommendations vary. Public health measures are essential for outbreak control and involve contact surveillance and monitoring through the incubation period, separating healthy from sick individuals, practising safe burial methods and ensuring appropriate infection control measures to protect health-care and laboratory workers, including provision of personal protective equipment such as gloves, gowns and full-face protection (face shield or masks combined with goggles). An Ebola glycoprotein vaccine, rVSV-ZEBOV, was shown to be effective in 2016 after a trial in West Africa and has been used in DRC. It is administered as a single dose and can be used in ring vaccination strategies during outbreaks. A viral vector vaccine, Ad26.ZEBOV/MVA-BN-Filo is also licensed and administered as a prime boost strategy with the second component given two months after the first.

Zika virus

Zika virus is a flavivirus spread from primate hosts by *Aedes aegypti* and *Aedes albopictus*, which bite during the day. Described in Africa and Asia since 2015, it has been epidemic in the Americas, where a mosquito–man–mosquito transmission cycle is established. It also can be transmitted in semen.

Clinical features

The incubation period is 3–12 days. Infection is asymptomatic or mild, resembling dengue with fever, arthralgia, conjunctivitis and maculopapular rash. Complications include increased reports of Guillain–Barré syndrome. Zika-related complications occur in 5%–15% of pregnant women with infection. The major concern has been a marked increase in microcephaly in pregnant women infected with Zika virus, as well as increased rates of cerebral calcification, deafness, visual problems such as chorioretinal scarring, joint contractures (arthrogryposis), hydrops fetalis and growth retardation.

Investigations

Routine blood tests are usually normal but may show leucopenia, thrombocytopenia or increased transaminases. PCR detects virus in the first week of illness or in urine up to 14 days. Serology provides a retrospective diagnosis but cross-reacts with other flaviviruses. Plaque-reduction neutralisation testing can be used to detect virus-specific neutralising antibodies and distinguishes between cross-reacting antibodies in primary flavivirus infections.

Prevention

Prevention focuses on avoiding mosquito bites. Since Zika virus may be found in the semen or genital secretions for prolonged periods, infected individuals should practise safe sex for at least 6 months and planned pregnancy should be postponed for at least 6 months. WHO guidance recommends individuals who have travelled to an endemic area but are asymptomatic should practise safe sex for 6 months in men and 2 months in women, but updated guidance should be sought. There is currently no vaccine.

Viral infections of the skin

Herpes simplex virus 1 and 2

Herpes simplex viruses (HSVs) cause recurrent mucocutaneous infection; HSV-1 typically involves the mucocutaneous surfaces of the head and neck (Fig. 14.29), while HSV-2 predominantly involves the genital mucosa (see p. 416), although there is overlap (see Box 14.46). The seroprevalence of HSV-1 is 30%–100%, varying by socioeconomic status, while that of HSV-2 is 20%–60%. Infection is acquired by inoculation of viruses shed by an infected individual on to a mucosal surface in a susceptible person. The virus infects sensory and autonomic neurons and establishes latent infection in the nerve ganglia. Primary infection is followed by life-long episodes of reactivation.

Clinical features

Primary HSV-1 or 2 infection is more likely to be symptomatic later in life, causing gingivostomatitis, pharyngitis or painful genital tract lesions. The primary attack may be associated with fever and regional lymphadenopathy.

Recurrence

Recurrent attacks occur, most often in association with concomitant medical illness, menstruation, mechanical trauma, immunosuppression, psychological stress or, for oral lesions, ultraviolet light exposure. HSV reactivation in the oral mucosa produces the classical ‘cold sore’ or ‘herpes labialis’. Prodromal hyperaesthesia is followed by rapid vesiculation, pustulation and crusting. Recurrent HSV genital disease is a common cause of recurrent painful ulceration. An inoculation lesion on the finger may cause a paronychia, termed a ‘whitlow’, in contacts of patients with herpetic lesions (see Fig. 14.29B).

Complications

Disseminated cutaneous lesions can occur in individuals with underlying dermatological diseases, such as eczema (eczema herpeticum) (see Fig. 14.29C). Herpes keratitis presents with pain and blurring of vision; characteristic dendritic ulcers are visible on slit-lamp examination and may produce corneal scarring and permanent visual impairment.

Primary HSV-2 can cause meningitis or transverse myelitis. HSV is the leading cause of sporadic viral encephalitis; this follows either primary or secondary disease, usually with HSV-1. A haemorrhagic necrotising temporal lobe cerebritis produces temporal lobe epilepsy and altered

consciousness/coma. Without treatment, mortality is 80%. HSV is also implicated in the pathogenesis of Bell palsy with a lower motor neuron 7th nerve palsy, although antivirals have not been demonstrated to improve outcome.

Neonatal HSV disease is usually associated with primary infection of the mother at term (see Box 14.24). In excess of two-thirds of cases develop disseminated disease with cutaneous lesions, hepatitis, pneumonitis and, frequently, encephalitis.

Immunocompromised hosts can develop visceral disease with oesophagitis, hepatitis, pneumonitis, encephalitis or retinitis.

Diagnosis

Differentiation from other vesicular eruptions is achieved by demonstration of virus in vesicular fluid, usually by direct immunofluorescence or PCR. PCR is also valuable for atypical appearances in PWH. HSV encephalitis is diagnosed by a positive PCR for HSV in CSF. Serology is of limited value.

Management

Therapy of localised disease must commence in the first 48 hours of clinical disease (primary or recurrent); thereafter it is unlikely to influence clinical outcome. Oral lesions in an immunocompetent individual may be treated with topical aciclovir. All severe manifestations should be treated, regardless of the time of presentation (see Box 14.47). Suspicion of HSV encephalopathy requires immediate antiviral therapy. Aciclovir resistance is encountered occasionally in immunocompromised hosts, in which case foscarnet is recommended.

Relapses of mucocutaneous lesions are common in immunocompromised patients, including PWH. Frequent relapses that persist despite ART or in the face of persistent immunosuppression should be treated with aciclovir 400 mg twice daily long term (see Box 14.47).

Human herpesvirus 8

Human herpesvirus 8 (HHV-8) (see Box 14.46) causes Kaposi sarcoma. HHV-8 is spread via saliva, and men who have sex with men have an increased incidence of infection. Seroprevalence varies widely, being highest in sub-Saharan Africa. Kaposi sarcoma (KS) is a spindle-cell tumour of lympho-endothelial origin. All forms of KS are due to sexually transmitted human herpesvirus 8, also known as KS-associated herpesvirus. KS occurs in four patterns:

- *classic KS*: rare, indolent and restricted largely to older men of Mediterranean or Jewish origin
- *endemic KS*: occurs in sub-Saharan Africa, is more aggressive, presents at earlier ages than classic KS, and affects men more than women
- *KS in patients on immunosuppressant drugs*: usually transplant recipients, who experience disseminated disease
- *AIDS-associated KS*: male-to-female ratio lower than endemic KS but remains male predominant (see p. 326)

HHV-8 also causes two rare haematological malignancies primarily in PWH: primary effusion lymphoma and multicentric Castleman disease. Kaposi sarcoma inflammatory cytokine syndrome is an HHV-8-associated syndrome that mimics sepsis. Current antivirals are not effective and treatment is with rituximab plus chemotherapy in the case of associated malignancy.

Enterovirus infections

Hand, foot and mouth disease

This systemic infection is caused by enteroviruses (mainly coxsackievirus A16 and enterovirus 71) and echoviruses. It affects children and occasionally adults, resulting in local or household outbreaks, particularly in the summer months, with recent epidemics in South-east Asia. A relatively mild illness with fever and lymphadenopathy develops after an incubation period of approximately 10 days; 2–3 days later, a painful papular or vesicular rash appears on palmoplantar surfaces of the hands and feet, with associated oral lesions on the buccal mucosa and tongue that ulcerate rapidly. A papular erythematous rash may appear on the buttocks and thighs. Enterovirus A71 and coxsackie A6 have been associated with more severe illness, including acute flaccid paralysis. Antiviral treatment is not available, and management consists of symptom relief with analgesics.

Herpangina

This infection, mainly caused by coxsackieviruses, primarily affects children and adolescents in the summer months. It is characterised by a small number of vesicles at the soft/hard palate junction, often associated with high fever, an extremely sore throat and headache. The lesions are short-lived, rupturing after 2–3 days and rarely persisting for more than 1 week. Treatment is with analgesics if required. Culture of the virus from vesicles or DNA detection by PCR differentiates herpangina from HSV.

Poxviruses

These DNA viruses rarely cause disease in humans but are common in animals.

Smallpox (variola)

Smallpox, which has high mortality, was eradicated worldwide by a global vaccination programme but remains a potential bioweapon. The virus is spread by the respiratory route or contact with lesions, and is highly infectious.

The incubation period is 7–17 days. A prodrome with fever, headache and prostration leads, in 1–2 days, to the rash, which develops through macules and papules to vesicles and pustules, worst on the face and distal extremities spreading more centrally (a centrifugal distribution). Lesions in one area are all at the same stage of development with no cropping (unlike chickenpox). Vaccination can lead to a modified course of disease with milder rash and lower mortality.

If a case of smallpox is suspected, national public health authorities must be contacted. Electron micrography (like Fig. 14.30) and DNA detection tests (PCR) are used to confirm diagnosis.

Mpox (Monkeypox)

There are two clades of Mpox: a more virulent Congo Basin clade I and a less virulent West African clade II. Despite the name, the animal reservoirs for this virus are small squirrels and rodents. It causes a rare zoonotic infection in communities in the rainforest belt of Central Africa, producing a vesicular rash that is indistinguishable from smallpox, but differentiated by the presence of lymphadenopathy. Since 2023 an outbreak has been ongoing in the DRC with over 20 000 reported cases. Outbreaks outside Africa have previously been linked to importation of

African animals as exotic pets. Diagnosis is by electron micrography or DNA detection (PCR).
